We could just as well write the planetary geostrophic equations (44.2) in terms of the full buoyancy

$$b = \tilde{b}(z) + b', \tag{44.3}$$

and full pressure,

$$p = p_0(z) + \rho_\circ\, \varphi. \tag{44.4}$$

Additionally, it is quite useful to include non-conservative terms such as buoyancy mixing, $\dot{b}$, to allow for the study of how stratification evolves, as well as horizontal frictional accelerations and/or boundary accelerations, $\boldsymbol{F}$, to include boundary stress driven circulations through Ekman

layers (Chapter 33). For these reasons, we take the frictional and diabatic planetary geostrophic equations as the basis for discussions in this chapter

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\rho_0^{-1}\,\nabla_{\!\mathrm{h}} p + \boldsymbol{F} \qquad \text{frictional geostrophy} \tag{44.5a}$$

$$(\partial_t + \boldsymbol{u} \cdot \nabla_{\!\mathrm{h}})\, b + N^2\, w = \dot{b} \qquad \text{diabatic buoyancy equation} \tag{44.5b}$$

$$\partial_z p = -\rho\, g \qquad \text{hydrostatic balance} \tag{44.5c}$$

$$\nabla \cdot \boldsymbol{v} = \nabla_{\!\mathrm{h}} \cdot \boldsymbol{u} + \partial_z w = 0 \qquad \text{non-divergent flow} \tag{44.5d}$$

$$N^2 = \partial_z b \qquad \text{squared buoyancy frequency} \tag{44.5e}$$

$$b = -g\,(\rho - \rho_o)/\rho_o \qquad \text{Archimedean buoyancy.} \tag{44.5f}$$

Note that the material time derivative in planetary geostrophy makes use of advection by the three velocity components, $\boldsymbol{v} = (\boldsymbol{u}, w)$, as seen in the buoyancy equation (44.5b), with the horizontal velocity components determined by the frictional geostrophic balance (44.5a). This situation contrasts to quasi-geostrophy, where it is only the horizontal advection by the geostrophic flow that contributes to material time evolution (Section 45.2).

As for the Boussinesq ocean equations discussed in Section 29.1.6, we sometimes find it convenient to combine the horizontal velocity equation with the hydrostatic balance to write

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla\varphi + b\,\hat{\boldsymbol{z}} + \boldsymbol{F}. \tag{44.6}$$

Furthermore, it is common to assume an equation of state that is independent of pressure, so that material time changes in buoyancy arise only from changes in Conservative Temperature and/or salinity

$$\dot{b} = \frac{\partial b}{\partial S}\,\dot{S} + \frac{\partial b}{\partial \Theta}\,\dot{\Theta}. \tag{44.7}$$

The partial derivatives, $\partial b/\partial\Theta$ and $\partial b/\partial S$, are commonly assumed constant in idealized studies.

44.1.2 Planetary geostrophic energetics

Since the velocity is diagnostic in planetary geostrophy, it is determined by the buoyancy field. In turn, there is a prognostic equation for potential energy that arises from the buoyancy equation, whereas kinetic energy is diagnostic. The energetics are thus a special case of the Boussinesq energetics studied in Section 29.6. We here consider just the basics.

General considerations

Multiplying the buoyancy equation (44.5b) by z leads to the potential energy equation

$$\partial_t P + \nabla \cdot (\boldsymbol{v}\, P) + w\, b = -z\, \dot{b}, \tag{44.8}$$

where we introduced the potential energy per mass relative to the reference density[1]

$$P = -z\, b = z\, g\,(\rho - \rho_o)/\rho_o. \tag{44.9}$$

Equation (44.8) says that the potential energy at a point in the planetary geostrophic fluid is affected by advective transport, buoyancy work, and diabatic processes. As we will see, diabatic processes such as diffusion provide a local source for potential energy, whereas buoyancy work transfers potential energy to kinetic energy.

[1] We considered this same form for the potential energy in Section 29.7 as well as Exercise 29.5 as part of the Boussinesq ocean chapter.

Projecting the geostrophic/hydrostatic balance equation (44.6) onto the velocity leads to the diagnostic balance between pressure work, buoyancy work, and friction

$$\boldsymbol{v} \cdot \nabla \varphi - w\, b = \boldsymbol{u} \cdot \boldsymbol{F}. \tag{44.10}$$

We can add this balance to the potential energy equation (44.8) to eliminate the buoyancy work term, $w\, b$, thus yielding

$$\partial_t P + \nabla \cdot (\boldsymbol{v}\, P + \boldsymbol{v}\, \varphi) = \boldsymbol{u} \cdot \boldsymbol{F} - z\, \dot{b}, \tag{44.11}$$

where we used $\nabla \cdot \boldsymbol{v} = 0$ to bring $\boldsymbol{v}\, \varphi$ inside the divergence. We thus see that potential energy at a point in the planetary geostrophic fluid is affected by reversible transport processes from advection and pressure work, along with irreversible processes from friction and material buoyancy changes.

Diffusively driven flow

It is revealing to consider the special case of a constant volume domain with static and rigid boundaries and with no boundary fluxes. We also assume that buoyancy is irreversibly modified through diffusion

$$\dot{b} = \nabla \cdot (\kappa\, \nabla b), \tag{44.12}$$

with $\kappa > 0$ an isotropic kinematic diffusivity that can be a function of space and time. Integrating the potential energy equation (44.11) over the domain leads to

$$\partial_t \langle P \rangle = \langle \boldsymbol{u} \cdot \boldsymbol{F} \rangle + \langle \kappa\, N^2 \rangle, \tag{44.13}$$

where the angle brackets signify volume means. To reach this identity we made use of

$$z\, \dot{b} = z\, \nabla \cdot (\kappa\, \nabla b) = \nabla \cdot (z\, \kappa\, \nabla b) - \kappa\, \partial_z b = \nabla \cdot (z\, \kappa\, \nabla b) - \kappa\, N^2, \tag{44.14}$$

with $\nabla \cdot (z\, \kappa\, \nabla b)$ integrating to zero in the absence of boundary fluxes. The global mean potential energy equation (44.13) indicates that diffusion increases volume mean potential energy for a stably stratified fluid ($N^2 > 0$), whereas friction generally dissipates potential energy since $\langle \boldsymbol{u} \cdot \boldsymbol{F} \rangle < 0$ (Section 26.3.3). So diffusion is the only source for potential energy, with spatial variations in potential energy leading to motion through the geostrophic balance. In the steady state this *diffusively driven flow* leads to the global mean balance between diffusion and friction

$$\langle \kappa\, N^2 \rangle = -\langle \boldsymbol{u} \cdot \boldsymbol{F} \rangle \qquad \text{steady state.} \tag{44.15}$$

44.2 Planetary geostrophic potential vorticity

In Section 41.5 we developed the potential vorticity equation for the hydrostatic Boussinesq ocean in the presence of horizontal friction in the momentum equation and diabatic terms in the buoyancy equation. Here we specialize that result to the case of planetary geostrophic system written in the form of equations (44.5a)-(44.5e).

44.2.1 Derivation

Derivation of the potential vorticity equation proceeds much like that for the hydrostatic Boussinesq ocean. The first step requires the planetary geostrophic vorticity equation as determined by taking the curl of the momentum equation (44.5a). The vertical component of this vorticity equation is given by (see also Section 31.5.2)

$$\beta\, v = f\, \partial_z w + \hat{\boldsymbol{z}} \cdot (\nabla_h \times \boldsymbol{F}) \qquad \text{with} \qquad \beta = \partial_y f. \tag{44.16}$$

Next, make use of frictional thermal wind balance

$$f\,\partial_z \boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla_h - \partial_z(\hat{\boldsymbol{z}} \times \boldsymbol{F}) \tag{44.17}$$

as well as the identities

$$N^2 \frac{\mathrm{D}f}{\mathrm{D}t} = N^2\,\beta\,v \tag{44.18a}$$

$$f \frac{\mathrm{D}N^2}{\mathrm{D}t} = f\,\frac{\partial \dot{b}}{\partial z} - f\,\nabla b \cdot \frac{\partial \boldsymbol{v}}{\partial z} \tag{44.18b}$$

$$f\,\nabla b \cdot \frac{\partial \boldsymbol{v}}{\partial z} = f\,N^2 \frac{\partial w}{\partial z} - \frac{\partial(\hat{\boldsymbol{z}} \times \boldsymbol{F})}{\partial z} \cdot \nabla_h b, \tag{44.18c}$$

to render

$$\frac{\mathrm{D}(f\,N^2)}{\mathrm{D}t} = N^2\,\beta\,v + f\,\frac{\partial \dot{b}}{\partial z} - f\,\nabla b \cdot \frac{\partial \boldsymbol{v}}{\partial z} \tag{44.19a}$$

$$= N^2 \left[f\,\frac{\partial w}{\partial z} + \hat{\boldsymbol{z}} \cdot (\nabla_h \times \boldsymbol{F}) \right] + f\,\frac{\partial \dot{b}}{\partial z} - f\,N^2 \frac{\partial w}{\partial z} + \frac{\partial(\hat{\boldsymbol{z}} \times \boldsymbol{F})}{\partial z} \cdot \nabla_h b \tag{44.19b}$$

$$= f\,\frac{\partial \dot{b}}{\partial z} + \nabla b \cdot (\nabla \times \boldsymbol{F}) \tag{44.19c}$$

$$= \nabla \cdot (f\,\dot{b}\,\hat{\boldsymbol{z}} + \boldsymbol{F} \times \nabla b). \tag{44.19d}$$

We thus identify the planetary geostrophic potential vorticity

$$Q^{\mathrm{pg}} = f\,N^2, \tag{44.20}$$

which is materially invariant in the absence of diabatic processes and friction

$$\frac{\mathrm{D}Q^{\mathrm{pg}}}{\mathrm{D}t} = 0 \qquad \text{if } \dot{b} = 0 \text{ and } \boldsymbol{F} = 0. \tag{44.21}$$

We can write the general budget equation in the form of an Eulerian flux-form expression

$$\partial_t Q^{\mathrm{pg}} + \nabla \cdot \boldsymbol{J}_{\mathrm{pg}} = 0, \tag{44.22}$$

where the planetary geostrophic potential vorticity flux is given by

$$\boldsymbol{J}_{\mathrm{pg}} = \boldsymbol{v}\,Q^{\mathrm{pg}} - \dot{b}\,f\,\hat{\boldsymbol{z}} + \nabla b \times \boldsymbol{F} + \nabla \times \boldsymbol{A}. \tag{44.23}$$

The vector $\boldsymbol{A}$ is an arbitrary gauge function that has no impact on the potential vorticity evolution. Comparing to the hydrostatic Boussinesq ocean expression (41.85), we see that the planetary geostrophic result follows by approximating the absolute vorticity by just the planetary vorticity.

44.2.2 Impermeability theorem

Following the discussion in Section 42.2.2, we verify that the potential vorticity flux vector (44.23) satisfies the impermeability theorem for buoyancy isosurfaces. We do so for the particular case of a zero gauge function ($\boldsymbol{A} = 0$), in which case

$$\boldsymbol{v}_{\mathrm{pg}} \cdot \nabla b = (\boldsymbol{J}_{\mathrm{PG}}/Q) \cdot \nabla b = \boldsymbol{v} \cdot \nabla b - \dot{b} = -\partial_t b, \tag{44.24}$$

so that

$$(\partial_t + \boldsymbol{v}_{\text{pg}} \cdot \nabla) b = 0. \tag{44.25}$$

Evidently, there is zero flux of PV-substance crossing buoyancy isosurfaces, even in the presence of irreversible processes that allow matter and buoyancy to cross those surfaces. As shown in the next subsection, we identify two more forms of the PV-substance flux vector that also satisfy impermeability, with these alternative forms differing by gauge transformations.

44.2.3 A kinematic PV flux satisfying impermeability

Following the discussion of impermeability for the Ertel potential vorticity in Section 42.2.2, we expose a purely kinematic means to derive the impermeability theorem for the planetary geostrophic potential vorticity. This derivation follows by computing the time tendency of the potential vorticity

$$\frac{\partial Q}{\partial t} = \frac{\partial}{\partial t} \nabla \cdot (f\, b\, \hat{\boldsymbol{z}}) = \nabla \cdot \left[f\, \frac{\partial b}{\partial t}\, \hat{\boldsymbol{z}} \right] \equiv -\nabla \cdot \tilde{\boldsymbol{J}}_{\text{pg}}, \tag{44.26}$$

where

$$\tilde{\boldsymbol{J}}_{\text{pg}} = -f\, \partial_t b\, \hat{\boldsymbol{z}}. \tag{44.27}$$

This form of the PV-substance flux also satisfies impermeability since

$$\tilde{\boldsymbol{v}}_{\text{pg}} \cdot \nabla b = (\tilde{\boldsymbol{J}}_{\text{pg}}/Q) \cdot \nabla b = -\partial_t b, \tag{44.28}$$

so that

$$(\partial_t + \tilde{\boldsymbol{v}}_{\text{pg}} \cdot \nabla) b = 0. \tag{44.29}$$

The PV-substance flux, $\tilde{\boldsymbol{J}}_{\text{pg}}$, vanishes in the steady state, whereas the steady state form of the alternative flux, $\boldsymbol{J}_{\text{PG}}$, is nonzero. Following the discussion in Section 42.3.2, we may choose to introduce a gauge transformation to the kinematic flux, $\tilde{\boldsymbol{J}}_{\text{pg}}$, so that it does not vanish in the steady state. Taking the small Rossby number limit of the flux (42.32) renders

$$\boldsymbol{J}_{\text{Q}}^{\text{marshall PG}} = -\nabla(g\, z + \varphi) \times \nabla b - f\, \partial_t b\, \hat{\boldsymbol{z}}. \tag{44.30}$$

This flux differs from $\tilde{\boldsymbol{J}}_{\text{pg}}$ by a curl

$$\nabla(g\, z + \varphi) \times \nabla b = \nabla \times [(g\, z + \varphi)\, \nabla b], \tag{44.31}$$

and it also satisfies the impermeability theorem. As discussed in Section 42.5.6, there are a variety of motivations for using one form of the PV-substance flux versus another. Some applications prefer a nonzero steady flux that also does not expose any irreversible processes, with $\boldsymbol{J}_{\text{Q}}^{\text{marshall PG}}$ satisfying these desires.

44.3 Depth integrated vorticity budget

In a planetary geostrophic flow, vorticity arises just from planetary vorticity since relative vorticity is negligible by comparison. With planetary vorticity a function just of latitude, a budget for the planetary geostrophic vorticity reveals how the curl of forces imparted to the fluid cause meridional motion as the fluid meets the constraints imposed by the vorticity equation. As per our discussion in Section 40.3.6, we refer to a force curl as a "torque" in our study of vorticity sources. However, one must keep in mind that more common usage in physics refers to a torque as affecting changes to angular momentum, with angular momentum generally distinct from vorticity (see Section 37.9 for a discussion of the distinction).

In this section we study the depth integrated vorticity budget for the planetary geostrophic fluid and derive implications for the meridional flow. For this purpose we focus on frictional and boundary accelerations that take the form of a vertical divergence of horizontal turbulent stress vector

$$\boldsymbol{F} = \partial_z \boldsymbol{\tau}. \tag{44.32}$$

The curl of this stress, as well as pressure forces, provide torques that generate meridional motion as revealed by the planetary geostrophic vorticity budget.

44.3.1 The β-effect, stretching, and meridional transport

In Section 31.5.2 we derived the vorticity equation for planetary geostrophy. We also encountered this equation when deriving the potential vorticity budget in Section 44.2.1. With friction written as a vertical divergence of horizontal turbulent stresses (equation (44.32)), the vertical component of the planetary geostrophic vorticity equation takes the form

$$\rho_\circ \, \beta \, v = \partial_z \left[\rho_\circ \, f \, w + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{\tau}) \right]. \tag{44.33}$$

Vertical integration from the ocean bottom at $z = \eta_\flat(x, y)$ to sea surface at $z = \eta(x, y, t)$ leads to[2]

$$\rho_\circ \, \beta \, V = \underbrace{\rho_\circ \, f \, [w(\eta) - w(\eta_\flat)]}_{\text{column stretching}} + \underbrace{\hat{\boldsymbol{z}} \cdot (\nabla \times \Delta \boldsymbol{\tau})}_{\text{boundary stresses}}, \tag{44.34}$$

where

$$V = \int_{\eta_\flat}^{\eta} v \, \mathrm{d}z \tag{44.35}$$

is the depth-integrated meridional flow, and

$$\Delta \boldsymbol{\tau} = \boldsymbol{\tau}(\eta) - \boldsymbol{\tau}(\eta_\flat) \tag{44.36}$$

is the difference in boundary stresses applied at the ocean surface and ocean bottom. Note that $\Delta \boldsymbol{\tau}$ is just a function of horizontal position and time.

For a planetary geostrophic flow, absolute vorticity is approximated by just the planetary vorticity

$$\zeta_\mathrm{a} = \zeta + f \approx f. \tag{44.37}$$

As revealed by the vorticity equation (44.34), vorticity sources in a planetary geostrophic fluid lead to meridional motion, with meridional motion the only way a planetary geostrophic fluid can modify its vorticity in response to vorticity sources.

The first term on the right hand side of the vorticity equation (44.34) arises from vertical stretching of the depth integrated column, as measured by differences in the vertical velocity at the ocean surface and bottom. For example, vertical stretching caused by positive surface velocity, $w(\eta) > 0$, or a negative bottom velocity, $w(\eta_\flat) < 0$, lead to poleward motion of the fluid column. Conversely, vertical squashing leads to equatorward motion. We emphasize that when studying the motion of the depth integrated flow, we are only concerned with vertical stretching from differences in the boundary vertical velocity rather than the vertical velocity within the fluid interior.

The second term in the vorticity equation (44.34) arises from differences in the vorticity imparted by surface and bottom boundary stresses. Positive vorticity is imparted to the fluid through a positive curl of wind stresses, $\hat{\boldsymbol{z}} \cdot [\nabla \times \boldsymbol{\tau}(\eta)] > 0$, or by a negative curl of bottom

[2] As a means to unclutter notation, we write ∇, rather than $\nabla_\hbar$, whenever acting on a field that is just a function of horizontal position, such as $p_\mathrm{a}, p_\flat, \eta_\flat$ and $\Delta \boldsymbol{\tau}$. We can do so since, for example, $\nabla p_\flat = \nabla_\hbar p_\flat$, since $\partial_z p_\flat = 0$.

stresses, $\hat{\boldsymbol{z}} \cdot [\nabla \times \boldsymbol{\tau}(\eta_b)] < 0$, with such stress curls leading to poleward motion of the fluid column. The opposite motion occurs from the converse curls.

The β-effect (Section 40.6.2) is a fundamental element of the depth integrated vorticity equation (44.34). Namely, as fluid columns are stretched or squashed, they must move meridionally to maintain vorticity balance for a planetary geostrophic fluid on a rotating spherical earth. The planetary geostrophic vorticity equation restricts attention to vertical stretching through vertical motion (the w terms) and through the vorticity imparted by the curl of boundary stresses. Notably, the curl of boundary stresses also imparts vertical motion through surface and bottom Ekman layer dynamics (see Chapter 33). Hence, the right hand side of the vorticity equation (44.34) is fundamentally related to vortex stretching.

Equation (44.34) is central to mechanical descriptions of large-scale ocean circulation. For many flow regimes, the curl of the surface wind stress dominates, thus allowing us to ignore the vertical velocity terms as well as bottom frictional stresses. Formally, we isolate the wind stress when studying a flat bottom rigid lid model, whereby $w(\eta) = w(\eta_b) = 0$. However, there can be nontrivial impacts from bottom pressure torques when flow interacts with sloping topography, with the North Atlantic and Southern Ocean providing important case studies. Other processes can be important in various flow regimes, thus prompting us to derive a full diagnostic framework to identify where these processes are important. To pursue that framework, we make use of the kinematic boundary conditions and the horizontal momentum equation to unpack the vertical velocity terms. Doing so reveals the forces and their curls that drive vertical motion at the boundaries for a planetary geostrophic flow.

44.3.2 Bottom kinematics and dynamics

The bottom kinematic boundary condition applied at $z = \eta_b(x, y)$ (Section 19.6.1) is given by

$$w = \boldsymbol{u} \cdot \nabla \eta_b \qquad \text{at } z = \eta_b(x, y). \tag{44.38}$$

This relation expresses the no-normal flow condition, $\hat{\boldsymbol{n}} \cdot \boldsymbol{v} = 0$, at the ocean bottom, with

$$\hat{\boldsymbol{n}} = -\frac{\nabla(z - \eta_b)}{|\nabla(z - \eta_b)|} = -\left[\frac{\hat{\boldsymbol{z}} - \nabla \eta_b}{\sqrt{1 + \nabla \eta_b \cdot \nabla \eta_b}}\right] \tag{44.39}$$

the outward unit normal to the bottom. The boundary condition constrains the flow so that any horizontal motion next to a sloping bottom that is oriented either up or down the slope must have an associated vertical motion. As we see in this section, such vertical motion next to the bottom boundary arises from force curls acting to stretch or squash a fluid column. In turn, through the vorticity equation (44.34), vertical motion at the bottom leads to meridional motion of the full fluid column.

Expressions for bottom vertical velocity

The bottom kinematic boundary condition holds for all dynamical flow regimes. For the particular case of planetary geostrophy, we garner insight into the forces that drive vertical flow near the bottom by making use of the planetary geostrophic momentum equation (44.5a). Evaluating the horizontal components of this equation at the ocean bottom yields[3]

$$\rho_o f \hat{\boldsymbol{z}} \times \boldsymbol{u} = -(\nabla p)_{z=\eta_b} + \boldsymbol{F}_b, \tag{44.40}$$

[3]Recall that since $p_b = p_b(x, y, t)$, we have $\nabla p_b = \nabla_h p_b$. As noted in the footnote on page 1267, we drop the z script to reduce notational clutter.

where $(\nabla p)_{z=\eta_b}$ is the horizontal pressure gradient evaluated at the ocean bottom and $\boldsymbol{F}_b(x, y, t)$ is the bottom friction. For the special case of a no-slip bottom, all velocity components vanish at $z = \eta_b$. In that case, we consider $\boldsymbol{u}$ in equation (44.40) to be the horizontal velocity averaged within the bottom boundary layer, and w the corresponding vertical velocity leaving the boundary layer.

It is convenient to decompose the bottom horizontal velocity into its geostrophic and Ekman[4] components via

$$\rho_o f \hat{\boldsymbol{z}} \times \boldsymbol{u}_g = -(\nabla p)_{z=\eta_b} \qquad \text{and} \qquad \rho_o f \hat{\boldsymbol{z}} \times \boldsymbol{u}_e = \boldsymbol{F}_b, \tag{44.41}$$

so that

$$\boldsymbol{u}_g = \frac{\hat{\boldsymbol{z}} \times (\nabla p)_{z=\eta_b}}{\rho_o f} \qquad \text{and} \qquad \boldsymbol{u}_e = -\frac{\hat{\boldsymbol{z}} \times \boldsymbol{F}_b}{\rho_o f}. \tag{44.42}$$

For the horizontal horizontal pressure gradient at the ocean bottom, we make use of equation (27.60b) to write

$$(\nabla_h p)_{z=\eta_b} = \nabla_h p_b + g\, \rho(\eta_b)\, \nabla_h \eta_b. \tag{44.43}$$

The corresponding bottom vertical velocity components are determined by inserting equations (44.42) and (44.43) into the bottom kinematic boundary condition (44.38)

$$w_g = \frac{\hat{\boldsymbol{z}} \cdot (-\nabla \eta_b \times \nabla p_b)}{\rho_o f} \qquad \text{and} \qquad w_e = \frac{\hat{\boldsymbol{z}} \cdot (\nabla \eta_b \times \boldsymbol{F}_b)}{\rho_o f}. \tag{44.44}$$

These equations reveal how the curl of pressure forces and boundary frictional forces drive a nonzero vertical motion next to the bottom, while maintaining the bottom kinematic boundary condition (44.38). As seen by these equations, is only the projection of ∇p_b and $\boldsymbol{F}_b$ onto the isobath direction that contributes to a nonzero vertical velocity. These along-isobath forces are needed to render a horizontal velocity that is itself misaligned with isobaths, thus satisfying the kinematic requirement for vertical motion.[5]

To further understand the bottom pressure term, we write it as

$$w_g = \frac{\hat{\boldsymbol{z}} \cdot (-\nabla \eta_b \times \nabla p_b)}{\rho_o f} = \frac{\hat{\boldsymbol{z}} \cdot [\nabla \times p_b \nabla \eta_b]}{\rho_o f}. \tag{44.45}$$

The numerator is the curl of the horizontal projection of the pressure contact force along the bottom, $p_b \nabla \eta_b$. This term is the topographic form stress discussed in Section 28.2 for a general fluid and in Section 39.7.6 for the shallow water. We thus conclude that vertical geostrophic motion next to the bottom arises from the curl of the topographic form stress. This is an important result that will appear again within this section as well as in Sections 44.5 and 44.6.

Comments on the bottom vertical geostrophic velocity

A large part of the bottom pressure gradient driving the horizontal geostrophic flow in equation (44.42) arises from changes in bottom depth. However, that portion of the bottom pressure gradient has no impact on w_g, since it only drives horizontal flow along isobaths. We see this property by writing

$$p_b = -\rho_o\, g\, \eta_b + p_b' \Longrightarrow w_g = \frac{\hat{\boldsymbol{z}} \cdot (-\nabla \eta_b \times \nabla p_b')}{\rho_o f}. \tag{44.46}$$

When there is misalignment between isolines of bottom pressure and bottom topography, the geostrophic flow in a fluid column crosses isobaths. Correspondingly, with the pressure force misaligned with topographic gradients, the fluid column experiences a twisting action akin

[4] Recall our discussion of Ekman mechanics in Chapter 33.

[5] Note that we derived the expression (44.44) for w_g in equation (40.196) when studying vorticity mechanics.

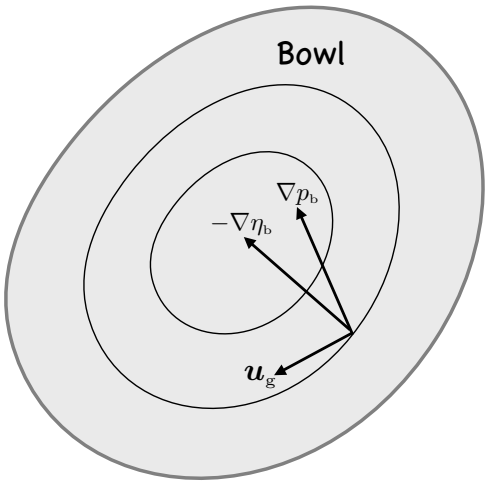

FIGURE 44.1: Depicting how bottom pressure gradients create vertical motion in planetary geostrophic flow next to a sloping bottom according to equations (44.44) and (44.46). Here we show a bowl or depression (local maximum in the depth) with $-\eta_b$ increasing inward toward the bowl center. Only those portions of ∇p_b and $\boldsymbol{F}_b$ that are aligned parallel to the topographic slope contribute to vertical motion. We illustrate here a case where the bottom pressure gradient leads to $-\nabla \eta_b \cdot \boldsymbol{u}_g > 0$ so that $w_g < 0$ in the northern hemisphere and $w_g > 0$ in the southern hemisphere.

to how baroclinicity spins a fluid element if the pressure force does not act through the fluid element's center of mass (see Section 40.4).

To illustrate the above, consider the topographic bowl in Figure 44.1, with sides steep enough so that the bottom pressure gradient is dominated by the topographic slopes. Along the bottom the pressure increases moving down (increasing depth) towards the bowl center. The corresponding bottom geostrophic flow is anti-cyclonic within the bowl and largely follows isobaths. As already noted, if the geostrophic flow exactly follows isobaths, then there is no corresponding vertical component to the bottom velocity. A vertical velocity arises only in the presence of an anomalous bottom pressure gradient, $\nabla p_b'$, that is misaligned with the bottom slope, $\nabla \eta_b$. This bottom pressure gradient balances a geostrophic flow that deviates from isobaths thus giving rise to a nonzero w_g. Similar geometric analysis holds for the bottom friction vector, $\boldsymbol{F}_b$, and how it gives rise to a nonzero vertical Ekman velocity, w_e.

What causes misalignment between p_b and η_b?

As we just discussed, misalignment of p_b and η_b lead to vertical geostrophic motion along the bottom. In Section 44.3.3 we will see a similar relation for vertical geostrophic motion at the ocean surface. But what causes such misalignment? The answer to this question is circular when working within planetary geostrophy since its momentum equation is diagnostic. Even so, we can offer some insight by returning to the depth-integrated vorticity balance (44.34) and rewriting it as an expression for vertical motion

$$\rho_o f [w(\eta_b) - w(\eta)] = -\rho_o \beta V + \hat{\boldsymbol{z}} \cdot (\nabla \times \Delta \boldsymbol{\tau}). \tag{44.47}$$

Hence, vertical motion at the surface and bottom balance meridional motion in the presence of planetary beta, plus the curl of surface and bottom stresses. The absence of planetary beta, and the absence of boundary stress curls, realizes $w(\eta_b) = w(\eta)$.

44.3.3 Surface kinematics and dynamics

For purposes of large-scale circulation studies using planetary geostrophy, it is generally sufficient to assume a rigid lid upper boundary condition, whereby $w(\eta) = w(0) = 0$. Even so, we find it revealing to present the results for a free surface in which there is the possibility of nonzero surface mass fluxes. This situation is commonly encountered in general circulation models. The surface kinematic boundary condition for a Boussinesq fluid (Section 21.3) is given by

$$w = -Q_{\mathrm{m}}/\rho_{\circ} + (\partial_t + \boldsymbol{u} \cdot \nabla)\eta \qquad \text{at } z = \eta(x, y, t). \tag{44.48}$$

We retain the sea surface time tendency, $\partial_t \eta$, even though for transient solutions the time tendency is many orders of magnitude smaller than the typical vertical velocity under the planetary geostrophic regime.[6] Evaluating the horizontal planetary geostrophic momentum equation (31.25a) at the ocean surface renders

$$\rho_{\circ}\, f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -(\nabla_{\mathrm{h}} p)_{z=\eta} + \boldsymbol{F}_{\eta}, \tag{44.49}$$

where $\boldsymbol{F}_{\eta}$ is the horizontal friction vector at the surface, and (see equation (27.60a))

$$(\nabla_{\mathrm{h}} p)_{z=\eta} = \nabla_{\mathrm{h}} p_{\mathrm{a}} + g\, \rho(\eta)\, \nabla_{\mathrm{h}} \eta \tag{44.50}$$

is the horizontal pressure gradient at the ocean surface. Like the bottom, we decompose the horizontal velocity into a geostrophic component and an Ekman component via

$$\rho_{\circ}\, f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -(\nabla_{\mathrm{h}} p)_{z=\eta} \qquad \text{and} \qquad \rho_{\circ}\, f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{e}} = \boldsymbol{F}_{\eta}, \tag{44.51}$$

so that

$$\boldsymbol{u}_{\mathrm{g}} = \frac{\hat{\boldsymbol{z}} \times (\nabla_{\mathrm{h}} p)_{z=\eta}}{\rho_{\circ}\, f} \qquad \text{and} \qquad \boldsymbol{u}_{\mathrm{e}} = -\frac{\hat{\boldsymbol{z}} \times \boldsymbol{F}_{\eta}}{\rho_{\circ}\, f}. \tag{44.52}$$

The corresponding vertical velocity components are determined by inserting into the surface kinematic boundary condition (44.48)

$$w_{\mathrm{Q}\eta} = -\frac{Q_{\mathrm{m}}}{\rho_{\circ}} + \frac{\partial \eta}{\partial t} \qquad \text{and} \qquad w_{\mathrm{g}} = \frac{\hat{\boldsymbol{z}} \cdot (-\nabla \eta \times \nabla p_{\mathrm{a}})}{\rho_{\circ}\, f} \qquad \text{and} \qquad w_{\mathrm{e}} = \frac{\hat{\boldsymbol{z}} \cdot (\nabla \eta \times \boldsymbol{F}_{\eta})}{\rho_{\circ}\, f}, \tag{44.53}$$

where we introduced a vertical velocity, $w_{\mathrm{Q}\eta}$, associated with the boundary mass flux and transient sea level fluctuations. As for the bottom, the second and third of these equations reveal how the curl of inviscid pressure forces and boundary frictional forces drive a nonzero vertical motion at the ocean surface, all while maintaining the surface kinematic boundary condition (44.48). Furthermore, it is only the projection of ∇p_{a} and $\boldsymbol{F}_{\eta}$ onto the direction parallel to sea surface height contours that contributes to a nonzero vertical velocity. This orientation of the surface forces is needed to render a horizontal velocity that is itself misaligned with sea surface height contours, thus satisfying the kinematics required to render vertical motion.

44.3.4 Summary of force curls driving depth integrated meridional flow

Plugging expressions (44.44), (44.46), and (44.53) into equation (44.34) renders the depth integrated planetary vorticity balance

$$\rho_{\circ}\, \beta\, V = f\, (-Q_{\mathrm{m}} + \rho_{\circ}\, \partial_t \eta) + \hat{\boldsymbol{z}} \cdot \left[\nabla \eta \times (\boldsymbol{F}_{\eta} - \nabla p_{\mathrm{a}}) - \nabla \eta_{\mathrm{b}} \times (\boldsymbol{F}_{\mathrm{b}} - \nabla p'_{\mathrm{b}}) + \nabla \times \Delta \boldsymbol{\tau}\right]. \tag{44.54}$$

[6] See Section 3.3 of *Samelson* (2011) for more details on this scaling of the planetary geostrophic equations.

Evidently, the force curls are symmetrically applied at the surface and bottom, which is part of the motivation for exposing the surface terms even though they are generally subdominant. In general, equation (44.54) shows that the depth integrated meridional flow, within the planetary geostrophic regime, is driven by the following processes.

Surface mass transport plus sea surface fluctuations

The term $f \rho_o (-Q_m/\rho_o + \partial_t \eta)$ arises from mass transport across the ocean surface plus fluctuations in the sea surface height. For example, as sea surface height increases or as water leaves the ocean surface, they impart a positive surface vertical velocity, $w(\eta) > 0$, thus causing column stretching and poleward meridional depth integrated flow. In the steady state, where it is just the mass flux term that contributes, the meridional circulation is known as the Goldsbrough-Stommel circulation (see *Huang and Schmitt* (1993) for a review).

Curl of turbulent boundary stresses

The term $\hat{\boldsymbol{z}} \cdot (\nabla \times \Delta \boldsymbol{\tau})$ arises from the curl of the turbulent wind stress and turbulent bottom stress. The wind stress term is generally larger than the bottom turbulent stress, with many theories for ocean circulation, particularly those with a flat bottom, almost exclusively focused on the role of surface stress in forcing planetary geostrophic vorticity. We comment more on this case in Section 44.4 where we discuss the *Sverdrup balance*.

Atmospheric pressure torque

The term

$$\nabla p_a \times \nabla \eta = \nabla \times (p_a \nabla \eta) = -\nabla \times (\eta \nabla p_a) \tag{44.55}$$

arises from differences in lines of constant atmospheric pressure and lines of constant sea surface height. Such misalignments create a torque akin to the baroclinicity detailed in Section 40.4, with these misalignments driving vertical motion and a corresponding depth integrated meridional flow.

Bottom pressure torque

The term

$$\nabla p'_b \times (-\nabla \eta_b) = \nabla \times (-p'_b \nabla \eta_b) = \nabla \times (\eta_b \nabla p'_b) \tag{44.56}$$

arises from differences in lines of constant bottom pressure and lines of constant bottom topography. That is, bottom pressure torque requires a gradient of bottom pressure along isobaths, thus producing a bottom geostrophic flow that deviates from isobaths. As for the atmospheric pressure torques, such misalignments create a torque that drives a depth integrated meridional flow, with this term vanishing when the bottom topography is flat. In many cases with strong flow next to sloping bottoms, this term can contribute more to the vorticity budget than the turbulent bottom stress. Indeed, in some cases it can rival contributions from the surface wind stress. We sketched out such cases for the shallow water when discussing western boundary currents in Section 39.7.6.

Surface frictional acceleration

The term

$$\hat{\boldsymbol{z}} \cdot (\nabla \eta \times \boldsymbol{F}_\eta) = \hat{\boldsymbol{z}} \cdot [\nabla \eta \times \partial_z \boldsymbol{\tau}_\eta] \tag{44.57}$$

arises from evaluating the vertical divergence of the frictional stress at the sea surface. A finite volume boundary layer treatment of this term prompts us to integrate the stress divergence over

the extent of the surface Ekman layer to render the alternative expression

$$\hat{\boldsymbol{z}} \cdot \int_{-h_{\text{e-surf}}}^{\eta} [\nabla \eta \times \partial_z \boldsymbol{\tau}] \, \mathrm{d}z = \hat{\boldsymbol{z}} \cdot [\nabla \eta \times \boldsymbol{\tau}(\eta)], \tag{44.58}$$

where we assumed $\boldsymbol{\tau}$ is negligible at the base of the surface Ekman layer, $z = -h_{\text{e-surf}}(x, y, t)$. The term $\hat{\boldsymbol{z}} \cdot [\nabla \eta \times \boldsymbol{\tau}(\eta)]$ creates a torque from that component of the surface turbulent stress that is aligned with isolines of the sea surface height.

Bottom frictional acceleration

The term

$$\hat{\boldsymbol{z}} \cdot (-\nabla \eta_{\mathrm{b}} \times \boldsymbol{F}_{\mathrm{b}}) = \hat{\boldsymbol{z}} \cdot \left[-\nabla \eta_{\mathrm{b}} \times \frac{\partial \boldsymbol{\tau}_{\mathrm{b}}}{\partial z} \right] \tag{44.59}$$

arises from evaluating the vertical divergence of the frictional stress at the ocean bottom. As for the analogous term for the surface, we offer a finite volume Ekman boundary layer treatment to render the alternative expression

$$\hat{\boldsymbol{z}} \cdot \int_{\eta_{\mathrm{b}}}^{h_{\text{e-bot}}} \left[-\nabla \eta_{\mathrm{b}} \times \frac{\partial \boldsymbol{\tau}}{\partial z} \right] \mathrm{d}z = \hat{\boldsymbol{z}} \cdot [-\nabla \eta_{\mathrm{b}} \times \boldsymbol{\tau}(\eta_{\mathrm{b}})], \tag{44.60}$$

where we assumed $\boldsymbol{\tau}$ is negligible at the top of the bottom Ekman layer, $z = -\eta_{\mathrm{b}} + h_{\text{e-bot}}$. The term $\hat{\boldsymbol{z}} \cdot [-\nabla \eta_{\mathrm{b}} \times \boldsymbol{\tau}(\eta_{\mathrm{b}})]$ creates a torque from that component of the bottom turbulent stress that is aligned with isobaths.

44.3.5 Integral constraints

The atmospheric and bottom pressure torques appearing in the depth integrated planetary vorticity balance (44.54) satisfy an integral constraint that follows from Stokes' curl theorem. To illustrate this constraint, consider the bottom pressure torque integrated over an arbitrary area along the bottom

$$\int (\nabla \eta_{\mathrm{b}} \times \nabla p'_{\mathrm{b}}) \cdot \hat{\boldsymbol{z}} \, \mathrm{d}A = \int [\nabla \times (\eta_{\mathrm{b}} \nabla p'_{\mathrm{b}})] \cdot \hat{\boldsymbol{z}} \, \mathrm{d}A \tag{44.61a}$$

$$= \oint \eta_{\mathrm{b}} \nabla p'_{\mathrm{b}} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s \tag{44.61b}$$

$$= - \oint p'_{\mathrm{b}} \nabla \eta_{\mathrm{b}} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s. \tag{44.61c}$$

We see that the bottom pressure torque vanishes when integrated around a closed loop that follows either an isobath or a bottom isobar, since the integrand vanishes identically. A similar constraint holds for the atmospheric pressure torque, whereas there is generally no analogous constraint satisfied by the turbulent boundary stresses.

One exception for the turbulent stresses occurs for f-plane flow ($\beta = 0$) where the depth integrated flow is non-divergent

$$\partial_t \eta - Q_{\mathrm{m}}/\rho_{\mathrm{o}} = -\nabla \cdot \boldsymbol{U} = 0, \tag{44.62}$$

and where the interior friction vanishes at the surface and bottom boundaries, $\boldsymbol{F}_\eta = \boldsymbol{F}_{\mathrm{b}} = 0$. From equation (44.54), we see that a steady state is realized only if there is a balance between pressure torques and turbulent boundary stresses

$$\hat{\boldsymbol{z}} \cdot (\nabla \eta \times \nabla p_{\mathrm{a}} - \nabla \eta_{\mathrm{b}} \times \nabla p'_{\mathrm{b}}) = \hat{\boldsymbol{z}} \cdot (\nabla \times \Delta \boldsymbol{\tau}). \tag{44.63}$$

Consider even further specialization in which the atmospheric pressure torque vanishes, and the bottom turbulent stress is negligible, in which case a steady state balance requires a balance between bottom pressure torques and torques from surface turbulent wind stress

$$-\hat{\boldsymbol{z}} \cdot (\nabla \eta_{\rm b} \times \nabla p'_{\rm b}) = \hat{\boldsymbol{z}} \cdot [\nabla \times \boldsymbol{\tau}(\eta)]. \tag{44.64}$$

Integration over either an isobath or bottom pressure isobar then requires, for a steady state, the following identity

$$\int [\nabla \times \boldsymbol{\tau}(\eta)] \cdot \hat{\boldsymbol{z}} \, \mathrm{d}A = \oint \boldsymbol{\tau}(\eta) \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s = 0 \quad f\text{-plane closed isobath or closed isobar.} \tag{44.65}$$

Deviation from this identity leads to non-steady flow on the f-plane. In contrast, the β-plane has no such steady state constraint since meridional flow can balance the circulation imparted by turbulent wind stresses.

44.4 Sverdrup balance and geostrophic Sverdrup balance

The balance (44.54) exposes the many processes that affect meridional flow in a planetary geostrophic fluid. However, when confronted with minimal information from ocean measurements, we are motivated to examine just the main contributors to this balance.

The *Sverdrup balance* is a very simplified form of the balance (44.54), and it was first encountered in Section 31.5.5

$$\rho_{\circ} \, \beta \, V_{\rm Sverdrup} = \hat{\boldsymbol{z}} \cdot [\nabla \times \boldsymbol{\tau}(\eta)] \qquad \text{Sverdrup balance.} \tag{44.66}$$

This balance arises from dropping the vertical velocity at both the ocean surface and ocean bottom; ignoring horizontal frictional stresses; and assuming $\partial_t \eta = -Q_{\rm m}/\rho_{\circ} = 0$ as per a rigid lid flow in which $\nabla \cdot \boldsymbol{U} = 0$. The Sverdrup balance offers a null hypothesis for the large-scale and low frequency meridional ocean circulation away from sloping sides; i.e., in regions where bottom pressure torques can be ignored.

To derive the Sverdrup balance (44.66), we performed a depth integral of the planetary geostrophic vorticity equation (44.33) from the ocean bottom to the free surface. This integral encompasses both the geostrophic interior and the ageostrophic Ekman flow in the top and bottom Ekman layers. In some treatments we focus exclusively on contributions from the geostrophic interior, in which case the depth integral extends from the top of the bottom Ekman layer, $z = \eta_{\rm eb}$, to the bottom of the top Ekman layer, $z = \eta_{\rm et}$, thus leading to the depth integrated geostrophic transport

$$V_{\rm g} \equiv \int_{\eta_{\rm eb}}^{\eta_{\rm et}} v \, \mathrm{d}z. \tag{44.67}$$

Integrating the planetary geostrophic vorticity balance (44.33) over this depth range, and ignoring contributions from friction since we are concerned just with the geostrophic interior, leads to

$$\rho_{\circ} \, \beta \, V_{\rm g} = f \, [w(\eta_{\rm et}) - w(\eta_{\rm eb})]. \tag{44.68}$$

This equation provides a balance between the depth integrated meridional transport within the geostrophic interior (left hand side), with the vertical vortex stretching within this depth range (right hand side).

We now make use of the Ekman theory from Chapter 33 to approximate the vertical velocities in equation (44.68). For this purpose we neglect both the time tendency for the vertical position of the Ekman layer and the slope of the Ekman layer, in which case the kinematic identity

(33.38), applied at the Ekman base, $z = \eta_{\rm e}(x, y, t)$, is approximated by

$$w^{(\dot\eta_{\rm e})} = w - (\partial_t z + \boldsymbol{u} \cdot \nabla z) \approx w \qquad \text{at } \; z = \eta_{\rm e}(x, y, t), \tag{44.69}$$

where $z = \eta_{\rm e}$ is ths vertical position of the Ekman layer. We now make use of the Ekman layer mass budgets to determine the entrainment velocity, $w^{(\dot\eta_{\rm e})}$. In particular, equation (33.45) is used for $w(\eta_{\rm et})$ to give

$$w(\eta_{\rm et}) \approx w^{(\dot\eta_{\rm e})}_{\text{Ekman-top}} = (1/\rho_{\rm o})\, \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}(\eta)/f)]. \tag{44.70}$$

with a similar treatment for the bottom leading to

$$w(\eta_{\rm eb}) \approx w^{(\dot\eta_{\rm e})}_{\text{Ekman-bot}} = (1/\rho_{\rm o}) f\, \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}(\eta_{\rm b})/f)]. \tag{44.71}$$

Bringing these results into equation (44.68) leads to

$$\rho_{\rm o}\, \beta\, V_{\rm g} = f\, \hat{\boldsymbol{z}} \cdot \nabla \times [\boldsymbol{\tau}(\eta)/f - \boldsymbol{\tau}(\eta_{\rm b})/f]. \tag{44.72}$$

Since the bottom turbulent stress is generally much smaller than the surface, it is typically ignored, in which case we reach the *geostrophic Sverdrup balance*

$$\rho_{\rm o}\, \beta\, V_{\rm g} = f\, \hat{\boldsymbol{z}} \cdot \nabla \times [\boldsymbol{\tau}(\eta)/f] \qquad \text{geostrophic Sverdrup balance.} \tag{44.73}$$

The geostrophic Sverdrup balance relates the meridional geostrophic transport to the curl of $\boldsymbol{\tau}/f$ due to upper ocean mechanical stresses from boundary processes; i.e., wind stress and ice-ocean stresses. It is differs from the full Sverdrup balance in equation (44.66) by the presence of the f outside of the curl and $1/f$ inside the curl. *Gray and Riser* (2014) assess the geostrophic Sverdrup balance based on ocean measurements.

44.5 Vorticity of the depth integrated velocity

In Section 44.3 we studied the depth integrated vorticity budget for planetary geostrophic flow. We were led to see how boundary torques (i.e., the curl of boundary forces) lead to vertical motion and in turn, through the β-effect, lead to meridional motion of the depth integrated flow. In this section we present another analysis of vorticity in the planetary geostrophic regime, here focusing on vorticity of the depth integrated velocity. Elements of this material were discussed in Section 40.9 without making the planetary geostrophic assumption. By assuming planetary geostrophy we can further constrain the flow by focusing just on vortex stretching.

44.5.1 Depth integrated velocity equation

The depth integrated horizontal velocity equation (44.5a) is given by

$$\rho_{\rm o}\, f\, \hat{\boldsymbol{z}} \times \boldsymbol{U} = -\int_{\eta_{\rm b}}^{\eta} \nabla_{\rm h} p \, {\rm d}z + \Delta\boldsymbol{\tau} \tag{44.74}$$

where

$$\boldsymbol{U} = \int_{\eta_{\rm b}}^{\eta} \boldsymbol{u} \, {\rm d}z \tag{44.75}$$

is the depth integrated horizontal velocity, and we assumed friction in the form of the vertical divergence of a horizontal turbulent stress as in equation (44.32). For the depth integrated

pressure gradient, we follow the decomposition in Section 28.4.4 by writing

$$\int_{\eta_b}^{\eta} p \, dz = \int_{\eta_b}^{\eta} [d(p\, z) - z \, dp] = p_a \, \eta - p_b \, \eta_b + \mathscr{P}, \tag{44.76}$$

where we used the hydrostatic balance to write $dp = -g \, \rho \, dz$, which is valid for each fluid column. We also introduced the potential energy per horizontal area of a fluid column

$$\mathscr{P} = \int_{\eta_b}^{\eta} g \, \rho \, z \, dz = (g \, \rho_o/2) \, (\eta^2 - \eta_b^2) + \int_{\eta_b}^{\eta} g \, \rho' \, z \, dz, \tag{44.77}$$

where

$$\rho' = \rho - \rho_o \tag{44.78}$$

is the density deviation from the background reference density. These results then lead to the depth integrated horizontal pressure gradient

$$\begin{aligned}
\int_{\eta_b}^{\eta} \nabla_h p \, dz &= \nabla_h \left[\int_{\eta_b}^{\eta} p \, dz \right] - p_a \nabla_h \eta + p_b \nabla_h \eta_b && \text{(44.79a)} \\
&= \nabla_h \left[p_a \, \eta - p_b \, \eta_b + \mathscr{P} \right] - p_a \nabla_h \eta + p_b \nabla_h \eta_b && \text{(44.79b)} \\
&= \eta \nabla_h p_a - \eta_b \nabla_h p_b + \nabla_h \mathscr{P}, && \text{(44.79c)} \\
&= \eta \nabla p_a - \eta_b \nabla p_b + \nabla \mathscr{P}, && \text{(44.79d)}
\end{aligned}$$

where the final equality follows since p_a, η_b, p_b, and $\mathscr{P}$, are functions just of horizontal position and time. We are thus led to the depth integrated planetary geostrophic momentum balance

$$\rho_o \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{U} = -\eta \, \nabla p_a + \eta_b \nabla p_b - \nabla \mathscr{P} + \Delta \boldsymbol{\tau}. \tag{44.80}$$

The depth integrated balance is here written in terms of gradients in the surface and bottom pressures, the gradient of the potential energy per area, and the difference in turbulent stresses at the top and bottom boundaries, $\Delta \boldsymbol{\tau} = \boldsymbol{\tau}(\eta) - \boldsymbol{\tau}(\eta_b)$.

44.5.2 Vorticity budget

Taking the curl of the depth integrated balance (44.80) annihilates the potential energy term, thus leaving

$$\rho_o \, \beta \, V = -\rho_o \, f \, \nabla \cdot \boldsymbol{U} + \hat{\boldsymbol{z}} \cdot \nabla \times [p_a \nabla \eta + \boldsymbol{\tau}(\eta) - p_b \nabla \eta_b - \boldsymbol{\tau}(\eta_b)]. \tag{44.81}$$

From Section 21.8, we know that the divergence of the depth-integrated flow for a steady Boussinesq fluid is given by

$$\rho_o \nabla \cdot \boldsymbol{U} = Q_m, \tag{44.82}$$

so that

$$\rho_o \, \beta \, V = -f \, Q_m + \hat{\boldsymbol{z}} \cdot \nabla \times [p_a \nabla \eta + \boldsymbol{\tau}(\eta) - p_b \nabla \eta_b - \boldsymbol{\tau}(\eta_b)]. \tag{44.83}$$

This is the vorticity equation for the depth integrated planetary geostrophic fluid. It is quite similar to the vorticity balance for a shallow water fluid as given by equation (39.106) (which considered zero atmospheric pressure). In the presence of β, meridional mass transport for the fluid column is balanced by surface mass fluxes, $Q_m \neq 0$; the curl of surface form stresses and surface turbulent stresses; and the curl of topographic form stresses and bottom turbulent stresses. This result follows quite naturally when recognizing that the forces acting on a depth integrated fluid column arise from the depth integrated stresses acting on the column sides plus those acting on the top and bottom boundaries. In the absence of interior friction stresses due to horizontal strains (as assumed here), it is only the depth integrated pressure that acts on the

column sides, and this term has zero curl. We are thus left just with the curl of the surface and bottom boundary form stresses and turbulent stresses, along with a contribution from boundary mass transport.

The Sverdrup balance (44.66) is a special case of the more complete vorticity budget (44.81). Furthermore, the *topographic Sverdrup balance* results when meridional transport balances the curl of the wind plus bottom pressure form stress

$$\rho_o \, \beta \, V_{\text{topo-Sverdrup}} = \hat{\boldsymbol{z}} \cdot \nabla \times (\boldsymbol{\tau}(\eta) - p_b \nabla \eta_b) \qquad \text{topographic Sverdrup balance.} \tag{44.84}$$

In the presence of flows interacting with topography, where bottom pressure torques are sizable, this balance is generally much more accurate than the Sverdrup balance.

44.5.3 Integral balances for steady flows

Following the discussion in Section 40.9.5, we write the vorticity balance (44.81) in the form

$$\rho_o \, \nabla \cdot (f \, \boldsymbol{U}) = \hat{\boldsymbol{z}} \cdot \nabla \times [p_a \nabla \eta + \boldsymbol{\tau}(\eta) - p_b \nabla \eta_b - \boldsymbol{\tau}(\eta_b)]. \tag{44.85}$$

Integrating over a horizontal area, $\mathcal{S}$, leads to

$$\rho_o \oint_{\partial \mathcal{S}} f \, \boldsymbol{U} \cdot \hat{\boldsymbol{n}} \, ds = \oint_{\partial \mathcal{S}} [p_a \nabla \eta + \boldsymbol{\tau}(\eta) - p_b \nabla \eta_b - \boldsymbol{\tau}(\eta_b)] \cdot \hat{\boldsymbol{t}} \, ds. \tag{44.86}$$

To reach this result we used Gauss's divergence theorem for the left hand side and Stokes' curl theorem for the right hand side. The unit vector $\hat{\boldsymbol{n}}$ points horizontally outward from the boundary of the area, whereas the unit vector $\hat{\boldsymbol{t}}$ is the counter-clockwise oriented tangent to the closed contour around the boundary. For the special case of $Q_m = 0$ we are afforded a steady state streamfunction for the depth-integrate flow since $\nabla \cdot \boldsymbol{U} = 0$. Choosing the area, $\mathcal{S}$, to be bounded by a closed streamline allows us to set $\boldsymbol{U} \cdot \hat{\boldsymbol{n}} = 0$ along that streamline. We thus see that for steady planetary geostrophic flow with $\nabla \cdot \boldsymbol{U} = 0$, any closed streamline of the flow must maintain the following work balance around the streamline

$$\oint_{\partial \mathcal{S}} [p_a \nabla \eta + \boldsymbol{\tau}(\eta) - p_b \nabla \eta_b - \boldsymbol{\tau}(\eta_b)] \cdot \hat{\boldsymbol{t}} \, ds = 0. \tag{44.87}$$

This equation is a simplified form of equation (40.208) that was formulated for a more general flow. We can rearrange equation (44.87) to display an integrated balance between the work done by boundary pressure form stresses around a closed streamline, and work done by boundary turbulent stresses around the same streamline

$$\oint_{\partial \mathcal{S}} (p_a \nabla \eta - p_b \nabla \eta_b) \cdot \hat{\boldsymbol{t}} \, ds = - \oint_{\partial \mathcal{S}} [\boldsymbol{\tau}(\eta) - \boldsymbol{\tau}(\eta_b)] \cdot \hat{\boldsymbol{t}} \, ds. \tag{44.88}$$

44.5.4 Comments

Yeager (2015) connects torques acting on the depth integrated horizontal flow in the North Atlantic to buoyancy forces affecting the Atlantic meridional overturning circulation, thus illustrating how the formulation in this section can be of use for the analysis of an ocean circulation model.

44.6 Vorticity equation for the depth averaged velocity

In some numerical models, it is more common to have access to the depth averaged velocity

$$\overline{\boldsymbol{u}} = \frac{1}{D} \int_{\eta_b}^{\eta} \boldsymbol{u} \, dz \qquad \text{with} \qquad D = \eta - \eta_b. \tag{44.89}$$

We thus find it useful to develop a budget for the vorticity of the depth averaged velocity. In this discussion we encounter a distinct means for describing how bottom topography, in the presence of baroclinicity, generates meridional flow.

44.6.1 Relating the depth average velocity to boundary velocities

Before studying the vorticity equation, we here relate the depth averaged velocity, $\overline{\boldsymbol{u}}(x, y, t)$, to the surface velocity, $\boldsymbol{u}(x, y, z = \eta, t)$, and bottom velocity, $\boldsymbol{u}(x, y, z = \eta_b, t)$. This analysis exposes some general features of how the boundary flows are driven away from the depth average.

The starting point is the identity

$$\int_{\eta_b}^{\eta} \boldsymbol{u} \, dz = (\eta - \eta_b) \, \boldsymbol{u}(\eta) - \int_{\eta_b}^{\eta} \frac{\partial \boldsymbol{u}}{\partial z} \, (z - \eta_b) \, dz, \tag{44.90}$$

which, along with the analogous identity for the bottom flow, leads to

$$\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta) = - \int_{\eta_b}^{\eta} \frac{\partial \boldsymbol{u}}{\partial z} \left[\frac{z - \eta_b}{\eta - \eta_b} \right] dz \qquad \text{and} \qquad \overline{\boldsymbol{u}} - \boldsymbol{u}(\eta_b) = \int_{\eta_b}^{\eta} \frac{\partial \boldsymbol{u}}{\partial z} \left[\frac{\eta - z}{\eta - \eta_b} \right] dz. \tag{44.91}$$

Note that $\boldsymbol{u}(\eta) - \boldsymbol{u}(\eta_b) = \int_{\eta_b}^{\eta} (\partial \boldsymbol{u}/\partial z) \, dz$ serves as a useful check on the manipulations leading to equation (44.91). We see that the difference between the depth averaged flow and the surface flow, $\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta)$, is determined by the integral of the weighted vertical shear, with the weight linearly decreasing from unity at the surface to zero at the bottom. The minus sign in front of the integral for $\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta)$ follows because if the flow increases in the positive direction from the bottom to the surface, then the depth averaged flow will have a smaller magnitude than the surface flow. The converse weighting holds for computing the difference $\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta_b)$.

The identities (44.91) hold for arbitrary horizontal velocity fields. Assuming the flow satisfies frictional geostrophy as per equation (44.5a) leads to the frictional thermal wind relation

$$f \, \boldsymbol{u} = \rho_o^{-1} \, \hat{\boldsymbol{z}} \times \nabla p - \hat{\boldsymbol{z}} \times \boldsymbol{F} \Longrightarrow f \, \partial_z \boldsymbol{u} = -(g/\rho_o) \, \hat{\boldsymbol{z}} \times \nabla \rho - \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{F}, \tag{44.92}$$

so that the velocity differences are given by

$$f \, [\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta)] = \int_{\eta_b}^{\eta} [(g/\rho_o) \, \hat{\boldsymbol{z}} \times \nabla \rho - \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{F}] \left[\frac{z - \eta_b}{\eta - \eta_b} \right] dz \tag{44.93a}$$

$$f \, [\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta_b)] = - \int_{\eta_b}^{\eta} [(g/\rho_o) \, \hat{\boldsymbol{z}} \times \nabla \rho - \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{F}] \left[\frac{\eta - z}{\eta - \eta_b} \right] dz. \tag{44.93b}$$

Hence, differences between the depth averaged flow and the boundary flows are determined by weighted integrals of the baroclinicity and vertical friction shears.

44.6.2 Formulation of the vorticity equation

To develop the vorticity equation, we start by deriving the momentum equation for the depth averaged flow. For that purpose, rearrange the depth integrated momentum budget (44.80)

according to

$$\rho_o f \hat{\boldsymbol{z}} \times \boldsymbol{U} = -\eta \nabla_h (p_a - p_b) - D \nabla p_b - \nabla \mathscr{P} + \Delta \boldsymbol{\tau}, \tag{44.94}$$

and then divide by the column thickness, $D = \eta - \eta_b$, to render

$$\rho_o f \hat{\boldsymbol{z}} \times \overline{\boldsymbol{u}} = -(\eta/D) \nabla (p_a - p_b) - \nabla p_b + (1/D)(-\nabla \mathscr{P} + \Delta \boldsymbol{\tau}). \tag{44.95}$$

Taking the curl then leads to

$$\rho_o \nabla \cdot (f \overline{\boldsymbol{u}}) = -\hat{\boldsymbol{z}} \cdot \nabla \times [(\eta/D) \nabla (p_a - p_b)] + D^{-2} \hat{\boldsymbol{z}} \cdot [\nabla \times (D \nabla \mathscr{P})] + \hat{\boldsymbol{z}} \cdot [\nabla \times (D^{-1} \Delta \boldsymbol{\tau})] \tag{44.96a}$$

$$= \hat{\boldsymbol{z}} \cdot \nabla \times [(p_a - p_b) \nabla (\eta/D)] - D^{-2} \hat{\boldsymbol{z}} \cdot [\nabla \times (\mathscr{P} \nabla D)] + \hat{\boldsymbol{z}} \cdot [\nabla \times (D^{-1} \Delta \boldsymbol{\tau})]. \tag{44.96b}$$

The vorticity budget (44.96) is a bit less tidy than that for the depth integrated budget (44.83). Nonetheless, it offers some novel insights concerning the flow, which can be seen by writing the left hand side in the form

$$\nabla \cdot (f \overline{\boldsymbol{u}}) = \nabla \cdot [(f/D) \boldsymbol{U}], \tag{44.97}$$

with f/D reminiscient of the shallow water potential vorticity for the planetary geostrophic flow (Section 43.4). Motivated by this analog, we write the vorticity equation (44.96) in the form

$$\rho_o \boldsymbol{U} \cdot \nabla (f/D) = -\rho_o (f/D) \nabla \cdot \boldsymbol{U} + \hat{\boldsymbol{z}} \cdot \nabla \times [(p_a - p_b) \nabla (\eta/D)] \\ - D^{-2} \hat{\boldsymbol{z}} \cdot [\nabla \times (\mathscr{P} \nabla D)] + \hat{\boldsymbol{z}} \cdot [\nabla \times (D^{-1} \Delta \boldsymbol{\tau})]. \tag{44.98}$$

Contrary to the shallow water case, we here see that even for a perfect planetary geostrophic fluid, the depth-integrated flow does not generally follow contours of constant f/D. Even so, it is of interest to examine how the processes on the right hand side contribute to flow deviations from f/D contours. For that purpose we simplify the flow even more by making the rigid lid approximation.

44.6.3 Rigid lid approximation and the role of JEBAR

The rigid lid approximation is commonly made for studies of large-scale circulation. Indeed, it was the basis for many ocean general circulation models following the work of *Bryan* (1969). A fluid satisfying the rigid lid approximation has a vanishing horizontal divergence for the depth integrated flow

$$\text{rigid lid approximation} \implies \nabla \cdot \boldsymbol{U} = 0. \tag{44.99}$$

Furthermore, as part of the rigid lid approximation we assume the free surface undulations are much smaller than the resting ocean depth so that

$$|\eta| \ll |\eta_b| \implies \eta/D \approx 0 \tag{44.100a}$$

$$1/(\eta - \eta_b) \approx 1/(-\eta_b) = 1/\mathtt{H}. \tag{44.100b}$$

We introduced

$$\mathtt{H} = -\eta_b \tag{44.101}$$

to correspond to the literature for rigid lid models and the JEBAR term.[7] Hence, with the rigid lid approximation the vorticity equation (44.98) takes the simplified form

$$\boldsymbol{U} \cdot \nabla(f/\mathtt{H}) = \rho_o^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \times (\mathscr{P}\, \nabla \mathtt{H}^{-1}) + \nabla \times (\mathtt{H}^{-1}\, \Delta \boldsymbol{\tau})]. \tag{44.102}$$

Each term in this equation has dimensions of inverse squared time, T^{-2}.

JEBAR drives deviations from $f/\mathtt{H}$ aligned flow

The first term on the right hand side of the vorticity equation (44.102) is referred to as the Joint Effect of Baroclinicity and Relief (JEBAR)

$$\text{JEBAR} \equiv \rho_o^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \times (\mathscr{P}\, \nabla \mathtt{H}^{-1})] = \rho_o^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \mathscr{P} \times \nabla \mathtt{H}^{-1}]. \tag{44.103}$$

This name arises since JEBAR is nonzero only in the presence of non-flat topography ("relief") and (as shown below) when density is not a constant (i.e., for baroclinic flow). In addition to contributions from boundary stresses, equation (44.102) says that misalignment of $f/\mathtt{H}$ contours with the depth-integrated steady rigid lid flow is driven by misalignments of isobaths and isolines of the depth integrated potential energy.

Contributions to JEBAR arise only from the component of the potential energy that deviates from a constant density reference state. To show that property, note that in the rigid lid approximation, the potential energy in a column, as given by equation (44.77), takes the form

$$\mathscr{P} = (1/2)\, g\, \rho_o\, \mathtt{H}^2 + g \int_{-\mathtt{H}}^{0} \rho'\, z\, \mathrm{d}z, \tag{44.104}$$

where $\rho' = \rho - \rho_o$. With $\nabla \mathtt{H}^2 \times \nabla(1/\mathtt{H}) = 0$, we are left with just the contribution from ρ'

$$\text{JEBAR} = \rho_o^{-1}\, \hat{\boldsymbol{z}} \cdot \left[\nabla \left(g \int_{-\mathtt{H}}^{0} \rho'\, z\, \mathrm{d}z \right) \times \nabla \mathtt{H}^{-1} \right]. \tag{44.105}$$

JEBAR vanishes for a homogeneous density field, where ρ' is a constant, but is nonzero with a nonzero ρ'. In a Boussinesq ocean, a nonzero ρ' is associated with baroclinicity (Figure 40.10).

Relating JEBAR to pressure

JEBAR as given by equation (44.103) has the appearance of the curl of a form stress, and yet it is not. The reason is that $\mathscr{P}$ is the potential energy of the fluid column rather than bottom pressure. We make this point explicit by recalling the decomposition (44.76), here specialized to the rigid lid in which

$$\mathscr{P} = \mathtt{H}\, (\overline{p} - p_b) \qquad \text{with} \qquad \overline{p} = \mathtt{H}^{-1} \int_{-\mathtt{H}}^{0} p\, \mathrm{d}z = (-\eta_b)^{-1} \int_{\eta_b}^{0} p\, \mathrm{d}z. \tag{44.106}$$

Plugging into the vorticity equation (44.102) leads to

$$\rho_o\, \boldsymbol{U} \cdot \nabla(f/\mathtt{H}) = \mathtt{H}^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \mathtt{H} \times \nabla(\overline{p} - p_b)] + \hat{\boldsymbol{z}} \cdot \nabla \times (\mathtt{H}^{-1}\, \Delta \boldsymbol{\tau})]. \tag{44.107}$$

Evidently, JEBAR is nonzero where the depth averaged pressure deviates from the bottom pressure

$$\text{JEBAR} = \rho_o^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \mathscr{P} \times \nabla \mathtt{H}^{-1})] = (\rho_o\, \mathtt{H})^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \mathtt{H} \times \nabla(\overline{p} - p_b)]. \tag{44.108}$$

[7] Note that H is the vertical depth scale, which is a constant, and it is distinct from $\mathtt{H}(x,y) = -\eta_b(x,y)$, which is a function of horizontal position.

We can go one more step in exposing the pressure difference through use of equation (44.91), here applied to hydrostatic pressure, in which case (remember that $\mathtt{H} = -\eta_b$)

$$\overline{p} - p_b = \int_{\eta_b}^{0} \frac{\partial p}{\partial z} \frac{z}{\eta_b} \, dz = (g/\mathtt{H}) \int_{-\mathtt{H}}^{0} z \, \rho \, dz = \mathtt{H}^{-1} \, \mathscr{P}, \tag{44.109}$$

so that[8]

$$\nabla_h(\overline{p} - p_b) = -g \, \rho(z = -\mathtt{H}) \, \nabla_h \mathtt{H} + g \int_{-\mathtt{H}}^{0} \nabla_h(\rho \, z/\mathtt{H}) \, dz. \tag{44.110}$$

The first term arises from slopes in the bottom topography as weighted by the bottom density, whereas the second term arises from the integral of horizontal gradients in the $z/\mathtt{H}$ weighted density.

Alternatively, we can introduce a geostrophic velocity associated with the gradient of the bottom pressure as well as the vertically averaged pressure

$$\rho_o \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{gb} = -\nabla p_b \quad \text{and} \quad \rho_o \, f \, \hat{\boldsymbol{z}} \times \overline{\boldsymbol{u}}_g = -\nabla \overline{p} \Longrightarrow \nabla(\overline{p} - p_b) = \rho_o \, f \, \hat{\boldsymbol{z}} \times (\boldsymbol{u}_{gb} - \overline{\boldsymbol{u}}_g). \tag{44.111}$$

Doing so brings JEBAR from equation (44.108) into the form

$$\text{JEBAR} = (\rho_o \, \mathtt{H})^{-1} \, \hat{\boldsymbol{z}} \cdot [\nabla \mathtt{H} \times \nabla(\overline{p} - p_b)] = -f \, \mathtt{H}^{-1} \, \nabla \mathtt{H} \cdot (\overline{\boldsymbol{u}}_g - \boldsymbol{u}_{gb}). \tag{44.112}$$

JEBAR thus arises from a nonzero projection onto the bottom slope of the difference between the geostrophic velocity arising from the bottom pressure and the geostrophic velocity arising from the depth averaged pressure.

Equation (44.83) provides the budget for vorticity of the depth integrated flow, in which we find the curl of the topographic form stress leads to vortex stretching. For the vorticity of the depth averaged flow, we instead encounter the JEBAR term in equation (44.107), which is not a pure vortex stretching term. Instead, it accounts for the fact that it is the horizontal velocity flowing across isobaths, $\boldsymbol{u}(z = \eta_b)$, rather than depth averaged horizontal velocity, $\overline{\boldsymbol{u}}$, that leads to vortex stretching. Hence, when studying vorticity of the depth averaged velocity, $\overline{\boldsymbol{u}}$, accounting for the role of vortex stretching requires us to include JEBAR.

Integral balances

Since the depth integrated flow is assumed to be non-divergent in the rigid lid approximation, $\nabla \cdot \boldsymbol{U} = 0$, we know there exists a streamfunction for this flow. Consider a region where there are closed streamlines. Following the steps in Section (44.5.3), we integrate the steady vorticity equation (44.102) around the streamline. Noting that $\boldsymbol{U} \cdot \hat{\boldsymbol{n}} = 0$ along the streamline, where $\hat{\boldsymbol{n}}$ is the horizontal unit normal to the streamline, thus renders the steady balance

$$\oint_{\partial \mathcal{S}_{\text{streamline}}} (\mathscr{P} \, \nabla \mathtt{H}^{-1} + \mathtt{H}^{-1} \, \Delta \boldsymbol{\tau}) \cdot \hat{\boldsymbol{t}} \, ds = 0. \tag{44.113}$$

44.6.4 Further study

Mertz and Wright (1992) discuss the physics of how JEBAR relates to the curl of the topographic form stress as well as other mathematically equivalent forms. *Cane et al.* (1998) as well as Section 2.5 of *Drijfhout et al.* (2013) discusses how JEBAR can be physically misleading. For this reason, recent studies of vorticity budgets in ocean models generally eschew JEBAR, instead favoring an analysis of vorticity of the depth integrated flow as in Section 44.5 or the depth integrated

[8] We reintroduced the notation, ∇_h, given the presence of z and $\rho(z)$ in the integral in equation (44.110).

vorticity from Section 44.3. *Waldman and Giordani* (2023) provide a review of vorticity analysis for the ocean.

Chapter 45

FOUNDATIONS OF QUASI-GEOSTROPHY

Quasi-geostrophy (QG) is the canonical *balanced model* in geophysical fluid mechanics whereby the quasi-geostrophic potential vorticity is the sole prognostic field. All other fields, such as the velocity and buoyancy, are diagnosed from potential vorticity. The process of diagnosing the allied fields requires solving an elliptic boundary value problem to compute the geostrophic streamfunction with potential vorticity acting as the source. This connection between potential vorticity and streamfunction represents an *invertibility* principle, with the mathematical technology required for inversion shared with many other elliptic problems in mathematical physics.[1]

Quasi-geostrophy is an elegant theory of mathematical physics that offers physical and mathematical insights into the workings of geophysical fluid motions where rotation and stratification play leading roles. Our goal in this chapter is to provide a taste of its continuously stratified realization, offering a detailed derivation that builds from Chapters 43 and 44. We also sample some of its physical and mathematical content.

CHAPTER GUIDE

In this chapter we extend to continuously stratified fluids the shallow water discussion of quasi-geostrophy in Chapter 43. Continuously stratified quasi-geostrophy is not concerned with the processes that affect stratification, but instead with the processes that slightly perturb that stratification. We make use of stratified geophysical fluid dynamics from Chapters 24 and 31, as well as potential vorticity from Chapter 41. This chapter is essential for the study of Rossby waves and baroclinic instability in Chapter 62.

[1] See Section 6.5 for a summary of elliptic partial differential equations, and Chapter 9 for solution methods based on Green's functions.

45.1 Loose threads

- Solution needed for Exercise 45.4.

45.2 Non-dimensional equations of quasi-geostrophy

In deriving the quasi-geostrophic potential vorticity equation, we proceed much like for the single layer of shallow water fluid in Section 43.5. In particular, quasi-geostrophic scaling from Section 43.5.1 is relevant for both the shallow water and for the continuously stratified fluid. We employ an asymptotic expansion in the Rossby number and stop at the first nontrivial order, which (as for the shallow water) is Ro^1. For this purpose, recall the non-dimensional momentum and continuity equations from Section 43.7.8

$$\mathrm{Ro}\left[\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{t}} + (\widehat{\boldsymbol{u}}\cdot\widehat{\nabla}_{\widehat{z}})\,\widehat{\boldsymbol{u}} + \widehat{w}\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{z}}\right] + \widehat{\boldsymbol{f}}\times\widehat{\boldsymbol{u}} = -\widehat{\nabla}_z\,\widehat{\varphi} \tag{45.1a}$$

$$\frac{\partial \widehat{\varphi}}{\partial \widehat{z}} = \widehat{b} \tag{45.1b}$$

$$\widehat{\nabla}\cdot\widehat{\boldsymbol{v}} = 0 \tag{45.1c}$$

$$\frac{\mathrm{Ro}}{\mathrm{Bu}}\frac{\mathrm{D}\widehat{b}}{\mathrm{D}\widehat{t}} + \widehat{w} = 0. \tag{45.1d}$$

We expand all fields in an asymptotic series in Rossby number

$$\widehat{u} = \widehat{u}_0 + \mathrm{Ro}\,\widehat{u}_1 + \mathrm{Ro}^2\,\widehat{u}_2 + \ldots \tag{45.2a}$$

$$\widehat{v} = \widehat{v}_0 + \mathrm{Ro}\,\widehat{v}_1 + \mathrm{Ro}^2\,\widehat{v}_2 + \ldots \tag{45.2b}$$

$$\widehat{w} = \widehat{w}_0 + \mathrm{Ro}\,\widehat{w}_1 + \mathrm{Ro}^2\,\widehat{w}_2 + \ldots \tag{45.2c}$$
$$\widehat{b} = \widehat{b}_0 + \mathrm{Ro}\,\widehat{b}_1 + \mathrm{Ro}^2\,\widehat{b}_2 + \ldots \tag{45.2d}$$
$$\widehat{\varphi} = \widehat{\varphi}_0 + \mathrm{Ro}\,\widehat{\varphi}_1 + \mathrm{Ro}^2\,\widehat{\varphi}_2 + \ldots \tag{45.2e}$$

along with the expansion (43.55) for the Coriolis parameter

$$\widehat{f} = \widehat{f}_0 + \mathrm{Ro}\,\widehat{\beta}\,\widehat{y}, \tag{45.3}$$

and where (equation (43.56))

$$\widehat{\beta}\,\widehat{y} = \frac{\beta\, y}{\mathrm{Ro}\, f_\circ} = T\,\beta\, y. \tag{45.4}$$

As noted in Section 43.5.2, the velocity field is non-divergent at each order of Rossby number, so that

$$\nabla \cdot \widehat{\boldsymbol{v}}_n = 0 \quad \forall\, n. \tag{45.5}$$

The Burger number is order unity since the horizontal length scales of the flow considered here are on the order of the deformation radius

$$\mathrm{Bu} \sim 1 \Longrightarrow L \sim L_\mathrm{d}, \tag{45.6}$$

where we introduced the *internal deformation radius* from Section 43.7.6

$$L_\mathrm{d}(z) = H\,[N(z)/f_\circ]. \tag{45.7}$$

It is important to retain the depth dependence of the Burger number through its dependence on the background stratification $N^2(z)$

$$\mathrm{Bu}(z) = \left[\frac{L_\mathrm{d}}{L}\right]^2 = N^2(z)\left[\frac{H}{L\, f_\circ}\right]^2, \tag{45.8}$$

which motivates the name *Burger function* for continuously stratified quasi-geostrophy. Importantly, the Burger function does not commute with the vertical derivative operator.

45.2.1 Zeroth order asymptotic equations

The zeroth order asymptotic equations are

$$\widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z\, \widehat{\varphi}_0 \tag{45.9a}$$
$$\partial_{\widehat{z}} \widehat{\varphi}_0 = \widehat{b}_0 \tag{45.9b}$$
$$\widehat{\nabla}_z \cdot \widehat{\boldsymbol{u}}_0 + \partial_{\widehat{z}} \widehat{w}_0 = 0 \tag{45.9c}$$
$$\widehat{w}_0 = 0. \tag{45.9d}$$

The first equation represents f-plane geostrophy, which means that the horizontal velocity has zero divergence

$$\widehat{\nabla}_z \cdot \widehat{\boldsymbol{u}}_0 = 0. \tag{45.10}$$

Equation (45.9b) means the zeroth order buoyancy determines the zeroth order hydrostatic pressure. Since the horizontal velocity has zero divergence, the continuity equation (45.9c) means that the vertical velocity is depth independent

$$\partial_{\widehat{z}} \widehat{w}_0 = 0. \tag{45.11}$$

If it vanishes somewhere, such as a solid horizontal bottom boundary, then it vanishes everywhere. This is a manifestation of the Taylor-Proudman theorem (see Section 31.5.3). Indeed, a vanishing $\widehat{w}_0$ is required by the zeroth-order buoyancy equation (45.9d) even if the bottom is not flat. Hence, the non-dimensional velocity has a nonzero contribution only at order Ro^1

$$\widehat{w} = \mathrm{Ro}\,\widehat{w}_1 + \mathrm{Ro}^2\,\widehat{w}_2 + \ldots, \tag{45.12}$$

thus manifesting the vertical stiffening of fluid columns found in rotating fluids. Correspondingly, the dimensionful vertical velocity has the asymptotic expansion

$$w = W\widehat{w} = W\,\mathrm{Ro}\,(\widehat{w}_1 + \mathrm{Ro}\,\widehat{w}_2 + \ldots), \tag{45.13}$$

so that to leading to order Ro^1

$$\widehat{w}_1 = \frac{w}{W\,\mathrm{Ro}}. \tag{45.14}$$

Since the zeroth-order horizontal velocity is non-divergent, we can introduce a geostrophic streamfunction

$$\widehat{u}_0 = -\partial_{\widehat{y}}\widehat{\psi}_0 \qquad \text{and} \qquad \widehat{v}_0 = \partial_{\widehat{x}}\widehat{\psi}_0 \qquad \text{and} \qquad \widehat{\zeta}_0 = \widehat{\nabla}^2\widehat{\psi}_0, \tag{45.15}$$

where the zeroth-order streamfunction is the ratio of the zeroth order pressure to zeroth order Coriolis parameter

$$\widehat{\psi}_0 = \widehat{\varphi}_0/\widehat{f}_0. \tag{45.16}$$

Note also that the zeroth-order system satisfies the thermal wind balance

$$\widehat{\boldsymbol{f}}_0 \times \partial_{\widehat{z}}\widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z\,\widehat{b}_0. \tag{45.17}$$

Finally, note that the zeroth order buoyancy is determined by the streamfunction through the hydrostatic balance

$$\widehat{b}_0 = \partial_{\widehat{z}}\widehat{\varphi}_0 = \widehat{f}_0\,\partial_{\widehat{z}}\widehat{\psi}_0. \tag{45.18}$$

45.2.2 First order asymptotic equations

For a prognostic equation we must consider equations at order Ro^1

$$\frac{\mathrm{D}_0\widehat{\boldsymbol{u}}_0}{\mathrm{D}\widehat{t}} + \widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_1 + \widehat{\beta}\,\widehat{y}\,\hat{\boldsymbol{z}} \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z\widehat{\varphi}_1 \tag{45.19a}$$

$$\partial_{\widehat{z}}\widehat{\varphi}_1 = \widehat{b}_1 \tag{45.19b}$$

$$\widehat{\nabla}_z \cdot \widehat{\boldsymbol{u}}_1 + \partial_{\widehat{z}}\widehat{w}_1 = 0 \tag{45.19c}$$

$$\frac{1}{\mathrm{Bu}}\frac{\mathrm{D}_0\widehat{b}_0}{\mathrm{D}\widehat{t}} + \widehat{w}_1 = 0. \tag{45.19d}$$

The first order terms are often referred to as the *ageostrophic* components, though note that all contributions higher than zeroth order constitute ageostrophic contributions.

At order Ro^1, the material time derivative makes use *only* of the zeroth order horizontal geostrophic velocity

$$\frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}} = \frac{\partial}{\partial\widehat{t}} + \widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}. \tag{45.20}$$

To close this set of equations, we produce the vorticity equation from the momentum equation, and then combine the vorticity equation and buoyancy equation to produce the quasi-geostrophic potential vorticity equation. In Section 43.5, we performed the same procedure for deriving the shallow water quasi-geostrophic equations.

Taking the curl of the momentum equation (45.19a) eliminates the pressure gradient, $\widehat{\nabla}\widehat{\varphi}_1$, thus producing the vorticity equation

$$\partial_{\widehat{t}}\widehat{\zeta}_0 + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla})\,(\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y}) = -\widehat{f}_0\,\widehat{\nabla}_z \cdot \widehat{\boldsymbol{u}}_1. \tag{45.21}$$

We make use of the continuity equation (45.19c) to eliminate the horizontal convergence

$$\partial_{\widehat{t}}\widehat{\zeta}_0 + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla})\,(\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y}) = \widehat{f}_0\,\partial_{\widehat{z}}\widehat{w}_1. \tag{45.22}$$

The right hand side represents the contribution to vorticity evolution from stretching by the ageostrophic vertical velocity acting in a rotating reference frame. We can eliminate the ageostrophic vertical velocity through use of the buoyancy equation (45.19d). When doing so, it is important to keep the depth dependence of the Burger function, $\mathrm{Bu}(z)$, according to equation (45.8), with this depth dependence arising from the prescribed background stratification, $N^2(z)$. The resulting vorticity equation is

$$\partial_{\widehat{t}}\widehat{\zeta}_0 + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla})\,(\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y}) = -\widehat{f}_0\,\frac{\partial}{\partial \widehat{z}}\left[\frac{1}{\mathrm{Bu}}\,\frac{\mathrm{D}_0\widehat{b}_0}{\mathrm{D}\widehat{t}}\right]. \tag{45.23}$$

We now use the identity

$$\frac{\partial}{\partial \widehat{z}}\left[\frac{1}{\mathrm{Bu}}\,\frac{\mathrm{D}_0\widehat{b}_0}{\mathrm{D}\widehat{t}}\right] = \frac{\partial}{\partial \widehat{z}}\left[\frac{1}{\mathrm{Bu}}\left(\frac{\partial}{\partial \widehat{t}} + \widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}\right)\widehat{b}_0\right] \tag{45.24a}$$

$$= \frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}}\left[\frac{\partial}{\partial \widehat{z}}\left(\frac{\widehat{b}_0}{\mathrm{Bu}}\right)\right] + \frac{1}{\mathrm{Bu}}\,\frac{\partial \widehat{\boldsymbol{u}}_0}{\partial \widehat{z}} \cdot \widehat{\nabla}_z\widehat{b}_0 \tag{45.24b}$$

$$= \frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}}\left[\frac{\partial}{\partial \widehat{z}}\left(\frac{\widehat{b}_0}{\mathrm{Bu}}\right)\right], \tag{45.24c}$$

where we set

$$\partial_{\widehat{z}}\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}_z\widehat{b}_0 = 0 \tag{45.25}$$

since the zeroth-order velocity maintains thermal wind balance (45.17). Bringing terms together then leads to the material conservation equation for quasi-geostrophic potential vorticity

$$\frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}}\left[\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y} + \widehat{f}_0\,\frac{\partial}{\partial \widehat{z}}\left(\frac{\widehat{b}_0}{\mathrm{Bu}}\right)\right] = 0. \tag{45.26}$$

45.3 Dimensionful equations of quasi-geostrophy

To expose physical elements to the continusously stratified quasi-geostrophic theory, we reintroduce physical dimensions as done for shallow water quasi-geostrophy in Section 43.6. For that purpose, we write

$$\boldsymbol{u} \equiv \boldsymbol{u}_{\mathrm{g}} + \boldsymbol{u}_{\mathrm{ag}} = U\,(\widehat{\boldsymbol{u}}_0 + \mathrm{Ro}\,\widehat{\boldsymbol{u}}_1) \tag{45.27a}$$

$$w \equiv w_{\mathrm{ag}} = \mathrm{Ro}\,W\,\widehat{w}_1 \tag{45.27b}$$

$$b \equiv b_{\mathrm{g}} + B_{\mathrm{ag}} = B\,(\widehat{b}_0 + \mathrm{Ro}\,\widehat{b}_1) \tag{45.27c}$$

$$\varphi \equiv \varphi_{\mathrm{g}} + \varphi_{\mathrm{ag}} = f_\circ\,U\,L\,(\widehat{\varphi}_0 + \mathrm{Ro}\,\widehat{\varphi}_1). \tag{45.27d}$$

Reintroducing dimensions is straightforward but a bit tedious.

45.3.1 Hydrostatic balance

Hydrostatic balance is maintained for terms at each Rossby number order, so that we have the dimensional equations

$$\partial_z \varphi_{\mathrm{g}} = b_{\mathrm{g}} \quad \text{and} \quad \partial_z \varphi_{\mathrm{ag}} = B_{\mathrm{ag}}. \tag{45.28}$$

45.3.2 Continuity equation

The three dimensional velocity is non-divergent at each order in Rossby number. The zeroth order (geostrophic) flow is horizontally non-divergent so that

$$\nabla \cdot \boldsymbol{u}_{\mathrm{g}} = 0, \tag{45.29}$$

whereas the next order (ageostrophic) flow satisfies

$$\nabla \cdot \boldsymbol{v}_{\mathrm{ag}} = \nabla \cdot \boldsymbol{u}_{\mathrm{ag}} + \partial_z w_{\mathrm{ag}} = 0. \tag{45.30}$$

45.3.3 Geostrophic balance

The non-dimensional geostrophic balance for the zeroth order fields

$$\widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z \, \widehat{\varphi}_0 \tag{45.31}$$

takes on the dimensional form

$$\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}}/U = -L \, \nabla_{\mathrm{h}} \varphi_{\mathrm{g}}/(f_{\mathrm{o}} \, U \, L). \tag{45.32}$$

Canceling factors leads to the expected form of f-plane geostrophy

$$f_{\mathrm{o}} \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -\nabla_{\mathrm{h}} \varphi_{\mathrm{g}}. \tag{45.33}$$

45.3.4 Material time derivative

For the material time derivative operator we write

$$\begin{aligned}
\mathrm{D}/\mathrm{D}t &= \partial_t + \boldsymbol{u} \cdot \nabla + w \, \partial_z && \text{(45.34a)} \\
&= (1/T) \, \partial_{\widehat{t}} + (U/L) \, \widehat{\boldsymbol{u}} \cdot \widehat{\nabla} + (W/H) \, \widehat{w} \, \partial_{\widehat{z}} && \text{(45.34b)} \\
&= (1/T) \, (\partial_{\widehat{t}} + \widehat{\boldsymbol{u}} \cdot \widehat{\nabla} + \widehat{w} \, \partial_{\widehat{z}}) && \text{(45.34c)} \\
&= (1/T) \, (\partial_{\widehat{t}} + \widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}_z) + (\mathrm{Ro}/T) \, (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}_z + \widehat{w}_1 \, \partial_{\widehat{z}}) && \text{(45.34d)} \\
&= \partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}} + \boldsymbol{u}_{\mathrm{ag}} \cdot \nabla_{\mathrm{h}} + w_{\mathrm{ag}} \, \partial_z && \text{(45.34e)} \\
&\equiv \mathrm{D}_{\mathrm{g}}/\mathrm{D}t + \boldsymbol{u}_{\mathrm{ag}} \cdot \nabla_{\mathrm{h}} + w_{\mathrm{ag}} \partial_z, && \text{(45.34f)}
\end{aligned}$$

where time scales according to advection, $T = L/U$, vertical velocity scales according to continuity, $W = H \, U/L$, and we introduced the geostrophic material time derivative operator

$$\mathrm{D}_{\mathrm{g}}/\mathrm{D}t \equiv \partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}}. \tag{45.35}$$

45.3.5 Buoyancy equation

The buoyancy equation requires a bit more work. For that purpose, split buoyancy into a depth dependent static background and a deviation from the background

$$b = \tilde{b}(z) + b'(x, y, z, t), \tag{45.36}$$

with its vertical derivative

$$\partial_z b = \mathrm{d}\tilde{b}/\mathrm{d}z + \partial_z b' = N^2 + \partial_z b', \tag{45.37}$$

where $N^2(z)$ is the squared buoyancy frequency for the prescribed background buoyancy field. In this manner, the adiabatic buoyancy equation is

$$\frac{\partial b'}{\partial t} + \boldsymbol{u} \cdot \nabla b' + w\,(N^2 + \partial_z b') = 0. \tag{45.38}$$

We non-dimensionalize this equation by making use of the following relations between the scales

$$B = f_\circ\, U\, L/H \qquad W = H\,(U/L) \qquad \mathrm{Ro} = U/(f_\circ\, L) \qquad \mathrm{Bu} = (N\,H)^2/(f_\circ\, L)^2, \tag{45.39}$$

in which case the buoyancy equation takes the form

$$\partial_t b' + \boldsymbol{u} \cdot \nabla b' + w\,(N^2 + \partial_z b') = \frac{B}{T}\frac{\partial \widehat{b}}{\partial \widehat{t}} + \frac{U\,B}{L}\,\widehat{\boldsymbol{u}} \cdot \widehat{\nabla}_z \widehat{b} + W\,\widehat{w}\,N^2 + \frac{W\,B}{H}\,\widehat{w}\,\partial_{\widehat{z}}\widehat{b} = 0. \tag{45.40}$$

We find it useful to divide by $f_\circ\, N^2$, so that

$$\frac{1}{f_\circ\, N^2}\left[\partial_t b' + \boldsymbol{u} \cdot \nabla b' + w\,(N^2 + \partial_z\, b')\right] = \frac{H\,\mathrm{Ro}^2}{\mathrm{Bu}}\left[\partial_{\widehat{t}}\widehat{b} + \widehat{\boldsymbol{u}} \cdot \widehat{\nabla}\widehat{b} + \widehat{w}\,\partial_{\widehat{z}}\widehat{b}\right] + \mathrm{Ro}\,\widehat{w} = 0. \tag{45.41}$$

The vertical velocity component, $\widehat{w}$, is nonzero only at order Ro^1, so the term $\mathrm{Ro}\,\widehat{w}$ is order Ro^2 (recall equation (45.27b)). For the material time derivative term, we drop the vertical velocity term, $\widehat{w}\,\partial_{\widehat{z}}\widehat{b}$, since it is order Ro^1 smaller than the other terms in the material time operator. We thus retain only the zeroth order buoyancy contribution, $\widehat{b}_0$. Reintroducing physical dimensions then leads to the dimensional form of the quasi-geostrophic buoyancy equation

$$(\partial_t + \boldsymbol{u}_\mathrm{g} \cdot \nabla_\mathrm{h})\, b_\mathrm{g} + w_\mathrm{ag}\, N^2 = \frac{\mathrm{D}_\mathrm{g} b_\mathrm{g}}{\mathrm{D}t} + w_\mathrm{ag}\, N^2 = 0. \tag{45.42}$$

This equation means that the geostrophic transport of the geostrophic buoyancy is affected by a source due to the ageostrophic vertical advection of background buoyancy

$$\frac{\mathrm{D}_\mathrm{g} b_\mathrm{g}}{\mathrm{D}t} = -w_\mathrm{ag}\, N^2 \quad \text{with} \quad b_\mathrm{g} = f_\circ\, \partial_z \psi. \tag{45.43}$$

45.3.6 Vorticity equation

Reintroducing dimensions to the vorticity equation (45.22) yields[2]

$$\partial_{\widehat{t}}\widehat{\zeta}_0 + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}_\mathrm{h})\,(\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y}) - \widehat{f}_0\,\partial_{\widehat{z}}\widehat{w}_1 = T^2\,[\partial_t \zeta + \boldsymbol{u}_\mathrm{g} \cdot \nabla_\mathrm{h}(\zeta + \beta\, y)] - \frac{H}{W\,\mathrm{Ro}}\,\partial_z w_\mathrm{ag}. \tag{45.44}$$

The identity $H/(W\,\mathrm{Ro}) = f_\circ\, T^2$ leads to the order Ro^1 vorticity equation

$$\partial_t \zeta_\mathrm{a} + J(\psi, \zeta_\mathrm{a}) = f_\circ\, \partial_z w_\mathrm{ag}, \tag{45.45}$$

with the absolute vorticity given by the sum of the geostrophic relative vorticity plus the planetary beta contribution

$$\zeta_\mathrm{a} = \zeta_\mathrm{g} + \beta\, y. \tag{45.46}$$

Hence, the absolute geostrophic vorticity is advected by the geostrophic flow, and it has a source (right hand side of equation (45.45)) due to vertical stretching by the ageostrophic flow.

[2] Recall from equation (45.27b) that to order Ro^1 we have $W\,\widehat{w} = \mathrm{Ro}\,W\,\widehat{w}_1 = w_\mathrm{ag}$.

Expanding the Jacobian and introducing the geostrophic velocity, $\boldsymbol{u}_{\text{g}} = \hat{\boldsymbol{z}} \times \nabla\psi$, leads to the geostrophic relative vorticity equation

$$(\partial_t + \boldsymbol{u}_{\text{g}} \cdot \nabla_{\text{h}})\, \zeta_{\text{g}} = -\beta\, v_{\text{g}} + f_{\circ}\, \partial_z w_{\text{ag}}. \tag{45.47}$$

We thus see that the beta effect from the geostrophic flow, plus vertical stretching by the ageostrophic flow, provide local sources for geostrophic relative vorticity.

45.3.7 Potential vorticity

From equation (45.26), we identify the non-dimensional quasi-geostrophic potential vorticity

$$\widehat{q} = \widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y} + \widehat{f}_0\, \frac{\partial(\widehat{b}_0/\text{Bu})}{\partial \widehat{z}}. \tag{45.48}$$

Introducing dimensional quantities to the right hand side yields[3]

$$\widehat{q} = \frac{L}{U}\,[\zeta_{\text{g}} + \beta\, y] + \frac{\partial}{\partial z}\left[\frac{H\, b_{\text{g}}}{B\,\text{Bu}}\right] \tag{45.49a}$$

$$= (1/(f_{\circ}\,\text{Ro})\,(\zeta_{\text{g}} + \beta\, y) + \frac{H}{B}\,\frac{\partial}{\partial z}\left[\frac{b_{\text{g}}}{\text{Bu}}\right]. \tag{45.49b}$$

The scale for the fluctuating buoyancy is given by equation (43.160), $B = f_{\circ}\, U\, L/H$, and the inverse Burger function is given by equation (45.8), $\text{Bu}^{-1} = [(L\, f_{\circ})/(H\, N)]^2$, so that

$$\widehat{q} = (1/(f_{\circ}\,\text{Ro})\,(\zeta_{\text{g}} + \beta\, y) + \frac{H^2}{f_{\circ}\, U\, L}\,\frac{L^2\, f_{\circ}^2}{H^2}\,\frac{\partial}{\partial z}\left[\frac{b_{\text{g}}}{N^2}\right] \tag{45.50a}$$

$$= (1/(f_{\circ}\,\text{Ro})\,(\zeta_{\text{g}} + \beta\, y) + \text{Ro}^{-1}\,\partial_z(b_{\text{g}}/N^2). \tag{45.50b}$$

Introducing the geostrophic streamfunction,

$$\boldsymbol{u}_{\text{g}} = \hat{\boldsymbol{z}} \times \nabla_{\text{h}}\psi \quad \text{and} \quad \zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}_{\text{g}}) = \nabla_{\text{h}}^2\psi \quad \text{and} \quad b_{\text{g}} = f_{\circ}\,\partial_z\psi, \tag{45.51}$$

leads to

$$q \equiv f_{\circ}\,\text{Ro}\,\widehat{q} = \beta\, y + \zeta_{\text{g}} + \frac{\partial}{\partial z}\left[\frac{f_{\circ}^2}{N^2}\,\frac{\partial\psi}{\partial z}\right]. \tag{45.52}$$

Just as for the shallow water case in Section 43.6.1, the potential vorticity (45.52) scales as $f_{\circ}\,\text{Ro}$. The order Ro scaling is expected since it is only at this order that we realize a prognostic set of equations. We sometimes choose to add the constant $f_{\circ}$ to q, which has no effect on the dynamics but reveals the beta plane planetary vorticity

$$q = \underbrace{f_{\circ} + \beta\, y}_{\text{planetary vorticity}} + \underbrace{\nabla_{\text{h}}^2\psi}_{\text{relative vorticity}} + \underbrace{\frac{\partial}{\partial z}\left[\frac{f_{\circ}^2}{N^2}\,\frac{\partial\psi}{\partial z}\right]}_{\text{stretching by } f}. \tag{45.53}$$

Evidently, there are three contributions to the quasi-geostrophic potential vorticity.

- PLANETARY VORTICITY: The planetary vorticity contribution, $f_{\circ} + \beta\, y$, arises from rotation of the reference frame. As noted above, the $\beta\, y$ term is the only dynamically relevant contribution, so that we can equally well drop the $f_{\circ}$ contribution.

[3] Recall $\widehat{f}_0 = 1$ and $\widehat{\beta}\,\widehat{y} = T\,\beta\, y = (L/U)\,\beta\, y$.

- GEOSTROPHIC RELATIVE VORTICITY: The vertical component of the geostrophic relative vorticity, $\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) = \nabla_{\mathrm{h}}^2 \psi$, acts to bring out the smaller scale features in the streamfunction.

- VERTICAL STRETCHING: The final contribution arises from vertical stretching in the presence of a rotating planet. Equation (45.22) helps to remind us why this term arises from vortex stretching.

Material evolution of quasi-geostrophic potential vorticity follows the horizontal geostrophic flow

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}})\, q = 0. \tag{45.54}$$

Geostrophic material constancy of q represents a balance, following the geostrophic flow, of time changes for the planetary vorticity, relative vorticity, and vertical stretching. This is a remarkable property of quasi-geostrophic flows. It packs in a wealth of physical processes that act to evolve the geostrophic flow while maintaining an exact geostrophic balance at each point in space and time.

45.3.8 Velocity equation

The prognostic velocity equation arises from the first order asymptotic equation (45.19a)

$$\frac{\mathrm{D}_0 \widehat{\boldsymbol{u}}_0}{\mathrm{D}\widehat{t}} + \widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_1 + \widehat{\beta}\, \widehat{y}\, \hat{\boldsymbol{z}} \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z \widehat{\varphi}_1. \tag{45.55}$$

Our skills with reintroducing dimensional quantities should be sufficient to write down the dimensional velocity equation by inspection

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla)\, \boldsymbol{u}_{\mathrm{g}} + \beta\, y\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} + f_{\mathrm{o}}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{ag}} = -\nabla_{\mathrm{h}}\, \varphi_{\mathrm{ag}}. \tag{45.56}$$

We can also choose to add the geostrophic balanced flow that holds at order Ro^0, $f_{\mathrm{o}}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -\nabla_{\mathrm{h}}\, \varphi_{\mathrm{g}}$, so to have the equivalent equation

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla)\, \boldsymbol{u}_{\mathrm{g}} + \beta\, y\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} + f_{\mathrm{o}}\, \hat{\boldsymbol{z}} \times (\boldsymbol{u}_{\mathrm{g}} + \boldsymbol{u}_{\mathrm{ag}}) = -\nabla_{\mathrm{h}}\, (\varphi_{\mathrm{g}} + \varphi_{\mathrm{ag}}). \tag{45.57}$$

Observe that from equation (45.27d) that

$$\varphi_{\mathrm{ag}} = f_{\mathrm{o}}\, U\, L\, \mathrm{Ro}\, \widehat{\varphi}_1 = U^2\, \widehat{\varphi}_1, \tag{45.58}$$

so that the ageostrophic portion of the pressure scales according to pressure in a non-rotating fluid as discussed in Section 29.2.3.

45.3.9 Concerning the ageostrophic state in quasi-geostrophy

Following the shallow water discussion in Section 43.6.6, we here expose an ambiguity (i.e., *gauge freedom*) associated with the ageostrophic pressure, buoyancy, and velocity within quasi-geostrophy. This gauge freedom arises since the quasi-geostrophic potential vorticity equation remains unchanged upon adding an arbitrary horizontally non-divergent velocity to $\boldsymbol{u}_{\mathrm{ag}}$, along with an arbitrary gradient of a scalar to φ_{ag}. The freedom to modify these ageostrophic fields is constrained by taking the divergence of the velocity equation (45.56) to find (compare to equation (43.108) for shallow water quasi-geostrophy)

$$\nabla_{\mathrm{h}}^2 \varphi_{\mathrm{ag}} = 2\, J(u_{\mathrm{g}}, v_{\mathrm{g}}) + \beta\, (y\, \zeta_{\mathrm{g}} - u_{\mathrm{g}}) + f_{\mathrm{o}}\, \zeta_{\mathrm{ag}}, \tag{45.59}$$

where

$$\zeta_{\text{ag}} = \partial_x v_{\text{ag}} - \partial_y u_{\text{ag}} \tag{45.60}$$

is the relative vorticity contained in the horizontal ageostrophic flow. The constraint (45.59) means that adding a horizontally non-divergent velocity, $\widetilde{\boldsymbol{u}}$, to the ageostrophic velocity, $\boldsymbol{u}_{\text{ag}}$, requires a corresponding modification to the pressure via $\widetilde{\varphi}$ added to φ_{ag}, in which $\widetilde{\varphi}$ satisfies the Poisson equation

$$\nabla_{\text{h}}^2 \widetilde{\varphi} = f_{\text{o}}\, \hat{\boldsymbol{z}} \cdot (\nabla \times \widetilde{\boldsymbol{u}}). \tag{45.61}$$

Given the gauge freedom, we follow Section 6.3 of *Holton and Hakim* (2013) by choosing $\varphi_{\text{ag}} = 0$ (and thus $b_{\text{ag}} = 0$) so that all ageostrophic effects live within the velocity, $\boldsymbol{u}_{\text{ag}} + \hat{\boldsymbol{z}} w_{\text{ag}}$. In this case, the quasi-geostrophic velocity equation (45.56) simplifies to

$$(\partial_t + \boldsymbol{u}_{\text{g}} \cdot \nabla)\, \boldsymbol{u}_{\text{g}} + \beta\, y\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{g}} + f_{\text{o}}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{ag}} = 0. \tag{45.62}$$

Evidently, the Coriolis acceleration, $f_{\text{o}}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{ag}}$, provides the only place that ageostrophic effects couple to the geostrophic velocity equation.

45.4 Constraints on quasi-geostrophic evolution

How is it that quasi-geostrophic flow retains a geostrophically balanced state, $f_{\text{o}}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{g}} = -\nabla_{\text{h}} \varphi_{\text{g}}$, while allowing that state to evolve? The discussion thus far provides an operational means to answer that question via time integration of the quasi-geostrophic potential vorticity equation. Alternatively, let us consider the velocity equation and in so doing to expose a diagnostic balance of geostrophic and ageostrophic flow processes, with this balance ensuring that geostrophy is maintained. We derive this balance closely following that considered for shallow water quasi-geostrophy in Section 43.6.7.[4]

45.4.1 A balance between geostrophic and ageostrophic processes

Geostrophic balance is maintained for an observer following a fluid particle moving with the horizontal geostrophic velocity, so that

$$\frac{\mathrm{D}_{\text{g}}}{\mathrm{D}t}(f_{\text{o}}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{g}} + \nabla_{\text{h}} \varphi_{\text{g}}) = 0. \tag{45.63}$$

Performing the material time derivative, and making use of equation (45.62) for the geostrophic velocity and equation (45.43) for buoyancy, here written as

$$\frac{\mathrm{D}_{\text{g}} \boldsymbol{u}_{\text{g}}}{\mathrm{D}t} = -(\beta\, y)\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{g}} - f_{\text{o}}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{ag}} \tag{45.64a}$$

$$\frac{\mathrm{D}_{\text{g}} b_{\text{g}}}{\mathrm{D}t} = -w_{\text{ag}}\, N^2, \tag{45.64b}$$

leads to the balance

$$f_{\text{o}}\, \beta\, y\, \boldsymbol{u}_{\text{g}} + f_{\text{o}}^2\, \boldsymbol{u}_{\text{ag}} + \frac{\mathrm{D}_{\text{g}}(\nabla_{\text{h}} \varphi_{\text{g}})}{\mathrm{D}t} = 0. \tag{45.65}$$

We can derive a diagnostic balance (i.e., an equation without a time derivative) by taking the vertical derivative of equation (45.65) and using the hydrostatic balance and the buoyancy

[4] Enforcing geostrophy even while the flow evolves is analogous to constraints arising from non-divergent flow condition, $\nabla \cdot \boldsymbol{v} = 0$, in an evolving flow. As seen in Section 29.3, pressure in a Boussinesq ocean enforces flow non-divergence at each point in space and time.

equation. For that purpose we need

$$\partial_z[\mathrm{D}_{\mathrm{g}}(\nabla_{\mathrm{h}}\varphi)/\mathrm{D}t] = \mathrm{D}_{\mathrm{g}}(\nabla_{\mathrm{h}}b_{\mathrm{g}})/\mathrm{D}t) + (\partial_z \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}})\nabla_{\mathrm{h}}\varphi_{\mathrm{g}} \tag{45.66a}$$

$$= \nabla_{\mathrm{h}}(\mathrm{D}_{\mathrm{g}}b_{\mathrm{g}}/\mathrm{D}t) + \mathbf{Q} + (\partial_z \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}})\nabla_{\mathrm{h}}\varphi_{\mathrm{g}} \tag{45.66b}$$

$$= -\nabla_{\mathrm{h}}(N^2\, w_{\mathrm{ag}}) + \mathbf{Q} + (\partial_z \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}})\, \nabla_{\mathrm{h}}\varphi_{\mathrm{g}}, \tag{45.66c}$$

where we introduced the vector arising from the coupling of horizontal shears in the geostrophic flow with horizontal gradients in the geostrophic buoyancy

$$\mathbf{Q} = -\hat{\boldsymbol{x}}\, \partial_x \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}} b_{\mathrm{g}} - \hat{\boldsymbol{y}}\, \partial_y \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}} b_{\mathrm{g}}. \tag{45.67}$$

We can further simplify by use of thermal wind to write

$$\mathbf{Q} = -\hat{\boldsymbol{x}}\, \partial_x \boldsymbol{u}_{\mathrm{g}} \cdot (f_{\mathrm{o}}\, \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{u}_{\mathrm{g}}) - \hat{\boldsymbol{y}}\, \partial_y \boldsymbol{u}_{\mathrm{g}} \cdot (f_{\mathrm{o}}\, \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{u}_{\mathrm{g}}) \tag{45.68a}$$

$$= f_{\mathrm{o}}\, \hat{\boldsymbol{x}}\, (-\partial_x u\, \partial_z v + \partial_x v\, \partial_z u) + f_{\mathrm{o}}\, \hat{\boldsymbol{x}}\, (-\partial_y u\, \partial_z v + \partial_y v\, \partial_z u), \tag{45.68b}$$

and geostrophy to write

$$(\partial_z \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}})\, \nabla_{\mathrm{h}}\varphi_{\mathrm{g}} = f_{\mathrm{o}}\, (\partial_z \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_{\mathrm{h}})\, (-v_{\mathrm{g}}\, \hat{\boldsymbol{x}} + u_{\mathrm{g}}\, \hat{\boldsymbol{y}}) \tag{45.69a}$$

$$= f_{\mathrm{o}}\, \hat{\boldsymbol{x}}\, (-\partial_x u\, \partial_z v + \partial_x v\, \partial_z u) + f_{\mathrm{o}}\, \hat{\boldsymbol{x}}\, (-\partial_y u\, \partial_z v + \partial_y v\, \partial_z u) \tag{45.69b}$$

$$= \mathbf{Q}, \tag{45.69c}$$

so that

$$\partial_z[\mathrm{D}_{\mathrm{g}}(\nabla_{\mathrm{h}}\varphi)/\mathrm{D}t] = 2\, \mathbf{Q}. \tag{45.70}$$

Bringing terms together leads to the diagnostic balance

$$\underbrace{f_{\mathrm{o}}\, \beta\, y\, \partial_z \boldsymbol{u}_{\mathrm{g}} + 2\, \mathbf{Q}}_{\text{geostrophic}} + \underbrace{f_{\mathrm{o}}^2\, \partial_z \boldsymbol{u}_{\mathrm{ag}} - N^2\, \nabla_{\mathrm{h}} w_{\mathrm{ag}}}_{\text{ageostrophic}} = 0, \tag{45.71}$$

where we noted that the buoyancy frequency is a function only of the vertical. Equation (45.71) summarizes a wealth of geostrophic and ageostrophic processes that, when taken together, maintain geostrophy and thermal wind for evolving quasi-geostrophic flows. Note that when considered in isolation, each process acts to move the flow away from geostrophic balance (e.g., see *Hoskins* (1975) and Section 6.5 of *Holton and Hakim* (2013), who emphasize the nonlinear geostrophic term, $\mathbf{Q}$). It is only when all terms are considered together that they render an evolving flow respecting geostrophy.

45.4.2 Vertical motion and the ω-equation

As we discovered in this chapter, for quasi-geostrophy the vertical component to the velocity is non-zero only at first order in Rossby number, hence it is part of the ageostrophic flow. In contrast, the zeroth order flow is horizontally non-divergent and geostrophically balanced. To evolve the horizontal geostrophic flow it is not necessary to explicitly compute the ageostrophic vertical velocity. However, there are cases where vertical ageostrophic velocity is of interest. Since the vertical motion is relatively small, it is important to formulate the calculation of this motion in a manner that avoids computing small differences between large numbers. Namely, even if we knew the horizontal ageostrophic flow, vertically integrating the continuity equation, $\partial_z w_{\mathrm{ag}} = -(\partial_x u_{\mathrm{ag}} + \partial_y v_{\mathrm{ag}})$, is prone to errors since the horizontal convergence is typically the small difference of relatively large numbers. We here derive a more suitable means to diagnose w_{ag}, with the diagnostic equation known as the ω-equation. The name for this equation originates from the atmospheric community where ω is the common symbol for mass transport across pressure

surfaces (using pressure vertical coordinates rather than geopotential). Here, we make use of the Boussinesq ocean equations so that the vertical velocity component is across geopoential surfaces.

It turns out that we have done most of the work needed to derive an equation for w_{ag} as part of our derivation of the balance (45.71). Namely, by simply taking horizontal the divergence of (45.71) and noting that $\nabla \cdot \boldsymbol{u}_g = 0$, we have

$$(f_o^2\, \partial_{zz} + N^2\, \nabla_h^2) w_{ag} = (\nabla_h + \hat{\boldsymbol{z}} \partial_z) \cdot (2\, \mathbf{Q} + \hat{\boldsymbol{z}}\, f_o\, \beta\, v_g), \tag{45.72}$$

which corresponds to the second form of the ω-equation first derived by *Hoskins et al.* (1978). We identify the following convenient features of this ω-equation. First, the right hand side is determined solely from knowledge of the geostrophic flow, which contrasts to the approach from continuity. Second, the linear operator acting on w_{ag} is elliptic, so that w_{ag} is a smoothed version of the geostrophic forcing on the right hand side of equation (45.72). Third, maps of the vector field, $\mathbf{Q} + \hat{\boldsymbol{z}}\, f_o\, \beta\, v_g$, provide insights into regions where w_{ag} is prone to have large values. For example, where the divergence on the right hand side is positive, the vertical velocity is negative.[5]

45.4.3 Another derivation of the ω-equation

One commonly finds an alternative derivation in the literature. Here, we write the dimensional buoyancy equation (45.42) and vorticity equation (45.45) in the form

$$f_o\, \partial_{tz} \psi + J(\psi, b_g) + N^2\, w_{ag} = 0 \tag{45.73a}$$

$$\partial_t (\nabla_h^2 \psi) + J(\psi, \nabla_z^2 \psi + \beta\, y) - f_o\, \partial_z w_{ag} = 0. \tag{45.73b}$$

Taking the horizontal Laplacian of equation (45.73a) and subtracting it from f_o times the vertical derivative of equation (45.73b) allows us to cancel the time derivative and thus to render the Boussinesq form of the quasi-geostrophic ω-equation

$$(N^2 \nabla_h^2 + f_o^2\, \partial_{zz})\, w_{ag} = f_o\, \partial_z [J(\psi, \zeta_g + \beta\, y)] - \nabla_h^2 J(\psi, b_g). \tag{45.74}$$

The operator on the left hand side is a generalized Laplacian and all terms on the right hand side are known from the geostrophic streamfunction, including the vorticity, $\zeta_g = \nabla_h^2 \psi$, and buoyancy, $b_g = f_o\, \partial_z \psi$. This equation is thus in the form of a generalized Poisson equation, whose solution renders an expression for the vertical velocity valid to order Ro^1. Note that the right hand side can be written as the convergence of a flux

$$f_o\, \partial_z [J(\psi, \zeta_g + \beta\, y)] - \nabla_h^2 J(\psi, b_g) = -\nabla_h \cdot [\nabla_h\, J(\psi, b_g)] + f_o\, \partial_z [J(\psi, \zeta_g + \beta\, y)] \tag{45.75a}$$

$$= -\nabla \cdot \boldsymbol{G}, \tag{45.75b}$$

where the geostrophic forcing vector is given by

$$\boldsymbol{G} = \nabla_h J(\psi, b_g) - f_o\, \partial_z [J(\psi, \zeta_g + \beta\, y)]\, \hat{\boldsymbol{z}}. \tag{45.76}$$

It is a useful exercise to show that equations (45.74) and (45.72) are identical.

[5] Elliptic operators generally swap signs, which can be readily seen upon assuming a single Fourier mode solution to w_{ag}.

45.5 Connecting to Ertel potential vorticity

Following our treatment for the shallow water system in Section 43.6.4, we here determine how quasi-geostrophic potential vorticity relates to the Ertel potential vorticity from Chapter 41. For this purpose, consider the continuously stratified hydrostatic Boussinesq fluid and make use of the Ertel potential vorticity derived in Exercise 41.1

$$Q = (\boldsymbol{\omega} + \hat{\boldsymbol{z}}\, f) \cdot \nabla b = \frac{\partial u}{\partial z}\frac{\partial b}{\partial y} - \frac{\partial v}{\partial z}\frac{\partial b}{\partial x} + (\zeta + f)\,\frac{\partial b}{\partial z}. \tag{45.77}$$

In a perfect fluid we have the material conservation

$$(\partial_t + \boldsymbol{u} \cdot \nabla_{\!\mathrm{h}} + w\,\partial_z)\, Q = 0. \tag{45.78}$$

Our strategy in this section is to non-dimensionalize both Q and the material time operator, and then to organize terms in equation (45.78) according to the Rossby number. We then show that material conservation of Ertel potential vorticity, when expanded asymptotically to order Ro^1, leads to the geostrophic material conservation of quasi-geostrophic potential vorticity. The continuous stratification makes the derivation more involved than for the shallow water potential vorticity in Section 43.6.4, prompting us to expose the details.

45.5.1 Non-dimensionalizing the Ertel potential vorticity

As above for the buoyancy, we are led to write the Ertel potential vorticity in the form

$$\frac{Q - f_\circ\, N^2}{f_\circ\, N^2} = \frac{1}{f_\circ\, N^2}\left[\frac{\partial u}{\partial z}\frac{\partial b'}{\partial y} - \frac{\partial v}{\partial z}\frac{\partial b'}{\partial x}\right] + \frac{1}{N^2}\,\frac{\partial b'}{\partial z} + \frac{\beta\, y + \zeta}{f_\circ}\left[1 + \frac{1}{N^2}\,\frac{\partial b'}{\partial z}\right]. \tag{45.79}$$

with non-dimensionalization leading to

$$\frac{1}{f_\circ\, N^2}\left[\frac{\partial u}{\partial z}\frac{\partial b'}{\partial y} - \frac{\partial v}{\partial z}\frac{\partial b'}{\partial x}\right] = \frac{B\,U}{f_\circ\, N^2\, H\, L}\left[\frac{\partial \widehat{u}}{\partial \widehat{z}}\frac{\partial \widehat{b}}{\partial \widehat{y}} - \frac{\partial \widehat{v}}{\partial \widehat{z}}\frac{\partial \widehat{b}}{\partial \widehat{x}}\right] = \frac{\mathrm{Ro}^2}{\mathrm{Bu}}\left[\frac{\partial \widehat{u}}{\partial \widehat{z}}\frac{\partial \widehat{b}}{\partial \widehat{y}} - \frac{\partial \widehat{v}}{\partial \widehat{z}}\frac{\partial \widehat{b}}{\partial \widehat{x}}\right] \tag{45.80a}$$

$$\frac{1}{N^2}\,\frac{\partial b'}{\partial z} = \frac{B}{H\, N^2}\,\frac{\partial \widehat{b}}{\partial \widehat{z}} = \frac{\mathrm{Ro}}{\mathrm{Bu}}\,\frac{\partial \widehat{b}}{\partial \widehat{z}} \tag{45.80b}$$

$$\frac{\beta\, y + \zeta}{f_\circ} = \mathrm{Ro}\,(\widehat{\beta}\,\widehat{y} + \widehat{\zeta}). \tag{45.80c}$$

The order Ro^2 terms appearing in equation (45.80a) are dropped since they do not contribute to the quasi-geostrophic potential vorticity, which involve terms only up to order Ro^1. For the order Ro^1 term, we only retain the zeroth order buoyancy, $\widehat{b}_0 = b_{\mathrm{g}}/B$, and likewise we just retain the zeroth order relative vorticity, $\widehat{\zeta}_0 = (L/U)\,\zeta_{\mathrm{g}}$. Hence, the Ertel potential vorticity is given by

$$Q = N^2\,(f_\circ + q_*) + \mathcal{O}(\mathrm{Ro}^2) \tag{45.81}$$

where q_* is the order Ro^1 term

$$q_* = \mathrm{Ro}\, f_\circ\left[\frac{1}{\mathrm{Bu}}\,\frac{\partial \widehat{b}_0}{\partial \widehat{z}} + \widehat{\beta}\,\widehat{y} + \widehat{\zeta}_0\right] = \frac{f_\circ}{N^2}\,\frac{\partial b_{\mathrm{g}}}{\partial z} + \beta\, y + \zeta_{\mathrm{g}}. \tag{45.82}$$

45.5.2 Material conservation of Ertel PV to order Ro^1

The material conservation of Ertel PV now takes the form

$$(\partial_t + \boldsymbol{u}_g \cdot \nabla_h + w_{ag}\,\partial_z)\,(f_o\,N^2 + q_*\,N^2) = f_o\,w_{ag}\,\partial_z N^2 + N^2\,\mathrm{D}_g q_*/\mathrm{D}t = 0. \tag{45.83a}$$

We dropped the $w_{ag}\,\partial_z$ contribution to the advection of q_* since ageostrophic vertical advection of q_* is an order Ro^2 term. To eliminate the vertical ageostrophic velocity we make use of the buoyancy equation (45.42) so that

$$\frac{\mathrm{D}_g q_*}{\mathrm{D}t} + \frac{w_{ag}}{N^2}\,\frac{\partial N^2}{\partial z} = \frac{\mathrm{D}_g q_*}{\mathrm{D}t} - \frac{f_o}{N^4}\,\frac{\mathrm{D}_g b_g}{\mathrm{D}t}\,\frac{\partial N^2}{\partial z} = 0. \tag{45.84}$$

Writing

$$\frac{\partial}{\partial z}\left[\frac{1}{N^2}\right] = -\frac{1}{N^4}\frac{\partial N^2}{\partial z} \tag{45.85}$$

leads to

$$\frac{\mathrm{D}_g q_*}{\mathrm{D}t} + f_o\left[\frac{\partial N^{-2}}{\partial z}\right]\,\frac{\mathrm{D}_g b_g}{\mathrm{D}t} = 0. \tag{45.86}$$

Since the geostrophic material time derivative operator only involves horizontal advection, we can merge these two terms to render

$$\begin{aligned}
\frac{\mathrm{D}_g q_*}{\mathrm{D}t} + f_o\left[\frac{\partial N^{-2}}{\partial z}\right]\,\frac{\mathrm{D}_g b_g}{\mathrm{D}t} &= \frac{\mathrm{D}_g}{\mathrm{D}t}\left[q_* + f_o\,b_g\left(\frac{\partial N^{-2}}{\partial z}\right)\right] && \text{(45.87a)}\\
&= \frac{\mathrm{D}_g}{\mathrm{D}t}\left[\beta\,y + \zeta + \frac{f_o}{N^2}\left(\frac{\partial b_g}{\partial z}\right) + f_o\,b_g\left(\frac{\partial N^{-2}}{\partial z}\right)\right] && \text{(45.87b)}\\
&= \frac{\mathrm{D}_g}{\mathrm{D}t}\left[\beta\,y + \zeta + f_o\,\frac{\partial}{\partial z}\left(\frac{b_g}{N^2}\right)\right] && \text{(45.87c)}\\
&= \frac{\mathrm{D}_g q}{\mathrm{D}t} && \text{(45.87d)}\\
&= 0. && \text{(45.87e)}
\end{aligned}$$

In the penultimate step we introduced the quasi-geostrophic potential vorticity given by equation (45.53)

$$q = \beta\,y + \zeta + f_o\,\frac{\partial}{\partial z}\left[\frac{b_g}{N^2}\right] = q_* + f_o\,b_g\frac{\partial N^{-2}}{\partial z}. \tag{45.88}$$

We have thus established how material conservation of Ertel potential vorticity, when expanded asymptotically to order Ro^1, leads to the geostrophic material conservation of quasi-geostrophic potential vorticity.

45.6 Boundary conditions

We need boundary conditions on the geostrophic streamfunction, ψ, to invert the elliptic quasi-geostrophic PV equation (45.53), with boundary conditions the focus of this section.

45.6.1 Concerning doubly-periodic QG models

For lateral boundaries, we may choose to set the normal component of the flow to zero for the inviscid case, in which case ψ is a constant along material boundaries as discussed in Section 21.4.2. More commonly (at least for idealized studies), we remove the lateral boundaries altogether by assuming a doubly periodic domain. The value of the Coriolis parameter does

not appear in the potential vorticity equation (45.54). Rather, it is only $\partial_y f = \beta$ that appears. So even though the Coriolis parameter, $f = f_o + \beta\, y$, is not meridionally periodic, we can still consider a horizontally doubly-periodic domain in which there is periodicity in flow properties in both the zonal and meridional directions.

Furthermore, we can study quasi-geostrophic flows in doubly periodic domains in the presence of certain idealized background flows. Namely, for a prescribed depth-independent thermal wind flow, the corresponding buoyancy that supports this flow plays no role in the quasi-geostrophic potential vorticity. For example, if the buoyancy has the form

$$b = \underbrace{M^2\, y + N^2\, z}_{\text{prescribed background}} + b'(x, y, z, t), \tag{45.89}$$

with M and N constant frequencies, then the corresponding quasi-geostrophic potential vorticity is independent of M. In this manner, the background buoyancy, though not meridionally periodic, prescribes a background thermal wind shear that is constant and so is trivially periodic.

45.6.2 Buoyancy equation

To develop the vertical boundary conditions on the streamfunction, consider the quasi-geostrophic buoyancy equation (45.42)

$$\mathrm{D}_g b_g / \mathrm{D}t + w_{ag}\, N^2 = (\partial_t + \boldsymbol{u}_g \cdot \nabla)\, b_g + w_{ag}\, N^2 = 0, \tag{45.90}$$

where the buoyancy is related to the geostrophic streamfunction via

$$b_g = f_o\, \partial_z \psi, \tag{45.91}$$

which leads to the equivalent form of the buoyancy equation

$$(\partial_t + \boldsymbol{u}_g \cdot \nabla_h)\, (f_o\, \partial_z \psi) + w_{ag}\, N^2 = 0. \tag{45.92}$$

We now consider how the buoyancy equation appears at the top and bottom boundaries.

45.6.3 Top boundary condition

Assuming the top boundary is a material surface, we are led to the kinematic boundary condition (19.66)

$$w = (\partial_t + \boldsymbol{u}_g \cdot \nabla_h)\, \eta. \tag{45.93}$$

How does this vertical velocity compare to that associated with motion in the fluid interior? To answer that question we assume an advective scaling for time derivatives so that the vertical velocity at the free surface scales as

$$w_{\text{surf}} \sim U\, \eta / L \sim U\, p / (\rho_o\, g\, L) \sim U^2\, f_o / g, \tag{45.94}$$

where L is the horizontal length scale, and we scaled the surface pressure gradient according to the free surface gradient. A point in the fluid interior has a vertical velocity that scales according to the buoyancy equation (45.90),

$$w_{\text{interior}} \sim U\, b / (N^2\, L) \sim f_o\, U^2 / (H\, N^2), \tag{45.95}$$

where H is the vertical scale over which the thermal wind shear is sizable, and which scales the buoyancy frequency according to

$$N^2 \sim (g/\rho_o)\, \Delta\rho / H, \tag{45.96}$$

where $\Delta\rho \ll \rho_o$ is the scale for the density difference setting the size of the buoyancy frequency. The ratio of the two vertical velocities is thus given by

$$w_{\text{surf}}/w_{\text{interior}} = H\, N^2/g = \Delta\rho/\rho_o \ll 1. \tag{45.97}$$

Evidently, we can set the surface boundary condition to that of a rigid lid, in which $w_{ag} = 0$. In this case, the top boundary condition reduces to geostrophic advection of boundary buoyancy

$$(\partial_t + \boldsymbol{u}_g \cdot \nabla_h)\,(f_o\, \partial_z \psi) = (\partial_t + \boldsymbol{u}_g \cdot \nabla_h)\, b_g = 0 \quad \text{at top boundary where } w_{ag} = 0. \tag{45.98}$$

That is, the geostrophic buoyancy at the surface is a material constant when advected by the surface geostrophic flow.

45.6.4 Bottom boundary condition

With a nonzero slope in the bottom topography, $\nabla\eta_b \neq 0$, the bottom kinematic boundary condition (Section 19.6.1) says that velocity is constrained so that

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0 \Longrightarrow w = \boldsymbol{u} \cdot \nabla\eta_b, \tag{45.99}$$

where $\hat{\boldsymbol{n}} = -\nabla(z - \eta_b)/|\nabla(z - \eta_b)|$ is the boundary's outward normal. Expanding this kinematic boundary condition leads to

$$w_{ag} = (\boldsymbol{u}_g + \boldsymbol{u}_{ag}) \cdot \nabla\eta_b, \tag{45.100}$$

which means there is vertical ageostrophic motion at the bottom so long as the horizontal motion is not aligned with isobaths. To be clear on the implications of this boundary condition, it is useful to examine the asymptotics by non-dimensionalizing[6]

$$\boldsymbol{u}_g = U\, \widehat{\boldsymbol{u}}_0 \tag{45.101a}$$
$$w_{ag} = W\, \text{Ro}\, \widehat{w}_1 \tag{45.101b}$$
$$\boldsymbol{u}_{ag} = U\, \text{Ro}\, \widehat{\boldsymbol{u}}_1 \tag{45.101c}$$
$$\nabla\eta_b = (\mathcal{B}/L)\, \widehat{\nabla}\widehat{\eta}_b = (H\, \text{Ro}/L)\, \widehat{\nabla}\widehat{\eta}_b, \tag{45.101d}$$

which brings the kinematic boundary condition (45.100) to

$$f_o\, H\, \text{Ro}^2\, (\widehat{\boldsymbol{u}}_0 + \text{Ro}\, \widehat{\boldsymbol{u}}_1) \cdot \widehat{\nabla}\widehat{\eta}_b = W\, \text{Ro}\, \widehat{w}_1 \Longrightarrow (\widehat{\boldsymbol{u}}_0 + \text{Ro}\, \widehat{\boldsymbol{u}}_1) \cdot \widehat{\nabla}\widehat{\eta}_b = \widehat{w}_1. \tag{45.102}$$

Asymptotic consistency implies that

$$\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}\widehat{\eta}_b = \widehat{w}_1 \Longrightarrow \boldsymbol{u}_g \cdot \nabla\eta_b = w_{ag}. \tag{45.103}$$

Hence, for quasi-geostrophic flow, any projection of the horizontal geostrophic velocity in a direction not aligned with isobaths leads to an ageostrophic vertical velocity at the bottom.

Use of the bottom kinematic boundary condition (45.103) in the buoyancy equation (45.92) leads to the bottom boundary evolution of buoyancy

$$\partial_t(f_o\, \partial_z\psi) + \boldsymbol{u}_g \cdot \nabla_h \left[f_o\, \partial_z\psi + N^2\, \eta_b\right] = 0 \quad \text{at } z = \overline{\eta_b}, \tag{45.104}$$

which can be written in terms of the geostrophic buoyancy

$$\partial_t b_g + \boldsymbol{u}_g \cdot \nabla_h (b_g + N^2\, \eta_b) = 0 \quad \text{at } z = \overline{\eta_b}, \tag{45.105}$$

[6]The bottom topography slope is non-dimensionalized according to the shallow water discussion in Section 43.3.4.

The boundary condition is evaluated at the horizontally averaged bottom positin, $z = \overline{\eta_b}$, since the more precise boundary location, $z = \eta_b(x, y)$, is higher order in Rossby number. Since $N^2 \, \eta_b$ is time independent, the boundary condition (45.105) can be written as a material conservation statement for buoyancy at the bottom

$$(\partial_t + \boldsymbol{u}_g \cdot \nabla_h)(b_g + N^2 \, \eta_b) = \frac{D_g(b_g + N^2 \, \eta_b)}{Dt} = 0 \quad \text{at } z = \overline{\eta_b}. \tag{45.106}$$

When η_b is a constant, and since N^2 is just a function of z, then the bottom boundary condition becomes a statement about the material conservation of buoyancy along the bottom boundary

$$\frac{D_g b_g}{Dt} = 0 \quad \text{at } z = \overline{\eta_b} = 0, \tag{45.107}$$

which is the bottom analog of the top boundary condition (45.98) that holds when making the rigid lid approximation. The more general case of a nonzero bottom slope renders a source for bottom buoyancy

$$\frac{D_g b_g}{Dt} = -N^2 \, \boldsymbol{u}_g \cdot \nabla \eta_b = -N^2 \, w_{ag} \quad \text{at } z = \overline{\eta_b}. \tag{45.108}$$

In this manner we see that a material evolution of bottom buoyancy is associated with vertical ageostrophic flow at the bottom, and correspondingly to horizontal geostrophic flow that deviates from the contours of constant topography.

Finally, since N^2 is a function only of z, this boundary condition can be written in terms of the stretching term appearing in the potential vorticity

$$\frac{D_g}{Dt}\left[\frac{f_o \, b_g}{N^2}\right] = -f_o \, \boldsymbol{u}_g \cdot \nabla \eta_b \quad \text{at } z = \overline{\eta_b}. \tag{45.109}$$

Evidently, material evolution of vertical stretching is coupled to bottom geostrophic flow that crosses lines of constant topography.

45.7 Potential vorticity with Dirac delta sheets

Based on the boundary conditions derived in Section 45.6, we know that quasi-geostrophic theory is comprised of the material conservation of potential vorticity in the interior, along with material evolution of buoyancy at the boundaries, with the material evolution determined by the horizontal geostrophic velocity

$$\frac{D_g q}{Dt} = 0 \qquad \text{for } \overline{\eta_b} < z < 0 \tag{45.110a}$$

$$\frac{D_g b_g}{Dt} = 0 \qquad \text{for } z = 0 \tag{45.110b}$$

$$\frac{D_g b_g}{Dt} = -N^2 \, \boldsymbol{u}_g \cdot \nabla \eta_b \quad \text{for } z = \overline{\eta_b}, \tag{45.110c}$$

where the geostrophic velocity, buoyancy, material time derivative, and quasi-geostrophic potential vorticity are written in terms of the geostrophic streamfunction

$$\boldsymbol{u}_g = \hat{\boldsymbol{z}} \times \nabla \psi \tag{45.111a}$$

$$b_g = f_o \, \partial_z \psi \tag{45.111b}$$

$$D_g/Dt = \partial_t + \boldsymbol{u}_g \cdot \nabla \tag{45.111c}$$

$$q = f_o + \beta \, y + \nabla_h^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_o^2}{N^2}\frac{\partial \psi}{\partial z}\right] = f_o + \beta \, y + \nabla_h^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_o \, b_g}{N^2}\right]. \tag{45.111d}$$

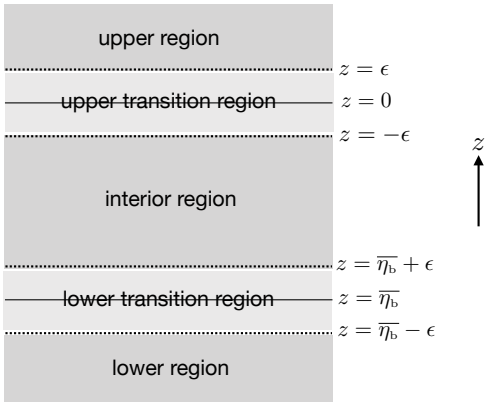

FIGURE 45.1: Geometry for the transition layers associated with the Dirac delta sheets at the upper and lower boundaries of the domain.

Studying the dynamics of boundary buoyancy constitutes the focus of *surface quasi-geostrophy*, as exemplified by *Held et al.* (1995) and whose mathematical foundations were examined by *Yassin and Griffies* (2022). In this section we focus on how to understand the transition from the interior to the boundaries. We follow the method of *Bretherton* (1966), where he noted that it can be conceptually convenient to bring the boundary conditions into the potential vorticity, much like when studying Green's functions for elliptic operators as in Chapter 9. In this manner, the boundary and interior terms can be placed on equal footing and thus their contribution to the potential vorticity directly compared.[7]

45.7.1 Transition between the interior and the boundaries

The transition from the interior to the boundary occurs over an infinitesimal region surrounding each boundary. There is a corresponding jump in the buoyancy as it moves from the domain interior to the boundaries. To help understand the nature of the jump it is useful to expand the infinitesimal thickness into a tiny but finite layer whose thickness, $\Delta z = \epsilon$, is later taken to vanish. For notational brevity introduce

$$S = b_{\mathrm{g}}/N^2, \tag{45.112}$$

and, with reference to the geometry in Figure 45.1, the full domain extent of this function is written

$$S^{\mathrm{ext}}(z) = \underbrace{S(\overline{\eta_{\mathrm{b}}} - \epsilon)\, \mathcal{H}(\overline{\eta_{\mathrm{b}}} - \epsilon - z)}_{\text{lower region}} + \underbrace{S(z)\, [\mathcal{H}(z - \overline{\eta_{\mathrm{b}}} - \epsilon) - \mathcal{H}(z + \epsilon)]}_{\text{interior region}} + \underbrace{S(\epsilon)\, \mathcal{H}(z - \epsilon)}_{\text{upper region}}, \tag{45.113}$$

where $\mathcal{H}$ is the Heaviside step function detailed in Section 7.5. Values within the outer edge of the transition regions (i.e., $S(\epsilon)$ and $S(\overline{\eta_{\mathrm{b}}} - \epsilon)$) are constructs whose values must be set consistent with the boundary conditions (45.110b) and (45.110c). We furthermore choose these values to be static, since we have no way to determine their evolution since they are outside the domain. The upper boundary satisfies the homogeneous boundary condition

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla) b_{\mathrm{g}} = 0, \tag{45.114}$$

which allows us to set

$$b_{\mathrm{g}}(\epsilon) = 0. \tag{45.115}$$

[7] See also Section 5.4.3 of *Vallis* (2017) for general comments on this approach.

Likewise, the lower boundary condition

$$(\partial_t + \boldsymbol{u}_\mathrm{g} \cdot \nabla) b_\mathrm{g} = -N^2 \, \boldsymbol{u}_\mathrm{g} \cdot \nabla \eta_\mathrm{b}, \tag{45.116}$$

is consistent with the choice

$$S(\overline{\eta_\mathrm{b}} - \epsilon) = -\eta_\mathrm{b}. \tag{45.117}$$

45.7.2 Calculating the stretching term over the extended domain

Since the derivative of a Heaviside step function yields a Dirac delta (Section 7.5), we have

$$\begin{aligned}\partial_z S^\mathrm{ext}(z) = \partial_z S(z) \, [\mathcal{H}(z - \overline{\eta_\mathrm{b}} - \epsilon) - \mathcal{H}(z + \epsilon)] + S(z) \, \delta(z - \overline{\eta_\mathrm{b}} - \epsilon) \\ - S(\overline{\eta_\mathrm{b}} - \epsilon) \, \delta(\overline{\eta_\mathrm{b}} - \epsilon - z) + S(\epsilon) \, \delta(z - \epsilon) - S(z) \, \delta(z + \epsilon),\end{aligned} \tag{45.118}$$

whose $\epsilon \to 0$ limit is

$$\partial_z S^\mathrm{ext}(z) = \partial_z S(z) \, [\mathcal{H}(z - \overline{\eta_\mathrm{b}}) - \mathcal{H}(z)] + [S(z) - S(\overline{\eta_\mathrm{b}} - \epsilon)] \, \delta(z - \overline{\eta_\mathrm{b}}) + [S(\epsilon) - S(z)] \, \delta(z). \tag{45.119}$$

Reintroducing the definition of S as per equation (45.112) yields the stretching term contribution to the potential vorticity, now defined over the full vertical extent of the domain (i.e., the domain interior and its boundaries)

$$\begin{aligned}\partial_z (f_\mathrm{o} \, b_\mathrm{g}/N^2)^\mathrm{ext} = \partial_z (f_\mathrm{o} \, b_\mathrm{g}/N^2) \, [\mathcal{H}(z - \overline{\eta_\mathrm{b}}) - \mathcal{H}(z)] \\ + \delta(z - \overline{\eta_\mathrm{b}}) \left[\frac{f_\mathrm{o} \, b_\mathrm{g}}{N^2} \right]_{z=\overline{\eta_\mathrm{b}}^-}^{z=\overline{\eta_\mathrm{b}}^+} + \delta(z) \left[\frac{f_\mathrm{o} \, b_\mathrm{g}}{N^2} \right]_{z=0^-}^{z=0^+},\end{aligned} \tag{45.120}$$

where the square bracket terms measure the jump in the stretching term taking place across the respective boundaries. The Heaviside term is nonzero only within the interior of the domain, whereas the two Dirac delta terms fire at their respective boundaries.

45.7.3 The extended potential vorticity

Making use of the extended stretching term (45.120) for the potential vorticity allows us to collapse the three equations (45.110a)-(45.110c) into the single equation valid over the domain interior as well as the domain boundaries

$$\frac{\mathrm{D}_\mathrm{g} q^\mathrm{ext}}{\mathrm{D}t} = 0 \quad \text{for } \overline{\eta_\mathrm{b}} \leq z \leq 0. \tag{45.121}$$

Bringing the above results together leads to the extended potential vorticity[8]

$$q^\mathrm{ext} = \underbrace{f_\mathrm{o} + \beta \, y + \nabla_\mathrm{h}^2 \psi + \frac{\partial}{\partial z} \left[\frac{f_\mathrm{o} \, b_\mathrm{g}}{N^2} \right]}_{\text{interior}} + \underbrace{\delta(z) \left[\frac{f_\mathrm{o} \, b_\mathrm{g}}{N^2} \right]_{z=0^-}^{z=0^+} + \delta(z - \overline{\eta_\mathrm{b}}) \left[\frac{f_\mathrm{o} \, b_\mathrm{g}}{N^2} \right]_{z=\overline{\eta_\mathrm{b}}^-}^{z=\overline{\eta_\mathrm{b}}^+}}_{\text{boundary contributions}}. \tag{45.122}$$

Note that the Dirac deltas have dimensions of inverse length (see Section 7.3), thus making this equation dimensionally consistent. We can make use of the transition region values (45.115) and

[8] We drop the Heaviside terms in equation (45.122) for brevity.

(45.117) to evaluate the jump conditions

$$\left[\frac{f_o\, b_g}{N^2}\right]_{z=0^-}^{z=0^+} = \left[\frac{f_o\, b_g}{N^2}\right]_{z=0} \tag{45.123a}$$

$$\left[\frac{f_o\, b_g}{N^2}\right]_{z=\overline{\eta_b}^-}^{z=\overline{\eta_b}^+} = \left[\frac{f_o\, b_g}{N^2}\right]_{z=\overline{\eta_b}} + f_o\, \eta_b, \tag{45.123b}$$

in which case the extended potential vorticity is

$$q^{ext} = \underbrace{f_o + \beta\, y + \nabla_h^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_o\, b_g}{N^2}\right]}_{\text{interior}} + \underbrace{\delta(z)\,(f_o\, b_g/N^2) + f_o\, \delta(z-\overline{\eta_b})\,(b_g/N^2 + \eta_b)}_{\text{boundary contributions}}. \tag{45.124}$$

For some studies it is useful to ignore the buoyancy contribution at the two boundaries by setting them to zero, in which case the potential vorticity is

$$q^{ext} = \underbrace{f_o + \beta\, y + \nabla_h^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_o\, b_g}{N^2}\right]}_{\text{interior}} + \underbrace{f_o\, \eta_b\, \delta(z-\overline{\eta_b})}_{\text{bottom topog}}. \tag{45.125}$$

Dropping the boundary buoyancy contributions allows one to focus on contributions from the bottom topography and interior processes, in isolation from the boundary buoyancy.

45.8 Mathematical expressions of the theory

In this section we sample various mathematical expressions of quasi-geostrophic theory.

45.8.1 The Jacobian form of geostropic advection

The geostrophic velocity, as a horizontally non-divergent field, can be written in terms of the quasi-geostrophic streamfunction

$$\boldsymbol{u}_g = \hat{\boldsymbol{z}} \times \nabla \psi. \tag{45.126}$$

We can thus write the following equivalent forms for the material time derivative of quasi-geostrophic PV

$$\frac{Dq}{Dt} = \partial_t q + \boldsymbol{u}_g \cdot \nabla q \tag{45.127a}$$

$$= \partial_t q + (\hat{\boldsymbol{z}} \times \nabla \psi) \cdot \nabla q \tag{45.127b}$$

$$= \partial_t q + (\nabla \psi \times \nabla q) \cdot \hat{\boldsymbol{z}} \tag{45.127c}$$

$$= \partial_t q + J(\psi, q). \tag{45.127d}$$

The final equality introduced the Jacobian operator

$$J(\psi, q) = (\nabla \psi \times \nabla q) \cdot \hat{\boldsymbol{z}}, \tag{45.128}$$

which is a notation commonly used in the geophysical fluids literature.[9]

For a perfect fluid, in which $Dq/Dt = 0$, a steady state (zero Eulerian time derivative) is realized when

$$\boldsymbol{u}_g \cdot \nabla\, q = (\nabla \psi \times \nabla q) \cdot \hat{\boldsymbol{z}} = J(\psi, q) = 0, \tag{45.129}$$

[9] Recall that we also encountered the Jacobian form for horizontally non-divergent two-dimensional advection in Section 38.2.4, as part of our study of the non-divergent barotropic flows.

which means that the steady velocity is parallel to surfaces of constant q. We are ensured that these equalities hold if the streamfunction is a function only of the potential vorticity

$$\psi = \psi(q) \Longrightarrow (\nabla\psi \times \nabla q) \cdot \hat{\boldsymbol{z}} = J(\psi, q) = 0. \tag{45.130}$$

As the steady state is of physical interest, this functional relation between streamfunction and potential vorticity commonly arises in applications.

45.8.2 The case of constant background buoyancy frequency

Consider the quasi-geostrophic potential vorticity for the special case of a constant background buoyancy frequency, $N^2 = \text{constant}$, in which the relative potential vorticity (45.52) takes on the form

$$q - \beta\, y = \nabla_{\mathsf{h}}^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_{\mathsf{o}}^2}{N^2}\frac{\partial\psi}{\partial z}\right] \tag{45.131a}$$

$$= \frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{f_{\mathsf{o}}^2}{N^2}\frac{\partial^2\psi}{\partial z^2} \tag{45.131b}$$

$$= [\partial_{xx} + \partial_{yy} + \partial_{\tilde{z}\tilde{z}}]\psi. \tag{45.131c}$$

For the final equality we introduced the vertical coordinate

$$z = (f/N)\,\tilde{z} \Longleftrightarrow \tilde{z} = (N/f)\,z, \tag{45.132}$$

where f/N is the Prandtl ratio introduced by equation 43.169. Since $|N/f| >> 1$ the stably stratified flows considered in QG, $\tilde{z}$ is a *stretched* vertical coordinate so that the Laplacian operator acting on ψ is anisotropic. The linear operator acting on ψ remains elliptic even in the more general case of a depth dependent stratification, thus warranting the use of elliptical solvers when performing the inversion numerically.

45.8.3 Potential vorticity induction and impermeability

Outside of boundaries, the potential vorticity equation is the sole prognostic equation required to evolve the quasi-geostrophic flow. Consequently, one often ignores the quasi-geostrophic velocity and buoyancy equations. Even so, we found it useful to consider the buoyancy equation in Section 45.3.5 as part of connecting quasi-geostrophic potential vorticity to Ertel potential vorticity. Likewise, there are occasions when it is useful to examine the velocity equation, with a similar discussion provided in Section 43.6.6. In this section we directly connect the velocity and buoyancy equations and then reveal their connection to the potential vorticity equation.

Combining the velocity and buoyancy equations

Consider the quasi-geostrophic velocity and buoyancy equations derived in Section 45.3

$$(\partial_t + \boldsymbol{u}_{\mathsf{g}} \cdot \nabla)\boldsymbol{u}_{\mathsf{g}} + \hat{\boldsymbol{z}} \times (\beta\, y\, \boldsymbol{u}_{\mathsf{g}} + f_{\mathsf{o}}\, \boldsymbol{u}_{\mathsf{ag}}) = -\nabla_{\mathsf{h}}\, \varphi_{\mathsf{ag}} + \boldsymbol{F} \tag{45.133a}$$

$$(\partial_t + \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}})b_{\mathsf{g}} + w_{\mathsf{ag}}\, N^2 = \dot{b} \tag{45.133b}$$

$$f_{\mathsf{o}}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathsf{g}} + \nabla_{\mathsf{h}}\varphi_{\mathsf{g}} = 0 \tag{45.133c}$$

$$\nabla \cdot \boldsymbol{u}_{\mathsf{g}} = \partial_x u_{\mathsf{g}} + \partial_y v_{\mathsf{g}} = 0 \tag{45.133d}$$

$$\nabla \cdot \boldsymbol{v}_{\mathsf{ag}} = \nabla \cdot \boldsymbol{u}_{\mathsf{ag}} + \partial_z w_{\mathsf{ag}} = 0, \tag{45.133e}$$

where we added a non-conservative force per mass, $\boldsymbol{F}$ (e.g., friction, wind stress), and irreversible buoyancy source, $\dot{b}$ (e.g., diffusion, boundary fluxes). Taking $-\hat{\boldsymbol{z}}\times$ on the velocity equation[10] and multiplying the buoyancy equation by $f_\circ/N^2$ leads to

$$(\partial_t + \boldsymbol{u}_\mathrm{g}\cdot\nabla)(-\hat{\boldsymbol{z}}\times\boldsymbol{u}_\mathrm{g}) + \beta\, y\, \boldsymbol{u}_\mathrm{g} + f_\circ\, \boldsymbol{u}_\mathrm{ag} = \hat{\boldsymbol{z}}\times\nabla_\mathrm{h}\varphi_\mathrm{ag} - \hat{\boldsymbol{z}}\times\boldsymbol{F} \tag{45.134a}$$

$$(\partial_t + \boldsymbol{u}_\mathrm{g}\cdot\nabla_\mathrm{h})(f_\circ\, b_\mathrm{g}/N^2) + f_\circ\, w_\mathrm{ag} = f_\circ\, \dot{b}/N^2. \tag{45.134b}$$

Introduce the following vector fields

$$\boldsymbol{D} \equiv -\hat{\boldsymbol{z}}\times\boldsymbol{u}_\mathrm{g} + (f_\circ/N^2)\, b_\mathrm{g}\, \hat{\boldsymbol{z}} = \nabla_\mathrm{h}\psi + (f_\circ/N)^2\, \partial_z\psi\, \hat{\boldsymbol{z}} \tag{45.135a}$$

$$\boldsymbol{R} \equiv -\hat{\boldsymbol{z}}\times\boldsymbol{F} + (f_\circ/N^2)\, \dot{b}\, \hat{\boldsymbol{z}}, \tag{45.135b}$$

with $\boldsymbol{D}$ built from both the velocity and buoyancy fields and $\boldsymbol{R}$ built from the corresponding non-conservative tendencies. These vectors allow us to combine the velocity and buoyancy equations into a single vector equation

$$(\partial_t + \boldsymbol{u}_\mathrm{g}\cdot\nabla)\, \boldsymbol{D} + \beta\, y\, \boldsymbol{u}_\mathrm{g} + f_\circ\, \boldsymbol{v}_\mathrm{ag} = \hat{\boldsymbol{z}}\times\nabla_\mathrm{h}\varphi_\mathrm{ag} + \boldsymbol{R}. \tag{45.136}$$

Potential vorticity induction

The divergence of $\boldsymbol{D}$ yields the relative quasi-geostrophic potential vorticity

$$\nabla\cdot\boldsymbol{D} = q - (f_\circ + \beta\, y), \tag{45.137}$$

where we made use of the expression (45.53) for the potential vorticity. In analogy to Gauss's law of electromagnetism, we refer to $\boldsymbol{D}$ as the quasi-geostrophic potential vorticity *induction vector*.[11] Additionally, the potential vorticity equation can be written (see Exercise 45.3)

$$(\partial_t + \boldsymbol{u}_\mathrm{g}\cdot\nabla)\, q = \nabla\cdot\boldsymbol{R}, \tag{45.138}$$

so that the quasi-geostrophic potential vorticity flux vector

$$\boldsymbol{J}^\mathrm{q} = \boldsymbol{u}_\mathrm{g}\, q - \boldsymbol{R} \tag{45.139}$$

allows us to write the potential vorticity equation in the Eulerian flux-form

$$\partial_t q = -\nabla\cdot\boldsymbol{J}^\mathrm{q}. \tag{45.140}$$

Kinematic PV flux and impermeability

Taking the Eulerian time derivative of the potential vorticity induction equation (45.137) renders

$$\partial_t q = \partial_t(\nabla\cdot\boldsymbol{D}) = \nabla\cdot(\partial_t\boldsymbol{D}) \equiv -\nabla\cdot\boldsymbol{J}^\mathrm{q\text{-}kin}, \tag{45.141}$$

where we introduced the kinematic form of the potential vorticity flux

$$\boldsymbol{J}^\mathrm{q\text{-}kin} \equiv -\partial_t\boldsymbol{D} = \boldsymbol{J}^\mathrm{q} + \nabla\times\boldsymbol{A}, \tag{45.142}$$

with $\boldsymbol{A}$ a gauge function. This equation is analogous to the kinematic Ertel PV flux discussed in Section 42.2.2. We determine the explicit expression for the gauge function in Exercise 45.4.

[10] The operation $-\hat{\boldsymbol{z}}\times$ acts to rotate by $\pi/2$ in the clockwise direction.

[11] This connection between potential vorticity dynamics and electromagnetism was pointed out by *Schneider et al.* (2003) and further examined by *Maddison and Marshall* (2013).

45.9 Energetics for quasi-geostrophic flow

Consider a quasi-geostrophic fluid configured with flat upper (rigid lid) and lower boundaries, and assume the lateral boundaries are periodic or material solid boundaries. These restrictive assumptions allow us to more readily study energetics within the fluid, sans the impacts from nontrivial boundary effects. To study energetics we make use of the quasi-geostrophic buoyancy equation (45.42) and relative vorticity equation (45.47)

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\, b = -w\, N^2 \tag{45.143a}$$
$$(\partial_t + \boldsymbol{u} \cdot \nabla)\, \zeta = -\beta\, v + f_\circ\, \partial_z w, \tag{45.143b}$$

where all labels are dropped from the variables to reduce clutter, and where

$$\frac{\mathrm{D}}{\mathrm{D}t} = \partial_t + \boldsymbol{u} \cdot \nabla \qquad b = f_\circ\, \partial_z \psi \qquad u = -\partial_y \psi \qquad v = \partial_x \psi \qquad \zeta = \nabla_{\mathrm{h}}^2 \psi. \tag{45.144}$$

45.9.1 Kinetic energy

The kinetic energy per mass for the total fluid domain is given by the integral

$$\mathcal{K} = \frac{1}{2} \int \boldsymbol{u} \cdot \boldsymbol{u}\, \mathrm{d}V = \frac{1}{2} \int \nabla_{\mathrm{h}} \psi \cdot \nabla_{\mathrm{h}} \psi\, \mathrm{d}V, \tag{45.145}$$

and its time derivative is

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = \int \nabla_{\mathrm{h}} \psi \cdot \nabla_{\mathrm{h}} (\partial_t \psi)\, \mathrm{d}V. \tag{45.146}$$

For the kinetic energy time derivative we noted that the fluid domain has a constant volume to allow the time derivative to move inside the integral without introducing boundary terms. Manipulation renders

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = \int \nabla_{\mathrm{h}} \psi \cdot \nabla_{\mathrm{h}} (\partial_t \psi)\, \mathrm{d}V \tag{45.147a}$$
$$= \int \left[\nabla_{\mathrm{h}} \cdot [\psi\, \nabla_{\mathrm{h}} (\partial_t \psi)] - \psi\, \partial_t (\nabla_{\mathrm{h}}^2 \psi) \right] \mathrm{d}V \tag{45.147b}$$
$$= -\int \psi\, \partial_t \zeta\, \mathrm{d}V, \tag{45.147c}$$

where we dropped the lateral boundary term and introduced relative vorticity. Use of the vorticity equation (45.143b) yields

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = -\int \psi\, \partial_t \zeta\, \mathrm{d}V = \int \psi\, [\boldsymbol{u} \cdot \nabla_{\mathrm{h}} \zeta + \beta\, v - f_\circ\, \partial_z w]\, \mathrm{d}V. \tag{45.148}$$

The first and second terms vanish since

$$\int \psi\, (\boldsymbol{u} \cdot \nabla_{\mathrm{h}} \zeta + \beta\, v)\, \mathrm{d}V = \int \psi\, \boldsymbol{u} \cdot \nabla_{\mathrm{h}} (\zeta + f)\, \mathrm{d}V \tag{45.149a}$$
$$= \int \psi\, \nabla_{\mathrm{h}} \cdot (\boldsymbol{u}\, \zeta_{\mathrm{a}})\, \mathrm{d}V \tag{45.149b}$$
$$= \int [\nabla_{\mathrm{h}} \cdot (\psi\, \boldsymbol{u}\, \zeta_{\mathrm{a}}) - \nabla_{\mathrm{h}} \psi \cdot \boldsymbol{u}\, \zeta_{\mathrm{a}}]\, \mathrm{d}V = 0. \tag{45.149c}$$

The final equality holds since the boundary term vanishes, and $\boldsymbol{u} \cdot \nabla_{\mathrm{h}} \psi = 0$ since ψ is the streamfunction for the horizontal geostrophic flow. We are thus left with the expression for the

kinetic energy evolution

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = -f_\circ \int \psi\, \partial_z w \,\mathrm{d}V. \tag{45.150}$$

Since the top and bottom are assumed flat and rigid, the vertical velocity vanishes on these boundaries so that

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = -f_\circ \int \psi\, \partial_z w \,\mathrm{d}V = -f_\circ \int [\partial_z(w\,\psi) - w\,\partial_z\psi]\,\mathrm{d}V = f_\circ \int w\,\partial_z\psi \,\mathrm{d}V. \tag{45.151}$$

Introducing the quasi-geostrophic buoyancy through $b = f_\circ\, \partial_z\psi$ leads to

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = \int w\, b \,\mathrm{d}V. \tag{45.152}$$

Kinetic energy thus increases when vertical motion is positively correlated with buoyancy. For example, upward motion ($w > 0$) of a positive buoyancy anomaly (relatively light water has $b > 0$) increases kinetic energy, as does downward motion of a negative buoyancy anomaly. This behavior is also reflected in the full fluid system discussed in Section 26.4.

45.9.2 Available potential energy

Available potential energy was introduced in Section 29.9 within the context of the Boussinesq ocean. An approximate form of the APE is given by equation (29.236), which we here write as

$$\mathcal{A}_{\text{bouss}} \approx \frac{1}{2}\int (b/N)^2 \mathrm{d}V = \frac{1}{2}\int [(f_\circ/N)\,\partial_z\psi]^2 \,\mathrm{d}V, \tag{45.153}$$

where we set $b = f_\circ\, \partial\psi/\partial z$ for the second equality. Taking a time derivative leads to

$$\frac{\mathrm{d}\mathcal{A}}{\mathrm{d}t} = \int (f_\circ/N)^2\, \partial_z\psi\, \partial_{tz}\psi \,\mathrm{d}V = \int (f_\circ/N)^2\, \partial_z\psi \left[-w\, N^2 - \nabla_{\!\mathrm{h}} \cdot (\boldsymbol{u}\, b)\right] \mathrm{d}V, \tag{45.154}$$

where we used the buoyancy equation (45.143a) for the second equality. The second term vanishes since

$$\int (f_\circ/N)^2\, \partial_z\psi\, [\nabla_{\!\mathrm{h}} \cdot (\boldsymbol{u}\, b)]\,\mathrm{d}V = \int \left[(f_\circ/N)^2\, \partial_z\psi\right] \boldsymbol{u} \cdot \nabla_{\!\mathrm{h}}\, (\partial_z\psi)\,\mathrm{d}V \tag{45.155a}$$

$$= \frac{1}{2}\int \nabla_{\!\mathrm{h}} \cdot \left[\boldsymbol{u}\, \left((f_\circ/N)\,\partial_z\psi\right)^2\right] \mathrm{d}V \tag{45.155b}$$

$$= 0. \tag{45.155c}$$

Consequently, the quasi-geostrophic APE has a time derivative given by

$$\frac{\mathrm{d}\mathcal{A}}{\mathrm{d}t} = -\int w\, f_\circ\, \partial_z\psi \,\mathrm{d}V = -\int w\, b \,\mathrm{d}V, \tag{45.156}$$

so that the APE evolves oppositely to the kinetic energy.

45.9.3 Exchange of mechanical energy

We refer to the term

$$\text{buoyancy work} = \int w\, f_\circ\, \partial_z\psi \,\mathrm{d}V = \int w\, b \,\mathrm{d}V, \tag{45.157}$$

as the buoyancy work conversion term. It has the same form as that encountered for the conversion between potential energy and kinetic energy in the unapproximated equations studied in Section 26.4.

The evolution of kinetic energy involves the relative vorticity equation, whereas evolution of the APE involves the buoyancy equation. However, their sum remains constant in time. The reason for the exact exchange of energy is that, when the kinetic energy increases through buoyancy work, the available potential energy decreases

$$\frac{\mathrm{d}(\mathcal{K} + \mathcal{A})}{\mathrm{d}t} = 0. \tag{45.158}$$

This is a relatively simple mechanical energy budget equation reminscent of a classical point particle discussed in Section 14.7. In particular, note the absence of a pressure work term that appears in the mechanical energy budget for other fluids such as for the Euler equations (Section 26.4) and Boussinesq ocean (Sections 29.6 and 29.8). We anticipate the absence of pressure work since knowledge of potential vorticity is sufficient to know all quasi-geostrophic dynamical fields, and yet pressure plays no explicit role in potential vorticity evolution.

45.9.4 Scaling APE and KE

The scale for kinetic energy in a quasi-geostrophic flow is given by

$$\mathcal{K} = \frac{1}{2} \int (\nabla_{\mathrm{h}} \psi \cdot \nabla_{\mathrm{h}} \psi) \, \mathrm{d}V \sim L^{-2} \, \Psi^2 \, V \tag{45.159}$$

and the scale for the APE is

$$\mathcal{A} = \frac{1}{2} \int \left[\frac{f_\circ}{N} \frac{\partial \psi}{\partial z} \right]^2 \mathrm{d}V \sim H^{-2} \, (f_\circ / N)^2 \Psi^2 \, V = L_{\mathrm{d}}^{-2} \, \Psi^2 \, V, \tag{45.160}$$

where we wrote Ψ for the streamfunction scale, V for the domain volume, and $L_{\mathrm{d}} = H \, (N/f_\circ)$ is the deformation radius (see equation (45.7)). Taking the ratio yields

$$\frac{\mathcal{K}}{\mathcal{A}} \sim \left[\frac{L_{\mathrm{d}}}{L} \right]^2 = \left[\frac{H}{L} \right]^2 \left[\frac{N}{f_\circ} \right]^2 = \mathrm{Bu}. \tag{45.161}$$

Hence, the Burger number is the ratio of the scale for quasi-geostrophic kinetic energy to the scale for quasi-geostrophic available potential energy. A large Burger number means that the horizontal scales of the flow are smaller than the deformation radius, in which case the quasi-geostrophic dynamics is dominated by its kinetic energy. In contrast, for scales larger than the deformation radius (not much larger, as then the flow would not satisfy quasi-geostrophic scaling), the Burger number is less than unity, in which case the quasi-geostrophic dynamics is dominated by available potential energy.

45.10 Exercises

EXERCISE 45.1: A VARIETY OF POTENTIAL VORTICITIES
Give the mathematical expressions for dimensionful potential vorticity in the following fluid models. Define all terms in the respective expressions. Give the physical dimensions and/or SI units for the potential vorticity. Hint: the answers can be found somewhere in this book.

(a) Ertel potential vorticity for compressible fluid in a rotating reference frame using potential temperature as the tracer.

(b) Ertel potential vorticity for a Boussinesq ocean in a rotating reference frame using Archimedean buoyancy as the tracer.

(c) Single shallow water layer on a beta plane

(d) Continuously stratified planetary geostrophy

(e) Continously stratified quasi-geostrophy on a beta plane

EXERCISE 45.2: QUASI-GEOSTROPHIC PV EVOLUTION WITH VERTICAL FRICTION

The first part of this exercise involves elements of the asymptotic method used for deriving the quasi-geostrophic equations, only now with the advent of a non-zero friction. Use is made to incorporate the non-dimensionalization detailed in Section 33.1, which provides a detailed discussion of the Ekman number and Ekman layers. The second part of this exercise makes use of the thermal wind balance to connect horizontal buoyancy transfer to the vertical viscous transfer of horizontal momentum.

(a) Derive the material evolution equation for quasi-geostrophic potential vorticity in a continuously stratified Boussinesq fluid in the presence of friction, $\boldsymbol{F}$. Assume the Ekman number is on the order of the Rossby number, so that the zeroth order asymptotic solution satisfies the usual inviscid f-plane geostrophic balance. Friction only appears in the first order equations.

(b) Assume friction arises just from vertical shears in the horizontal velocity, so that

$$\boldsymbol{F} = \frac{\partial}{\partial z}\left[\nu \frac{\partial \boldsymbol{u}}{\partial z}\right], \tag{45.162}$$

where $\nu = \nu(z)$ is a vertical eddy viscosity that is a function of depth (dimensions of squared length per time). Also assume an approximate form of quasi-geostrophic potential vorticity in which we drop relative vorticity (i.e., quasi-geostrophic potential vorticity is dominated by planetary vorticity and stretching). Determine the form for the vertical eddy viscosity so that the approximate form of quasi-geostrophic PV is laterally diffused via

$$\frac{\mathrm{D}q^{\text{approx}}}{\mathrm{D}t} = A \nabla_z^2 q^{\text{approx}}, \tag{45.163}$$

where A is a constant eddy diffusivity for the potential vorticity.

Hint: to leading order, the friction operator is a function just of the geostrophic velocity.

EXERCISE 45.3: QGPV FLUX-FORM EQUATION WITH NON-CONSERVATIVE PROCESSES

Derive the quasi-geostrophic potential vorticity equation (45.138). Show all the relevant steps. Hint: the key step requires showing that

$$\nabla \cdot [(\boldsymbol{u}_{\text{g}} \cdot) \boldsymbol{D}] = (\boldsymbol{u}_{\text{g}} \cdot) \nabla \cdot \boldsymbol{D}. \tag{45.164}$$

To do so, it is useful to express $\boldsymbol{u}_{\text{g}}$ and b_{g} in terms of the geostrophic streamfunction.

EXERCISE 45.4: QGPV GAUGE FUNCTION

Derive the gauge function, $\boldsymbol{A}$, that connects the two forms of the quasi-geostrophic flux vector as per equation (45.142).

Part IX

Hamilton's principle for fluid flows

In this part of the book we add a new layer to the conceptual foundations of fluid mechanics, and we do so by making use of *Hamilton's variational principle* to develop the equations for continuum motion. To appreciate the various aspects of Hamilton's principle requires revisiting a number of foundational topics and making use of distinct mathematical methods. Hamilton's principle is applicable to conservative physical systems, so that we only consider perfect fluids in this part of the book (i.e., single-component fluids without diffusion, conduction, or friction). Even so, Hamilton's principle provides a satisfying means to unify across the variety of physical content within perfect fluid mechanics. On a practical side, it offers a useful framework to develop approximate theories. Namely, by developing approximations within the action, one is ensured that the associated Euler-Lagrange equations satisfy corresponding conservation laws. In a nutshell, this part of the book will appeal to those interested in understanding the whys of fluid mechanics as a complement to the hows.

The continuum expression of Hamilton's variational principle, and the associated continuum *Euler-Lagrange field equations*, are the foundations for both classical and quantum field theory. Among the most celebrated payoffs for developing the variational formalism, we are afforded the origin story for differential conservation laws (e.g., linear momentum, angular momentum, mechanical energy, potential vorticity) that is otherwise obscure using alternative approaches (i.e., by inspired manipulations of the dynamical equations). It does so by directly connecting continuous space-time symmetries of the action to differential conservation laws through use of the celebrated *Noether's theorem* (*Noether*, 1918; *Noether and Tavel*, 2018). We used Noether's theorem in our study of analytical particle mechanics in Chapter 12. Noether's original work concerned field theory, so our use of Noether's theorem for continuum mechanics is directly connected to her work.

Hamilton's principle and Lagrangian kinematics

Many practitioners of fluid mechanics are neither aware of, nor concerned with, the use of Hamilton's variational principle for continuum mechanics. One reason for the intellectual distance arises from success of the Eulerian description of fluid mechanics, in which there is no concern for the flow map induced by the motion field, nor for the corresponding trajectories of fluid particles (see Chapter 18). Rather, the Eulerian approach focuses on the fluid velocity as a classical field, and the enumeration of forces acting on a fluid element that lead to accelerations via Newton's law. This approach offers a sufficient means to formulate the suite of fluid dynamical equations. Even so, there is more to the story that is revealed through the paired use of Hamilton's principle and Noether's theorem.

The absence of trajectories in Eulerian fluid mechanics distinguishes it from point particle mechanics and, it turns out, makes Hamilton's principle less transparent when formulated using Eulerian kinematics. In particular, Eulerian kinematics introduces nuances to Hamilton's principle related to the need to employ constraint fields not encountered with Lagrangian kinematics. These features of the Eulerian approach to Hamilton's principle have, whether fairly or unfairly, turned many practitioners away from Hamilton's principle. The nature of an Eulerian formulation of Hamilton's principle was clarified by *Salmon* (1988), who provided a systematic connection between Eulerian and Lagrangian formulations. Nonetheless, the direct connection between Lagrangian fluid kinematics to the kinematics of point particles offers a relatively straightforward extension (both conceptually and technically) of Hamilton's principle to fluid mechanics. It also more closely aligns to the methods used in continuum mechanics and quantum field theory. It is for these reasons that we embrace Lagrangian kinematics in our study of Hamilton's principle in this part of the book.[12]

[12] It is notable that in solid mechanics, Hamilton's principle is more routinely used (e.g., see Chapter 2 of *Tromp* (2025a)), presumably since Lagrangian kinematics is more routinely used in solid mechanics. Those interested in the Eulerian approach will find Chapter 8 of *Salmon* (1998) a valuable introduction.

Harmonic oscillator versus the motion field

We start this part of the book in Chapter 46 by focusing on Hamilton's principle for a continuous scalar field, following approaches standard in the quantum field theory literature (e.g., *Quigg* (1983); *Ryder* (1985); *Ramond* (1990)). In this treatment, we establish the Euler-Lagrange field equations by taking the continuum limit of a discrete version of Hamilton's principle applied to coupled simple harmonic oscillators. As such, we are afforded a pedagogical introduction to Hamilton's principle for a continuum that builds from the earlier work with particles in Chapters 12 and 15. This approach then lends the conceptual picture of the continuous field as representing small amplitude (linear) fluctuations relative to an equilibrium state.

In Chapter 47, we meld the classical field theory from Chapter 46 to the Lagrangian kinematics of continuum matter from Chapters 18 and 19. Doing so offers a suitable framework to use Hamilton's principle for describing fluid flows. Notably, through the advent of the motion field, $\varphi(\boldsymbol{a}, T)$, appearing in Lagrangian kinematics, we appreciate that continuum mechanics is a fundamentally nonlinear field theory and thus it is not generally amenable to the harmonic oscillator paradigm that forms the foundation for much of classical and quantum field theory.[13] That is, motion of continuum matter is not restricted to small fluctuations relative to an equilibrated state. So to examine the gamut of fluid motions, in Chapter 47 we apply Hamilton's principle to the fluid motion field, $\boldsymbol{\varphi}$. We thus develop a field theory for the motion field as it appears in Lagrangian space-time. Even given this distinction between the scalar field theory from Chapter 46 to the Lagrangian space-time of the motion field, it is remarkable that the perfect fluid Euler-Lagrange equation (47.43a) is mathematically identical to equation (46.43) formulated for the continuous scalar field.

Concerning local field theory

In our studies of continuum mechanics in general, or fluid mechanics in particular, we rely on *local fields* to formulate the equations describing motion of continuous matter. Namely, all fields (e.g., temperature, velocity, energy) depend locally on positions in Galilean space-time. The use of fields and the corresponding local approach were discussed in Chapter 16 in the context of the continuum approximation. Local field theories embody the inability for information to transfer at speeds faster than light or, for our studies that ignore electromagnetism, for signals to travel faster than acoustic waves. Furthermore, local field theories are ubiquitous in physics in part since they offer a robust conceptual and operational foundation that is simpler than non-local approaches.[14] As noted on page 24 of *Ramond* (1990), local field theories are so well trusted that they are commonly used for describing non-local phenomena. For our study of fluid mechanics, we make use of both the Lagrangian and Eulerian reference frames. The Eulerian approach considers fields that are local in the Eulerian $\boldsymbol{x}$-space, whereas the Lagrangian approach considers fields that are local in the material $\boldsymbol{a}$-space.

These remarks about the relevance of local field theory might seem obvious, with action-at-a-distance phenomena absent from any fundamental processes in classical physics. Even so, there are approximate theories where we assume a wave speed to be infinite, thus transitioning from a hyperbolic system to an elliptic system. The primary example occurs when assuming a non-divergent fluid flow, as in the Boussinesq ocean. For this case, the pressure is purely mechanical (i.e., it is not related to internal energy via a thermodynamic derivative), and it solves an elliptic boundary value problem to enforce the non-divergence nature of the flow. That is, for non-divergent flow, pressure is the Lagrange multiplier that ensure the constraint of $\nabla \cdot \boldsymbol{v} = 0$ is maintained at each point in space and time, with the acoustic wave speed assumed

[13] The study of linear waves in Part X is one area where the harmonic oscillator paradigm is suited for fluid mechanics.

[14] Chapter 1 of *Morse and Feshbach* (1953) provides an insightful discussion of fields and their use in physics.

infinite. In general, if encountering a non-local process in classical physics, we must inquire about the corresponding unapproximated process in order to determine if the non-local theory is a physically sensible approximation to a local theory. If not, then the non-local theory is not a viable theory of classical continuum mechanics.

Chapter 46

Scalar field theory in Galilean space-time

In this chapter we study *classical scalar field theory* in Galilean space-time from the perspective of *Hamilton's principle* of stationary action. We motivate this study by considering the continuum limit of a system of coupled simple harmonic oscillators, which provides the canonical example of how to extend Lagrangian particle mechanics to Lagrangian continuum mechanics. We then develop the equations of motion within the continuum and make use of Noether's theorem to derive dynamical conservation laws connected to space-time symmetries.

CHAPTER GUIDE

This chapter relies on the formulation of Lagrangian mechanics and Hamilton's principle from Chapter 12 and 15. We also make use of general tensor formalism from Chapters 1 through 4. The use of general tensors here anticipates their use for the perfect fluid in Chapter 47. This chapter serves as the foundations for applying Hamilton's variational principle for fluid mechanics in Chapter 47, for potential flow in Section 52.2.9, and various topics in wave mechanics found in Part X.

46.1 Continuum limit of coupled harmonic oscillators

Further study of the discrete coupled oscillator system from Section 15.7 involves the introduction of discrete normal modes and the examination of energy moving through discrete waves (e.g., see Section 24 of *Fetter and Walecka* (2003)). However, that analysis takes us somewhat outside the main topic of this book. Instead, we here examine the continuum limit of the oscillator system. The purpose of this study is to extend discrete Lagrangian mechanics and Hamilton's principle to the continuum, thus providing a direct connection to fluid mechanics and classical field theory.

46.1.1 Continuum limit

We work in a classical physics universe, so that we have no concern for the quantum nature of matter. As such, the continuum limit is here considered as a mere mathematical transition from discrete classical matter to continuous classical matter. This approach is physically naive in the face of the molecular and atomic nature of matter as described by quantum mechanics. Even so, it provides a suitable mathematical framework for studying the classical mechanics of continuous media, and as such it serves the needs of this book. See Chapter 16 for more discussion of the physical basis for the continuum limit.

The continuum limit for the coupled harmonic oscillator system is realized by the following (see Section 15.7 for notation):

$$\Delta \to \mathrm{d}x \qquad \text{equilibrium distance betwen particles becomes infinitesimal} \tag{46.1a}$$

$$N \to \infty \qquad \text{infinite number of particles} \tag{46.1b}$$

$$(N+1)\,\Delta = \ell \qquad \text{equilibrium length remains constant} \tag{46.1c}$$

$$m/\Delta = \sigma \qquad \text{mass per length} \tag{46.1d}$$

$$\Gamma\,\Delta = \tau \qquad \text{compressive/expansive force} \tag{46.1e}$$

$$\mathsf{n}\,\Delta = x \qquad \text{continuous coordinate for equilibrium position} \tag{46.1f}$$

$$\xi_{\mathsf{n}}(t) \to \xi(x,t) \qquad \text{displacement becomes function of space and time.} \tag{46.1g}$$

The displacement function, $\xi(x,t)$, measures the displacement of an infinitesimal piece of matter whose equilibrium position is x. As such, the coordinate x acts as a parameter that labels an infinitesimal piece of matter whose equilibrium position is x and whose instantaneous position is $x + \xi(x,t)$.[1]

We take the continuum limit starting from two different perspectives. First we focus on the equation of motion (15.146) for the coupled oscillators, which is the topic of Section 46.1.2. Alternatively, we take the continuum limit of the Lagrangian and then derive the corresponding Euler-Lagrange equations, with this approach considered in Section 46.1.3. The second approach is aligned with the approach in classical field theory used in later sections.

[1]The displacement field, $\xi(x,t)$, is a one-dimensional version of the vector field, $\boldsymbol{\xi}(\boldsymbol{x},t)$, used for the *generalized Lagrangian mean* of Section 70.2.

46.1.2 Continuum limit and the wave equation

Introducing the notation from equations (46.1a)-(46.1g), yet without taking the continuum limit, brings the coupled oscillator equation (15.146) into the form

$$\ddot{\xi}_{\mathsf{n}} = \frac{\Gamma}{m}\left(\xi_{\mathsf{n}+1} - 2\,\xi_{\mathsf{n}} + \xi_{\mathsf{n}-1}\right) \tag{46.2a}$$

$$= \frac{\Gamma\,\Delta}{m/\Delta}\,\frac{\xi_{\mathsf{n}+1} - 2\,\xi_{\mathsf{n}} + \xi_{\mathsf{n}-1}}{\Delta^2} \tag{46.2b}$$

$$= \frac{\tau}{\sigma}\left[\frac{\xi_{\mathsf{n}+1} - 2\,\xi_{\mathsf{n}} + \xi_{\mathsf{n}-1}}{\Delta^2}\right]. \tag{46.2c}$$

To take the continuum limit, note that the finite difference on the right hand side approximates the second order spatial derivative operator, so that in the continuum limit we recover the one dimensional *wave equation*

$$(\partial_{tt} - c^2\,\partial_{xx})\,\xi = 0, \tag{46.3}$$

with the wave speed given by

$$c = (\tau/\sigma)^{1/2}. \tag{46.4}$$

We studied the mathematics of the wave equation (46.3) in Section 6.7 in the context of hyperbolic partial differential equations. A general solution is given by

$$\xi(x,t) = A(x - c\,t) + B(x + c\,t), \tag{46.5}$$

where A and B are arbitrary smooth functions determined by the initial conditions and boundary conditions. The solution $A(x - c\,t)$ is a signal moving in the $+\hat{\boldsymbol{x}}$ direction, whereas $B(x - c\,t)$ is a signal moving in the $-\hat{\boldsymbol{x}}$ direction, both moving at speed c.

We have restricted attention to motion constrained to a line whereby the harmonic oscillators render a series of alternative rarefactions and compressions that lead to wave-like motions along that line. Upon taking the continuum limit, we find that each piece of the continuum oscillates about its equilibrium position, again with the oscillations in a direction aligned with the waves. Such motions are the defining characteristic of *longitudinal waves*. The longitudinal waves resulting from the continuum limit of coupled harmonic oscillators offers a prototype for the acoustic waves studied in Chapter 51.

46.1.3 Continuum limit of the Lagrangian

Rather than taking the continuum limit of the equation of motion, we here consider the continuum limit of the Lagrangian and then derive the corresponding Euler-Lagrange equation of motion. This approach accords with the methods of classical field theory and it will serve many purposes in this book.

Recall the discrete Lagrangian given by equation (15.155)

$$L = \sum_{\mathsf{n}=1}^{N+1}\left[\frac{m}{2}\,(\dot{\xi}_{\mathsf{n}})^2 - \frac{\Gamma}{2}\,(\xi_{\mathsf{n}} - \xi_{\mathsf{n}-1})^2\right]. \tag{46.6}$$

The continuum limit from Section 46.1.2 brings the kinetic energy to

$$\frac{m}{2}\sum_{\mathsf{n}=1}^{N+1}(\dot{\xi}_{\mathsf{n}})^2 = \frac{\sigma}{2}\sum_{\mathsf{n}=1}^{N+1}(\dot{\xi}_{\mathsf{n}})^2\,\Delta \longrightarrow \frac{\sigma}{2}\int_0^{\ell}(\partial_t\xi)^2\,\mathrm{d}x, \tag{46.7}$$

where we set $m = \sigma\,\Delta$ according to equation (46.1d), and made the correspondence

$$\sum_{n=1}^{N+1} \Delta \longrightarrow \int_0^\ell dx. \tag{46.8}$$

Similarly, the continuum limit of the potential energy yields

$$\frac{\Gamma}{2}\sum_{n=1}^{N+1}(\xi_n - \xi_{n-1})^2 = \frac{\Gamma\,\Delta}{2}\sum_{n=1}^{N+1}\frac{(\xi_n - \xi_{n-1})^2}{\Delta^2}\,\Delta \longrightarrow \frac{\tau}{2}\int_0^\ell (\partial_x\xi)^2\,dx, \tag{46.9}$$

where we set $\Gamma\,\Delta = \tau$ according to equation (46.1e). As a result, the Lagrangian has the continuum limit

$$L = \sum_{n=1}^{N+1}\left[\frac{m}{2}(\dot\xi_n)^2 - \frac{\Gamma}{2}(\xi_n - \xi_{n-1})^2\right] \longrightarrow \frac{1}{2}\int_0^\ell [\sigma\,(\partial_t\xi)^2 - \tau\,(\partial_x\xi)^2]\,dx \equiv \int_0^\ell \mathcal{L}\,dx, \tag{46.10}$$

where we defined the *Lagrangian density*

$$\mathcal{L} = [\sigma\,(\partial_t\xi)^2 - \tau\,(\partial_x\xi)^2]/2. \tag{46.11}$$

Now observe that

$$\frac{\partial}{\partial t}\frac{\partial \mathcal{L}}{\partial(\partial_t\xi)} + \frac{\partial}{\partial x}\frac{\partial \mathcal{L}}{\partial(\partial_x\xi)} = \sigma\,\partial_{tt}\xi - \tau\,\partial_{xx}\xi = \sigma\,(\partial_{tt}\xi - c^2\,\partial_{xx}\xi) = 0. \tag{46.12}$$

This result hints at a means to derive the Euler-Lagrange equation using a continuum version of Hamilton's principle, which is the topic of Section 46.2.

46.1.4 Further study

In transitioning from the discrete harmonic oscillators to the continuum field theory, we are inspired by treatments from *Fetter and Walecka* (2003) (chapters 4, 6, and 8), chapter 12 of *Goldstein* (1980), chapter 9 of *José and Saletan* (1998), and Chapter 2 of *Soper* (2008). Note that some of these treatments (e.g., Chapter 4 of *Fetter and Walecka* (2003)) works through the continuum limit of a string, which accords quite closely to the continuum limit of simple harmonic oscillators considered here.

46.2 Hamilton's principle and the Euler-Lagrange equations

The continuum limit considered in Section 46.1 suggests that we can study the mechanics of continuous media using the methods of Lagrangian mechanics and Hamilton's principle, and that we can pursue this approach without concern for the discrete nature of matter. In this section we explore the rudiments of the resulting field theory for scalar fields. For simplicity, we focus here on the case of one space dimension, along with time. Generalizations to higher space dimensions are straightforward, in which case the space-time domain, R, includes higher dimensional region of space, $\mathcal{R}$, along with a time interval.

46.2.1 The action for a continuous field

In Section 12.6 we applied Hamilton's principle to the trajectories of discrete particles moving through space, with the spatial position specified by generalized coordinates and the position along a trajectory parameterized by time. Hamilton's principle states that the physically realized

trajectory is that trajectory that makes the action stationary. Here we postulate that Hamilton's principle for point particles can be extended to continuous matter whose mechanics is described by space-time fields. Many steps in the derivation here are straightforward extensions of the discrete particle discussion.

Consider a 1+1 dimensional field, $\psi = \psi(x,t)$, that is a function of one Cartesian space coordinate, x, and time, t. For example, $\psi(x,t)$ can represent the displacement field, $\xi(x,t)$, introduced by the continuum limit of the oscillators studied in Section 46.1. In this manner, the continuum extension of the discrete particle action defined by equation (12.63) is here given by the space-time integral

$$\mathcal{S}[t_{\mathsf{A}}, x_{\mathsf{A}}, t_{\mathsf{B}}, x_{\mathsf{B}}, \psi] = \int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}} L \, \mathrm{d}t = \int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}} \left[\int_{x_{\mathsf{A}}}^{x_{\mathsf{B}}} \mathcal{L}(\psi, \partial_t \psi, \partial_x \psi, x, t) \, \mathrm{d}x \right] \mathrm{d}t, \tag{46.13}$$

where $\mathcal{L}$ is the *Lagrangian density*[2] and the physical system lives on a space domain, $x \in [x_{\mathsf{A}}, x_{\mathsf{B}}]$, and evolves over the time range, $t \in [t_{\mathsf{A}}, t_{\mathsf{B}}]$. We refer to this space-time domain as

$$\mathrm{R} \equiv x \in [x_{\mathsf{A}}, x_{\mathsf{B}}] \oplus t \in [t_{\mathsf{A}}, t_{\mathsf{B}}], \tag{46.14}$$

and its boundary is $\partial\mathrm{R}$. On the left hand side of equation (46.13) we exposed the dependence of the action on the space and time endpoints, as well as the function, ψ. We generally omit such dependence for brevity in notation.

Note the presence of both space and time derivatives inside the action in equation (46.13), as per the use of both space and time as independent variables for the field, ψ. Evidently, the Lagrangian density, $\mathcal{L}$, is a functional[3] of the field, ψ, and its derivatives, $\partial_t \psi$ and $\partial_x \psi$. Since ψ is a function of (x,t), then the Lagrangian density, $\mathcal{L}$, is an implicit function of (x,t) through its dependence on $\psi(x,t)$, $\partial_t \psi(x,t)$, and $\partial_x \psi(x,t)$. Furthermore, we allow for $\mathcal{L}$ to be an explicit function of (x,t), which may arrive via other prescribed functions that contribute to the Lagrangian (e.g., a space-time dependent background field through which waves propagate, as studied in Chapter 50). In Section 46.3.1 we emphasize the importance of being mindful of the variety of explicit and implicit dependencies of the Lagrangian density.

46.2.2 Functional variation of the field

In the action (46.13), it is the field, $\psi(x,t)$, that is the continuum extension of the generalized coordinates used in the discrete particle mechanics action (12.63). Correspondingly, it is the field that is varied when varying the continuum action. Let $\psi(x,t)$ be the physically realized field and introduce a virtual variation around that field according to

$$\psi(x,t|\epsilon) = \psi(x,t) + \epsilon \, \chi(x,t) = \psi(x,t) + \delta\psi(x,t). \tag{46.15}$$

The first equality introduced a non-dimensional parameter, ϵ, that scales the perturbation field, χ, thus defining a one-parameter family of functions, $\psi(x,t|\epsilon)$. The second equality in equation (46.15) introduced the δ notion commonly used for variations (see Section 12.6). We emphasize that it is the field that is varied, so that the field parameters, (x,t), are the same across the two equalities in equation (46.15). Consequently, the δ operator commutes with space and time derivatives.

Figure 46.1 illustrates the field variation (46.15). There is a nonzero variation, $\delta\psi(x,t) = \epsilon \, \chi(x,t)$, for space-time points that are not on the space-time boundary, $(x,t) \notin \partial\mathrm{R}$. In contrast, the field is specified along $\partial\mathrm{R}$ to be the physically realized field, so that on the space-time

[2] We commonly refer to $\mathcal{L}$ as the "Lagrangian", thus omitting the "density" qualifier.
[3] A functional is a "function of a function".

boundary there is no variation

$$\delta\psi(x,t) = 0 \quad \forall\ (x,t) \in \partial\mathrm{R} \iff \frac{\partial\psi(x,t|\epsilon)}{\partial\epsilon} = 0 \quad \forall\ (x,t) \in \partial\mathrm{R}. \tag{46.16}$$

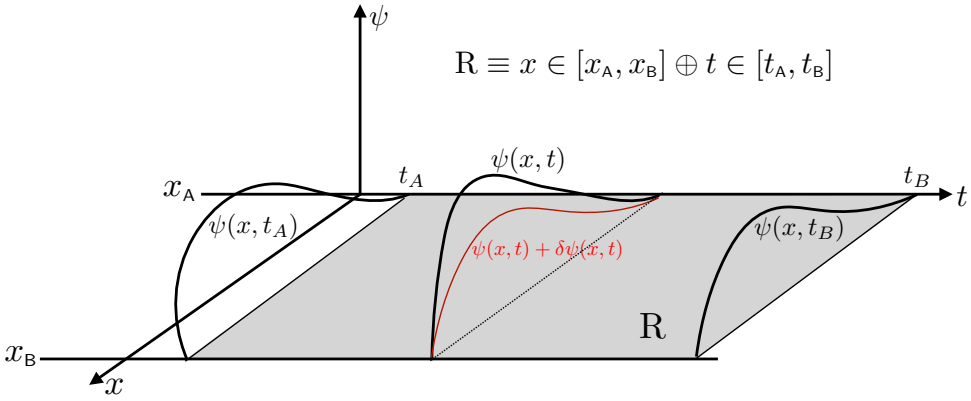

FIGURE 46.1: Illustrating the variation of a field for use in Hamilton's principle for continuous media. The field, $\psi(x,t)$, is specified along the space-time boundary of the domain, $\partial\mathrm{R}$, where R is the space domain $x \in [x_\mathrm{A}, x_\mathrm{B}]$ plus a time domain $t \in [t_\mathrm{A}, t_\mathrm{B}]$. When not on $\partial\mathrm{R}$, then there is a nonzero, $\delta\psi(x,t)$, whereas $\delta\psi = 0$ on the boundary, $\partial\mathrm{R}$. This figure is inspired by Figure 25.3 of *Fetter and Walecka* (2003).

46.2.3 Variation of the action

Hamilton's principles says that the physically realized field, $\psi(x,t|\epsilon = 0)$, makes the action stationary, which is mathematically stated as

$$\text{Hamilton's principle} \implies \left[\frac{\mathrm{d}\mathcal{S}}{\mathrm{d}\epsilon}\right]_{\epsilon=0} = \left[\frac{\mathrm{d}}{\mathrm{d}\epsilon}\int_\mathrm{R} \mathcal{L}\,\mathrm{d}x\,\mathrm{d}t\right]_{\epsilon=0} = 0. \tag{46.17}$$

Making use of the δ shorthand leads to

$$\text{Hamilton's principle} \implies \delta\mathcal{S} = \delta\left[\int_\mathrm{R} \mathcal{L}\,\mathrm{d}x\,\mathrm{d}t\right] = 0 \quad \text{with} \quad \delta = [\mathrm{d}/\mathrm{d}\epsilon]_{\epsilon=0}\,. \tag{46.18}$$

In varying the action we only vary the field and its derivatives, with the space-time domain, R, unchanged. Hence, the variation operator commutes with the space-time integral

$$\delta\mathcal{S} = \int_\mathrm{R} \delta\mathcal{L}\,\mathrm{d}x\,\mathrm{d}t. \tag{46.19}$$

Variation of the Lagrangian density is computed according to the chain rule

$$\delta\mathcal{L} = \left[\frac{\partial\mathcal{L}}{\partial\psi}\right]_{\partial_t\psi,\partial_x\psi}\delta\psi + \left[\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\right]_{\psi,\partial_x\psi}\delta(\partial_t\psi) + \left[\frac{\partial\mathcal{L}}{\partial(\partial_x\psi)}\right]_{\psi,\partial_t\psi}\delta(\partial_x\psi). \tag{46.20}$$

We exposed subscripts to denote which terms are held fixed during the partial functional derivative operation. This equation makes it clear that variation of the Lagrangian density occurs at a fixed space-time point, which explains why there are no $(\partial\mathcal{L}/\partial t)\,\delta t$ nor $(\partial\mathcal{L}/\partial x)\,\delta x$ terms. Correspondingly, under this variation we consider (x,t) as space-time parameters so that the ∂_x and ∂_t operators acting on ψ commute with the variation operator

$$\delta\mathcal{L} = \frac{\partial\mathcal{L}}{\partial\psi}\,\delta\psi + \frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\,\partial_t(\delta\psi) + \frac{\partial\mathcal{L}}{\partial(\partial_x\psi)}\,\partial_x(\delta\psi). \tag{46.21}$$

Further rearranging the space-time operators leads to the equivalent expression

$$\delta\mathscr{L} = \left[\frac{\partial\mathscr{L}}{\partial\psi} - \frac{\partial}{\partial t}\frac{\partial\mathscr{L}}{\partial(\partial_t\psi)} - \frac{\partial}{\partial x}\frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\right]\delta\psi + \frac{\partial}{\partial t}\left[\frac{\partial\mathscr{L}}{\partial(\partial_t\psi)}\,\delta\psi\right] + \frac{\partial}{\partial x}\left[\frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\,\delta\psi\right]. \tag{46.22}$$

46.2.4 Euler-Lagrange field equations

Plugging the result (46.22) into the action variation (46.19) leads to

$$\delta\mathcal{S} = \int_{\mathrm{R}} \delta\psi\left(\frac{\partial\mathscr{L}}{\partial\psi} - \frac{\partial}{\partial t}\frac{\partial\mathscr{L}}{\partial(\partial_t\psi)} - \frac{\partial}{\partial x}\frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\right)\mathrm{d}x\,\mathrm{d}t + \int_{\mathrm{R}}\left(\frac{\partial}{\partial t}\left[\frac{\partial\mathscr{L}}{\partial(\partial_t\psi)}\,\delta\psi\right] + \frac{\partial}{\partial x}\left[\frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\,\delta\psi\right]\right)\mathrm{d}x\,\mathrm{d}t. \tag{46.23}$$

As noted earlier, we are assuming the field variation vanishes on the space-time boundary, so that $\delta\psi = 0$ for points on $\partial\mathrm{R}$. Doing so eliminates the second integral since both terms integrate to boundary contributions. Furthermore, since $\delta\psi$ is an arbitary variation of the field within the interior of the domain, a general satisfaction of Hamilton's principle, $\delta\mathcal{S} = 0$, only holds if the integrand in the first integral vanishes for each space and time point, which thus leads to the continuum *Euler-Lagrange equations*

$$\delta\mathcal{S} = 0 \Longrightarrow \frac{\partial\mathscr{L}}{\partial\psi} - \frac{\partial}{\partial t}\left[\frac{\partial\mathscr{L}}{\partial(\partial_t\psi)}\right] - \frac{\partial}{\partial x}\left[\frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\right] = 0. \tag{46.24}$$

We emphasize here an important practical point related to computation of the partial derivatives. Namely, when performing the partial derivative on $\mathscr{L}$ with respect to ψ and its derivatives, $\partial_t\psi$ and $\partial_x\psi$, each of the other variables in the Lagrangian density are held fixed. However, when performing the space and time partial derivatives, ∂_x and ∂_t, we only maintain the complement space and time variable fixed, so that we need to employ the chain rule to extract all places where ∂_x and ∂_t affect. We offer details in Section 46.3.1 on these points about computing the partial derivatives.

46.2.5 Example Lagrangian densities

We have many opportunities in this book to use a Lagrangian density to derive the correspondingly Euler-Lagrange equations. Here we provide a few examples that lead to wave equations.

Acoustic wave equation

As studied in Section 46.1, the Lagrangian density

$$\mathscr{L} = [\sigma\,(\partial_t\psi)^2 - \tau\,(\partial_x\psi)^2]/2, \tag{46.25}$$

with σ and τ constants, renders the wave equation as the Euler-Lagrange equation

$$(\partial_{tt} - c^2\,\partial_{xx})\,\psi = 0, \tag{46.26}$$

where the wave speed is $c = \sqrt{\tau/\sigma}$ (equation (46.4)). Notice that the dimensions of $\mathscr{L}$ are energy per length, which accords with this being a wave equation in a single spatial dimension. The Lagrangian (46.25) and wave equation (46.26) also hold for the more general case of a tension that is a function of time, $\tau = \tau(t)$, and a mass density that is a function of space, $\sigma = \sigma(x)$, in which case the wave speed is a function of space and time

$$c^2(x,t) = \tau(t)/\sigma(x). \tag{46.27}$$

We derived the Lagrangian density (46.25) in Section 46.1 by taking the continuum limit of coupled harmonic oscillators, where $\psi(x,t)$ represents the $\hat{\boldsymbol{x}}$-displacement of a particle from its equilibrium position, so that linear fluctuations are *longitudinal waves* (wave motion in the same direction of the particle displacement). An analogous derivation leads to the same Lagrangian density for a tight string, with $\psi(x,t)$ now measuring the transverse displacements of the string from its equilibrium position (see Section 25 in *Fetter and Walecka* (2003)), and with linear oscillations leading to *transverse waves*.

Returning to the continuum harmonic oscillator, we note that it is directly related to the study of acoustic waves in a fluid. We pursue this study in Chapter 51, thus encountering the Lagrangian density

$$\mathscr{L} = [c_{\text{s}}^{-2}\,(\partial_t p')^2 - (\nabla p')^2]/(2\,\rho_{\text{e}}), \tag{46.28}$$

where ρ_{e} is the mass density of the background fluid state, c_{s} is the sound speed in the fluid, and p' is the perturbation pressure. In this case the Euler-Lagrange equation is the acoustic wave equation

$$\partial_t[(\rho_{\text{e}}\,c_{\text{s}}^2)^{-1}\,\partial_t p'] - \nabla\cdot(\rho_{\text{e}}^{-1}\,\nabla p') = 0, \tag{46.29}$$

which, in the special case of ρ_{e} and c_{s} independent of space and time, gives the wave equation

$$(\partial_{tt} - c_{\text{s}}^2\,\nabla^2)\,p' = 0. \tag{46.30}$$

Note that the physical dimensions of the Lagrangian density (46.28) are not energy per volume, so that the terms in the Lagrangian are thought of as pseudo-energy densities.

Sine-Gordon and Klein-Gordon wave equations

For another example, consider

$$\mathscr{L} = [\sigma\,(\partial_t\psi)^2 - \tau\,(\partial_x\psi)^2]/2 - \sigma\,\Gamma^2\,(1-\cos\psi), \tag{46.31}$$

where ψ is here a non-dimensional field. The corresponding Euler-Lagrange equation is known as the *sine-Gordon equation*

$$\partial_{tt}\psi - c^2\,\partial_{xx}\psi + \Gamma^2\sin\psi = 0. \tag{46.32}$$

As shown in Section 9.1.1 of *José and Saletan* (1998), the sine-Gordon equation is the continuum limit of a coupled pendulum-spring system, with Γ proportional to the gravitational acceleration. For small ψ, the sine-Gordon Lagrangian (46.31) and wave equation (46.32) reduce to the *Klein-Gordon* Lagrangian and Klein-Gordon equation

$$\mathscr{L} = [\sigma\,(\partial_t\psi)^2 - \tau\,(\partial_x\psi)^2]/2 + \sigma\,\Gamma^2\,\psi^2 \quad \text{and} \quad (\partial_{tt} - c^2\,\partial_{xx} + \Gamma^2)\,\psi = 0. \tag{46.33}$$

The Klein-Gordon equation forms the starting point for scalar quantum field theories (e.g., *Ryder* (1985)).

46.3 Operational aspects of Hamilton's principle

We here summarize a number of points about the formalism that are particularly relevant when performing the many operational steps with Hamilton's principle.

46.3.1 Care with the partial derivative operations

As noted in Section 46.2, the Lagrangian density, $\mathscr{L}$, is a functional of the field, ψ, as well as its space and time derivatives,

$$\frac{\partial\psi(x,t)}{\partial t} = \left[\frac{\partial\psi(x,t)}{\partial t}\right]_x \quad \text{and} \quad \frac{\partial\psi(x,t)}{\partial x} = \left[\frac{\partial\psi(x,t)}{\partial x}\right]_t , \tag{46.34}$$

where the subscripts on the right hand side of these equations indicate those variables held fixed while performing the partial derivative. We typically do not need this extra adornment for partial derivatives acting on functions of space and time. But the Lagrangian density is a rather loaded object, and so it is important to clarify what is meant by its derivatives.

With ψ and its derivatives explicit functions of (x,t), then $\mathscr{L}$ is an implicit function of (x,t). There are additional physical systems where the Lagrangian density picks up an explicit space and time dependence, such as when waves move through a space and time dependent background media (Section 50.5). Such added space and time dependence does not alter the derivation of the Euler-Lagrange field equation, since in that derivation we only vary the field and its derivatives. However, the distinction between implicit versus explicit functional dependence can easily lead to confusion when performing partial derivative manipulations involving ∂_t and ∂_x operations, such as when deriving the continuum conservation laws in Section 46.4. We thus find it useful to here write these derivatives for the record.

The partial time derivative of $\mathscr{L}$, computed at a fixed x position, is given by

$$\left[\frac{\partial\mathscr{L}}{\partial t}\right]_x = \left[\frac{\partial\mathscr{L}}{\partial\psi}\right]_{\partial_t\psi,\partial_x\psi}\frac{\partial\psi}{\partial t} + \left[\frac{\partial\mathscr{L}}{\partial(\partial_t\psi)}\right]_{\psi,\partial_x\psi}\frac{\partial^2\psi}{\partial t^2} + \left[\frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\right]_{\psi,\partial_t\psi}\frac{\partial^2\psi}{\partial x\partial t} + \left[\frac{\partial\mathscr{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,x} . \tag{46.35}$$

Exposing the subscripts on the $\mathscr{L}$ partial derivatives helps to distinguish the time derivative on the left hand side from the time derivative appearing in the final term on the right hand side. Namely, the $(\partial\mathscr{L}/\partial t)_x$ on the left hand side only holds x fixed, whereas the $(\partial\mathscr{L}/\partial t)_{\psi,\partial_t\psi,\partial_x\psi,x}$ on the right hand side holds the full gamut, $\psi, \partial_t\psi, \partial_x\psi, x$, fixed while computing the time derivative. Distinguishing these two derivatives is the primary point of confusion, so that for it is commonly sufficient to abbreviate this equation with the more succinct expression

$$\frac{\partial\mathscr{L}}{\partial t} = \frac{\partial\mathscr{L}}{\partial\psi}\frac{\partial\psi}{\partial t} + \frac{\partial\mathscr{L}}{\partial(\partial_t\psi)}\frac{\partial^2\psi}{\partial t^2} + \frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\frac{\partial^2\psi}{\partial x\partial t} + \left[\frac{\partial\mathscr{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,x} . \tag{46.36}$$

A similar expression holds for the partial space derivative computed at a fixed time,

$$\left[\frac{\partial\mathscr{L}}{\partial x}\right]_t = \left[\frac{\partial\mathscr{L}}{\partial\psi}\right]_{\partial_t\psi,\partial_x\psi}\frac{\partial\psi}{\partial x} + \left[\frac{\partial\mathscr{L}}{\partial(\partial_t\psi)}\right]_{\psi,\partial_x\psi}\frac{\partial^2\psi}{\partial t\partial x} + \left[\frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\right]_{\psi,\partial_t\psi}\frac{\partial^2\psi}{\partial x^2} + \left[\frac{\partial\mathscr{L}}{\partial x}\right]_{\psi,\partial_t\psi,\partial_x\psi,t} , \tag{46.37}$$

which also has the succinct form[4]

$$\frac{\partial\mathscr{L}}{\partial x} = \frac{\partial\mathscr{L}}{\partial\psi}\frac{\partial\psi}{\partial x} + \frac{\partial\mathscr{L}}{\partial(\partial_t\psi)}\frac{\partial^2\psi}{\partial t\partial x} + \frac{\partial\mathscr{L}}{\partial(\partial_x\psi)}\frac{\partial^2\psi}{\partial x^2} + \left[\frac{\partial\mathscr{L}}{\partial x}\right]_{\psi,\partial_t\psi,\partial_x\psi,t} . \tag{46.38}$$

[4]Note that some authors (e.g., chapter 12 of *Goldstein* (1980)), write $\mathrm{d}/\mathrm{d}t$ and $\mathrm{d}/\mathrm{d}x$ for the left hand side operators in equations (46.35) and (46.37), referring to these derivatives as "total time" and "total space" derivatives. We do not follow that nomenclature here.

46.3.2 Generalized spatial coordinates

As when studying discrete particle mechanics, we often find that Cartesian space coordinates are less suited to symmetry of the physical configuration. This point is particularly relevant for Chapter 47 when working with the Lagrangian space-time field theory relevant to fluids, in which we coordinate lines are attached to fluid particles. We thus now allow for the spatial coordinates, $x^a (a = 1, 2, 3)$, to be arbitrary general coordinates rather than restricted to Cartesian. To do so requires results from general tensor analysis in Chapters 3 and 4. In particular, we need the invariant volume element given by equation (4.60)

$$\mathrm{d}V = g \, \mathrm{d}^3 x, \tag{46.39}$$

where g is the square root of the spatial metric tensor's determinant as represented by the arbitrary spatial coordinates (see Sections 4.5.2 and 4.5.3), and

$$\mathrm{d}^3 x = \mathrm{d}x^1 \, \mathrm{d}x^2 \, \mathrm{d}x^3 \tag{46.40}$$

is a shorthand for the spatial coordinate element. Note that g can generally be a function of space and time.

We are thus led to a variation of the action[5]

$$\delta \mathcal{S} = \int_{\mathrm{R}} (\delta \mathcal{L}) \, g \, \mathrm{d}^3 x \, \mathrm{d}t. \tag{46.41}$$

Generalizing the Cartesian coordinate derivation requires us now to keep track of g, so that

$$\int_{\mathrm{R}} \delta\psi \left[\frac{\partial \mathcal{L}}{\partial \psi} - \frac{1}{g} \frac{\partial}{\partial t} \left[g \, \frac{\partial \mathcal{L}}{\partial (\partial_t \psi)} \right] - \frac{1}{g} \frac{\partial}{\partial x^a} \left[g \, \frac{\partial \mathcal{L}}{\partial (\partial_a \psi)} \right] \right] g \, \mathrm{d}^3 x \, \mathrm{d}t. \tag{46.42}$$

Setting $\delta \mathcal{S} = 0$ leads to the Euler-Lagrange equation

$$\frac{\partial \mathcal{L}}{\partial \psi} - \frac{1}{g} \frac{\partial}{\partial t} \left[g \, \frac{\partial \mathcal{L}}{\partial (\partial_t \psi)} \right] - \frac{1}{g} \frac{\partial}{\partial x^a} \left[g \, \frac{\partial \mathcal{L}}{\partial (\partial_a \psi)} \right] = 0. \tag{46.43}$$

From our discussion in Section 4.15, we see that the covariant divergence of a vector natually appears in this formulation. Namely, from equation (4.134) we have the covariant divergence

$$\nabla_a \left[\frac{\partial \mathcal{L}}{\partial (\partial_a \psi)} \right] = \frac{1}{g} \frac{\partial}{\partial x^a} \left[g \, \frac{\partial \mathcal{L}}{\partial (\partial_a \psi)} \right], \tag{46.44}$$

where ∇_a is the covariant derivative operator. For the remainder of this chapter we make use of general spatial coordinates since they are necessary for the study of fluids in Chapter 47 using Lagrangian space-time.

46.3.3 Natural spatial boundary conditions

As seen in Section 46.2.4, the Euler-Lagrange field equations arise by setting the field variation, $\delta\psi$, to zero on both the space and times boundaries. This assumption is typical of many treatments given that it offers a sensible generalization of the discrete case in Section 12.6, in which the variation vanishes at the initial and final times. It is also relevant for the case without boundaries, with all terms assumed to vanish at infinity. However, for geophysical fluid

[5]The variation (46.41) only varies the field, ψ, which means there is no variation of the space-time element, $g \, \mathrm{d}^3 x \, \mathrm{d}t$. In Section 46.5 we allow for coordinates to be varied, in which case we must consider variations of $g \, \mathrm{d}^3 x \, \mathrm{d}t$.

mechanics the question of spatial boundary conditions is often of primary importance. We thus investigate alternatives to setting $\delta\psi = 0$ on the spatial boundaries.[6]

In particular, consider a situation where the fluid is bounded by a static material boundary, $\partial\mathcal{R}$. All fields, whether the actual physical field or variations around this field, must satisfy the relevant kinematic boundary conditions. In terms of the Lagrangian density, the natural boundary condition is given by

$$\hat{\boldsymbol{n}} \cdot \frac{\partial \mathscr{L}}{\partial(\nabla\psi)} = \hat{n}_a \frac{\partial \mathscr{L}}{\partial(\partial_a\psi)} = 0 \quad \text{on } \partial\mathcal{R}, \tag{46.45}$$

where $\hat{\boldsymbol{n}}$ is the outward normal along the spatial boundary, $\partial\mathcal{R}$. The boundary condition (46.45) means that there is no generalized forces acting on the physical field at the boundaries. If this boundary condition is satisfied, then the Euler-Lagrange equation (46.24) follows even without specifying how $\delta\psi$ behaves on the spatial boundaries.

What if the boundary is dynamical and thus feels forces, such as occurs in free boundary problems? For example, the boundary could represent the material interface between the ocean and atmosphere, in which forces are imparted at the boundary. In this case the boundary itself is dynamical and so it too must be incorporated into Hamilton's principle. This situation is more subtle than when the boundary is static, and we explore an example in Section 52.2 when studying potential flow in a homogeneous fluid layer with a dynamical free surface.

46.3.4 Galilean space-time notation

In certain places in the following, it proves useful to streamline the notation by making use of the space-time tensor notation from Section 3.5.4. Here, we introduce the Greek index, $\alpha = 0, 1, 2, 3$ with $\alpha = 0$ corresponding to the time index and $\alpha = 1, 2, 3$ for space. In this manner the Euler-Lagrange field equation

$$\frac{\partial \mathscr{L}}{\partial \psi} - \frac{1}{g}\frac{\partial}{\partial t}\left[\frac{\partial \mathscr{L}}{\partial(\partial_t\psi)}\right] - \frac{1}{g}\frac{\partial}{\partial x^a}\left[\frac{\partial \mathscr{L}}{\partial(\partial_a\psi)}\right] = 0, \tag{46.46}$$

takes on the more compact form

$$\frac{\partial \mathscr{L}}{\partial \psi} - \frac{1}{g}\frac{\partial}{\partial x^\alpha}\left[\frac{\partial \mathscr{L}}{\partial(\partial_\alpha\psi)}\right] = 0, \tag{46.47}$$

or even more succinct by making use of the covariant space-time divergence

$$\frac{\partial \mathscr{L}}{\partial \psi} - \nabla_\alpha\left[\frac{\partial \mathscr{L}}{\partial(\partial_\alpha\psi)}\right] = 0. \tag{46.48}$$

Integrals over space and time take on the form

$$\int \int_{\mathscr{R}} g \, \mathrm{d}^3x \, \mathrm{d}t = \int_{\mathrm{R}} g \, \mathrm{d}^4x, \tag{46.49}$$

so that the action is written

$$\mathcal{S} = \int_{\mathrm{R}} \mathscr{L}(\psi, \partial_\alpha\psi, x^\alpha) \, g \, \mathrm{d}^4x. \tag{46.50}$$

Additionally, for brevity we sometimes write x rather than x^α when there is no need to expose the coordinate labels.

In the study of continuum conservation laws from Noether's theorem (Sections 46.4 and

[6] See Section 41 of *Fetter and Walecka* (2003) for similar considerations.

46.5), we encounter continuity equations of the form

$$\nabla_\alpha J^\alpha = g^{-1}\left[\partial_t(g\,J^0) + \partial_a(g\,J^a)\right] = 0, \tag{46.51}$$

where J^α is a Galilean four-vector. Integration over the global spatial domain renders,

$$\int_{\mathcal{R}} \nabla_\alpha J^\alpha \; g\,\mathrm{d}^3x = 0, \tag{46.52}$$

which for a time-independent domain yields the global conservation law

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} J^0\, g\,\mathrm{d}^3x = -\int_{\partial\mathcal{R}} J^a\,\hat{n}_a\, g\,\mathrm{d}\mathcal{S}. \tag{46.53}$$

If the boundary integral vanishes then we have a global constant of integration, which corresponds to a symmetry of the action.

46.3.5 Mechanical equivalence of Lagrangians

In Section 12.6.6 we noted that the mechanics of discrete particles is unchanged if the Lagrangian for a particle system is modified by a total time derivative of a function of the generalized coordinates. Analogously, the mechanics of a continuum field remains unchanged if the Lagrangian density is modified by a space and/or time derivative of functions that have zero variation along the boundaries. More specifically, consider the two Lagrangian densities and briefly return to Cartesian coordinates in 1+1 dimensions

$$\mathscr{L}^{\mathsf{new}} = \mathscr{L}^{\mathsf{old}} + \partial_t\Gamma(\psi,\partial_t\psi,\partial_x\psi,x,t) + \partial_x\Sigma(\psi,\partial_t\psi,\partial_x\psi,x,t), \tag{46.54}$$

where Γ and Σ are arbitrary functions of the field, ψ, its derivatives, $\partial_t\psi, \partial_x\psi$, as well as the space and time positions. To examine mechanical equivalance, consider a space-time domain $\mathrm{R} = [x_\mathsf{A}, x_\mathsf{B}] \oplus [t_\mathsf{A}, t_\mathsf{B}]$, so that the action transforms into

$$\begin{aligned}\mathcal{S}^{\mathsf{new}} = \mathcal{S}^{\mathsf{old}} &+ \int_{x_\mathsf{A}}^{x_\mathsf{B}} \left(\Gamma[\psi(t_\mathsf{B}),\partial_t\psi(t_\mathsf{B}),\partial_x\psi(t_\mathsf{B}),x,t_\mathsf{B}] - \Gamma[\psi(t_\mathsf{A}),\partial_t\psi(t_\mathsf{A}),\partial_x\psi(t_\mathsf{A}),x,t_\mathsf{A}]\right)\mathrm{d}x \\ &+ \int_{t_\mathsf{A}}^{t_\mathsf{B}} \left(\Sigma[\psi(x_\mathsf{B}),\partial_t\psi(x_\mathsf{B}),\partial_x\psi(x_\mathsf{B}),x_\mathsf{B},t] - \Sigma[\psi(x_\mathsf{A}),\partial_t\psi(x_\mathsf{A}),\partial_x\psi(x_\mathsf{A}),x_\mathsf{A},t]\right)\mathrm{d}t.\end{aligned} \tag{46.55}$$

The added terms in the first integral are evaluated at the time boundaries, t_A and t_B, whereas the second integral is evaluated at the space boundaries, x_A and x_B. So mechanical equivalence depends arises if the field has zero variation along the space and time boundaries, in which case

$$\delta\mathcal{S}^{\mathsf{new}} = \delta\mathcal{S}^{\mathsf{old}}, \tag{46.56}$$

which then means that the associated Euler-Lagrange equation is unchanged.

A more general approach, allowing for arbitrary coordinates, is given by

$$\mathscr{L}^{\mathsf{new}} = \mathscr{L}^{\mathsf{old}} + \nabla_\alpha J^\alpha, \tag{46.57}$$

where $\nabla_\alpha J^\alpha$ is a Galilean space-time divergence of a four-vector, J^α. In this case the action changes by

$$\mathcal{S}^{\mathsf{new}} = \mathcal{S}^{\mathsf{old}} + \int_{\partial\mathrm{R}} J^\alpha\,\hat{n}_\alpha\,\mathrm{d}\mathcal{S}, \tag{46.58}$$

where we made use of the space-time form of the divergence theorem from Section 4.19, thus rendering a boundary integral of the flux projected onto the space-time boundary. Mechanical

equivalence thus depends on how J^α behaves along the space-time boundaries. Details depend on specifics of the variation, in particular whether we are considering Hamilton's principle to derive the Euler-Lagrange equations, or whether we are probing symmetries of the dynamical system to determine conservation laws. We further pursue these points when studying symmetries in Sections 46.4 and 46.5, as well as in Section 52.2.9 when using Hamilton's principle for potential flow.

46.3.6 The absence of second or higher derivatives in the Lagrangian

It is notable that the Lagrangian in equation (46.13) is a functional of the field, ψ, and its first derivatives, $\partial_\alpha \psi$. We were originally motivated to consider just the field and its first derivatives based on the continuum limit of coupled oscillators from Section 46.1, where the discrete Lagrangian (46.6) only includes the displacement field and its first time derivative. But when moving away from the discrete limit, we might wish to include higher derivatives for continuum fields. Yet, as noted in Section 1.5 of *Ramond* (1990), higher derivatives in the Lagrangian can lead to non-causal behavior in the corresponding Euler-Lagrange field equations, with the Lorentz-Dirac equation of electrodynamics an example. Heading Ramond's warning motivates us to also restrict Lagrangians to have no second or higher order derivatives.

46.4 Space-time symmetry and stress-energy-momentum

An experiment conducted on a mechanically closed and isolated physical system does not care about the origin of space or time. That is, an experiment conducted in London in the year 1900 yields the same results as when done in New York in the year 2000, assuming all relevant conditions are the same. This observation can be formalized by deriving conservation laws that arise from the absence of a dependence on the space-time origin. Operationally, we expose the equations describing the physical system to a coordinate variation, δx^α, that represents a bulk shift of every point within the physical system. *Noether's theorem* (*Noether*, 1918; *Noether and Tavel*, 2018) provides the means to derive a corresponding conservation law.

In this section we derive conservation laws arising from symmetry in the space-time position. These conservation laws are maintained by the physically realized field, ψ, that satisfy the Euler-Lagrange equation. As noted in Section 12.9 when studying classical point particles, to connect a symmetry to a conservation law it is sufficient to focus on the Lagrangian as it encapsulates the mechanics. In this section we identify cyclic coordinates in the Lagrangian density, with these coordinates then reflecting a symmetry of the physical system that leads to a corresponding conservation law. We consider an alternative approach in Section 46.5 that focuses on the action.

46.4.1 Time symmetry and the Hamiltonian density

Consider a physical system that respects time homogeneity. What does this symmetry imply about the dynamical fields? To answer this question, return to the partial time derivative in equation (46.36)

$$\frac{\partial \mathscr{L}}{\partial t} = \frac{\partial \mathscr{L}}{\partial \psi} \frac{\partial \psi}{\partial t} + \frac{\partial \mathscr{L}}{\partial (\partial_\alpha \psi)} \frac{\partial}{\partial x^\alpha} \frac{\partial \psi}{\partial t} + \left[\frac{\partial \mathscr{L}}{\partial t} \right]_{\psi, \partial_\alpha \psi, x^a}. \tag{46.59}$$

Now make use of the Euler-Lagrange equation (46.48) to have

$$\frac{\partial \mathscr{L}}{\partial \psi} \frac{\partial \psi}{\partial t} = \nabla_\alpha \left[\frac{\partial \mathscr{L}}{\partial (\partial_\alpha \psi)} \right] \frac{\partial \psi}{\partial t} = g^{-1} \frac{\partial}{\partial x^\alpha} \left[g \frac{\partial \mathscr{L}}{\partial (\partial_\alpha \psi)} \right] \frac{\partial \psi}{\partial t}, \tag{46.60}$$

which then leads to

$$\frac{\partial \mathscr{L}}{\partial t} = g^{-1} \frac{\partial}{\partial x^\alpha} \left[g \frac{\partial \mathscr{L}}{\partial(\partial_\alpha \psi)} \frac{\partial \psi}{\partial t} \right] + \left[\frac{\partial \mathscr{L}}{\partial t} \right]_{\psi, \partial_t \psi, \partial_x \psi, \boldsymbol{x}}. \tag{46.61}$$

We now assume spatial coordinates whose representation of the metric tensor is time-independent so that

$$\partial_t g = 0. \tag{46.62}$$

This assumption holds for Eulerian coordinates and for Lagrangian coordinates used in fluid mechanics (with the time derivative taken holding the corresponding spatial coordinates fixed).[7] With this assumption we have

$$\frac{\partial}{\partial t} \left[\frac{\partial \mathscr{L}}{\partial(\partial_t \psi)} \frac{\partial \psi}{\partial t} - \mathscr{L} \right] + \nabla_a \left[\frac{\partial \mathscr{L}}{\partial(\partial_a \psi)} \frac{\partial \psi}{\partial t} \right] = - \left[\frac{\partial \mathscr{L}}{\partial t} \right]_{\psi, \partial_t \psi, \partial_x \psi, \boldsymbol{x}}. \tag{46.63}$$

Following the discrete case discussed in Section 12.10, introduce the *generalized (or canonical) momentum density*, $\mathscr{P}$, and the *Hamiltonian density*, $\mathscr{H}$, along with the energy flux, $\boldsymbol{\mathscr{F}}$,

$$\mathscr{P} \equiv \frac{\partial \mathscr{L}}{\partial(\partial_t \psi)} \quad \text{and} \quad \mathscr{H} = \mathscr{P}\, \partial_t \psi - \mathscr{L} \quad \text{and} \quad \mathscr{F}^a = \frac{\partial \mathscr{L}}{\partial(\partial_a \psi)} \frac{\partial \psi}{\partial t}. \tag{46.64}$$

These definitions bring equation (46.63) to the form of a budget equation for the Hamiltonian density

$$\partial_t \mathscr{H} + \nabla \cdot \boldsymbol{\mathscr{F}} = - \left[\frac{\partial \mathscr{L}}{\partial t} \right]_{\psi, \partial_t \psi, \partial_x \psi, \boldsymbol{x}}. \tag{46.65}$$

Evidently, the Hamiltonian density at a point in space evolves according to the covariant convergence of the flux, $\boldsymbol{\mathscr{F}}$, along with a source term due to any explicit time dependence of the Lagrangian density.

When the Lagrangian density has no explicit time dependence, so that

$$\mathscr{L} = \mathscr{L}(\psi, \partial_t \psi, \partial_a \psi, x^a), \tag{46.66}$$

then the budget equation (46.65) reduces to the *Hamiltonian density continuity equation*

$$\partial_t \mathscr{H} + \nabla \cdot \boldsymbol{\mathscr{F}} = 0. \tag{46.67}$$

This equation is written in the form of a continuum conservation law, with such conservation laws encountered throughout this book.[8] Evidently, for the special case of a time independent spatial domain, and with the flux, $\boldsymbol{\mathscr{F}}$, having zero area integrated normal projection at the domain boundary, we are led to the conservation of the domain integrated Hamiltonian

$$\frac{\mathrm{d}H}{\mathrm{d}t} = 0 \quad \text{with} \quad H = \int_{\mathscr{R}} \mathscr{H}\, \mathrm{d}V = \int_{\mathscr{R}} \mathscr{H}\, g\, \mathrm{d}^3 x, \tag{46.68}$$

where $\mathscr{R}$ is the spatial domain. This result constitutes an expression of Noether's theorem arising from time symmetry.

[7] The metric tensor is generally time dependent when represented using generalized vertical coordinates considered in Part XII of this book. We return to this point in Part XII when formulating a Hamilton's principle with generalized vertical coordinates.

[8] See Section 26.12 for more discussion on such continuum conservation laws.

46.4.2 Stress-energy-momentum tensor

The derivation in Section 46.4.1 can be generalized to yield a budget equation built from elements of the *stress-energy-momentum tensor*. The space-time derivative of the Lagrangian density is given by (again, being careful with partial derivatives as discussed in Section 46.3.1)

$$\frac{\partial \mathscr{L}}{\partial x^\beta} = \frac{\partial \mathscr{L}}{\partial \psi} \frac{\partial \psi}{\partial x^\beta} + \frac{\partial \mathscr{L}}{\partial (\partial_\alpha \psi)} \frac{\partial}{\partial x^\alpha} \frac{\partial \psi}{\partial x^\beta} + \left[\frac{\partial \mathscr{L}}{\partial x^\beta} \right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}}. \tag{46.69}$$

Use of the Euler-Lagrange equation (46.48) leads to

$$\frac{\partial \mathscr{L}}{\partial x^\beta} = g^{-1} \frac{\partial}{\partial x^\alpha} \left[g \frac{\partial \mathscr{L}}{\partial (\partial_\alpha \psi)} \frac{\partial \psi}{\partial x^\beta} \right] + \left[\frac{\partial \mathscr{L}}{\partial x^\beta} \right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}}. \tag{46.70}$$

Now assume the metric determinant is independent of coordinate x^β so that

$$\partial g / \partial x^\beta = 0, \tag{46.71}$$

in which case we have

$$g^{-1} \frac{\partial}{\partial x^\alpha} \left[-g \, \delta^\alpha{}_\beta \, \mathscr{L} + g \frac{\partial \mathscr{L}}{\partial (\partial_\alpha \psi)} \frac{\partial \psi}{\partial x^\beta} \right] = - \left[\frac{\partial \mathscr{L}}{\partial x^\beta} \right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}}. \tag{46.72}$$

Introducing the *stress-energy-momentum tensor*

$$T^\alpha{}_\beta = -\delta^\alpha{}_\beta \, \mathscr{L} + \frac{\partial \mathscr{L}}{\partial (\partial_\alpha \psi)} \frac{\partial \psi}{\partial x^\beta}, \tag{46.73}$$

brings equation (46.72) to the form

$$g^{-1} \, \partial_\alpha (g \, T^\alpha{}_\beta) = - \left[\frac{\partial \mathscr{L}}{\partial x^\beta} \right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}}, \tag{46.74}$$

For each value of β, this equation says that the four-divergence of $T^\alpha{}_\beta$ is determined by the partial derivative of the Lagrangian with respect to x^β. Integrating over the global space domain, and assuming the domain is time-independent, leads to

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathscr{R}} T^0{}_\beta \, g \, \mathrm{d}^3 x = - \int_{\partial \mathscr{R}} T^a{}_\beta \, \hat{n}_a \, \mathrm{d}\mathcal{S} - \int_{\mathscr{R}} \left[\frac{\partial \mathscr{L}}{\partial x^\beta} \right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}} g \, \mathrm{d}^3 x, \tag{46.75}$$

where we used the general coordinate version of the divergence theorem from Section 4.19. If the Lagrangian is not an explicit function of x^β, and we have a vanishing boundary integral of the flux, $T^a{}_\beta$, projected onto the outward normal, then there is a global conserved quantity

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathscr{R}} T^0{}_\beta \, g \, \mathrm{d}^3 x = 0 \quad \Longleftarrow x^\beta \text{ is a cyclic coordinate.} \tag{46.76}$$

In the study of analytical mechanics in Section 12.10.1, we referred to x^β as a *cyclic* coordinate. Cyclic coordinates arise from a symmetry of the physical system, and the coordinates used to represent the system, along the direction defined by the cyclic coordinate. This symmetry then leads to a conservation law, as we just showed. This result represents an example implication of Noether's theorem: any symmetry gives rise to a conservation law. We offer more on Noether's theorem in Section 46.5. Note that when $\beta = 0$, the budget equation (46.74) includes equation

(46.65) for Hamiltonian density

$$\mathcal{H} = T^0{}_0 = -\mathcal{L} + \frac{\partial \mathcal{L}}{\partial(\partial_t \psi)} \frac{\partial \psi}{\partial t} \qquad \text{Hamiltonian density} \tag{46.77a}$$

$$\mathcal{F}^a = T^a{}_0 = \frac{\partial \mathcal{L}}{\partial(\partial_a \psi)} \frac{\partial \psi}{\partial t} \qquad \text{Hamiltonian density flux,} \tag{46.77b}$$

and for $\beta = b > 0$ we define

$$T^0{}_b = \frac{\partial \mathcal{L}}{\partial_t \psi} \frac{\partial \psi}{\partial x^b} \qquad \text{momentum density} \tag{46.78a}$$

$$T^a{}_b = -\mathcal{L}\, \delta^a{}_b + \frac{\partial \mathcal{L}}{\partial_a \psi} \frac{\partial \psi}{\partial x^b} \qquad \text{stress tensor.} \tag{46.78b}$$

46.4.3 An auxiliary functional for deriving conservation laws

Hayes (1970) introduced an alternative method for computing conservation laws, with particular application to the wave-action conservation law (see Section 50.5). In this method we introduce the functional

$$\mathcal{E}(\psi, \Phi) = \frac{\partial \mathcal{L}}{\partial(\partial_\alpha \psi)} \frac{\partial \Phi}{\partial x^\alpha} + \frac{\partial \mathcal{L}}{\partial \psi} \Phi \tag{46.79a}$$

$$= \frac{\partial \mathcal{L}}{\partial(\partial_\alpha \psi)} \frac{\partial \Phi}{\partial x^\alpha} + g^{-1} \frac{\partial}{\partial x^\alpha} \left[g \frac{\partial \mathcal{L}}{\partial(\partial_\alpha \psi)} \right] \Phi \tag{46.79b}$$

$$= g^{-1} \frac{\partial}{\partial x^\alpha} \left[g \frac{\partial \mathcal{L}}{\partial(\partial_\alpha \psi)} \Phi \right] \tag{46.79c}$$

$$= \nabla_\alpha \left[\frac{\partial \mathcal{L}}{\partial(\partial_\alpha \psi)} \Phi \right], \tag{46.79d}$$

where we used the Euler-Lagrange equation (46.48) for ψ, and where $\Phi(\boldsymbol{x}, t)$ is an arbitrary function yet to be specified. As a four-divergence, the functional, $\mathcal{E}$, has a spatial domain integral depending on the boundary conditions.

Separating the space and time derivative terms, and introducing the canonical momentum from equation (46.64), leads to

$$\mathcal{E}(\psi, \Phi) = g^{-1}\, \partial_t (g\, \Phi\, \mathcal{P}) + g^{-1} \frac{\partial}{\partial x^a} \left[g\, \Phi\, \frac{\partial \mathcal{L}}{\partial(\partial_a \psi)} \right]. \tag{46.80}$$

Now we specify $\Phi = \partial\psi/\partial t$ to render

$$\mathcal{E} = g^{-1} \left[\frac{\partial [g\, (\mathcal{H} + \mathcal{L})]}{\partial t} \right]_{\boldsymbol{x}} + \nabla_a \mathcal{F}^a = \left[\frac{\partial \mathcal{L}}{\partial t} \right]_{\boldsymbol{x}} - \left[\frac{\partial \mathcal{L}}{\partial t} \right]_{\psi, \partial_t \psi, \partial_x \psi, \boldsymbol{x}}, \tag{46.81}$$

where $\mathcal{F}^a$ are components to the energy flux (46.64), we introduced the Hamiltonian density, $\mathcal{H}$, also given by equation (46.64), and made use of equation (46.61) to introduce the partial time derivatives. If the metric is independent of time, then the $[\partial \mathcal{L}/\partial t]_{\boldsymbol{x}}$ term cancels on both sides, which then renders the Hamiltonian continuity equation (46.65). We can likewise derive the momentum conservation equations from Section 46.4.2 through setting $\Phi = \partial_a \psi$. In Section 50.5 we introduce yet another choice useful for the study of waves.

46.4.4 Summary of the cyclic coordinate method

A physical system has no dependence on cyclic coordinates, so there is an arbitrariness associated with the value of the coordinate. This arbitrariness then leads to a corresponding differential conservation law in the form of a continuity equation. We here summarize the cyclic coordinate method used in this section to construct conservation laws. Generalizing the discussion of *mechanical equivalence* from Section 46.3.5, we know that a space-time variation has no impact on the physical system if the Lagrangian density changes only by a total divergence

$$\delta\mathcal{L} = \mathcal{L}[\psi(x'), \partial_\alpha\psi(x'), x'] - \mathcal{L}[\psi(x), \partial_\alpha\psi(x), x] = \delta x^\alpha\, \partial_\alpha\mathcal{L}. \tag{46.82}$$

If the Lagrangian has no explicit dependence on any of the space-time coordinates, x^α, then

$$\delta\mathcal{L} = \delta x^\alpha\, \partial_\alpha\mathcal{L} = \delta x^\alpha \left[\frac{\partial\mathcal{L}}{\partial\psi}\,\frac{\partial\psi}{\partial x^\alpha} + \frac{\partial\mathcal{L}}{\partial(\partial_\beta\psi)}\,\frac{\partial}{\partial x^\beta}\frac{\partial\psi}{\partial x^\alpha}\right]. \tag{46.83}$$

Thus far we have not used the Euler-Lagrange equations, so that equation (46.83) results solely due to the absence of an explicit dependence of $\mathcal{L}$ on the space-time coordinates, x^α. An alternative approach to computing the variation is found by writing

$$\delta\mathcal{L} = \frac{\partial\mathcal{L}}{\partial\psi}\,\delta\psi + \frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\,\delta(\partial_\alpha\psi), \tag{46.84}$$

where we again assumed $\mathcal{L}$ has no explicit dependence on any of the space-time coordinates, x^α. We now make use of the Euler-Lagrange equation (46.48) to bring equation (46.84) into the form

$$\delta\mathcal{L} = g^{-1}\,\frac{\partial}{\partial x^\alpha}\left[g\,\frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\,\delta\psi\right] = g^{-1}\,\delta x^\beta\,\frac{\partial}{\partial x^\alpha}\left[g\,\frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\,\frac{\partial\psi}{\partial x^\beta}\right], \tag{46.85}$$

where we made use of the variation of the field and its derivative

$$\delta\psi = \psi(x') - \psi(x) = \delta x^\beta\,\partial_\beta\psi(x) \tag{46.86a}$$

$$\delta(\partial_\alpha\psi) = \partial_\alpha[\psi(x') - \psi(x)] = \delta x^\beta\,\partial_\beta\partial_\alpha\psi(x), \tag{46.86b}$$

and remembered that δx^β is a constant. Setting $\delta\mathcal{L}$ from equation (46.83) equal to $\delta\mathcal{L}$ from equation (46.85) leads to

$$\delta x^\beta\, g^{-1}\,\partial_\alpha(g\,T^\alpha{}_\beta) = 0, \tag{46.87}$$

where we introduced the stress-energy-momentum tensor from equation (46.73)

$$T^\alpha{}_\beta = -\delta^\alpha{}_\beta\,\mathcal{L} + \frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\,\frac{\partial\psi}{\partial x^\beta}. \tag{46.88}$$

We have thus established four conservation laws (one for each value of $\beta = 0, 1, 2, 3$) that correspond to the space-time shift symmetry

$$\nabla_\alpha T^\alpha{}_\beta = g^{-1}\,\partial_\alpha(g\,T^\alpha{}_\beta) = 0. \tag{46.89}$$

There is no conservation law for those coordinates that have an explicit appearance in the Lagrangian. For example, if the Lagrangian has an explicit time dependence, such as when considering astronomical tidal forcing on the ocean, then the total energy of the system (as measured by the globally integrated Hamiltonian density) is not a constant. Instead, the system's energy is affected by the astronomical forces whose dynamics is described by another Lagrangian density that sits outside of the ocean that serves to modify the gravitational force. That is, a non-constant energy is generally a consequence of a physical system being mechanically open.

Similarly, if the Lagrangian is a function of one of the spatial coordinates, then that indicates the absence of spatial symmetry in that direction and so the absence of a global conservation law.

46.5 Noether's theorem and symmetries of the action

In Section 46.4 we derived dynamical conservation laws by identifying cyclic coordinates in the Lagrangian density. Here we further our understanding of how symmetries give rise to conservation laws by introducing a few more concepts and methods. Central to these concepts is the notion of a transformation, and we are only concerned with smooth and continuous transformations rather than discrete. To determine physical implications of a continuous transformation, it is sufficient to examine how the action varies under an infinitesimal transformation, which we refer to as a *variation*. This treatment is convenient since deriving the implications of infinitesimal variations is simpler mathematically than finite transformations. In effect, we only need to work to leading order in a Taylor expansion to deduce the differential conservation laws.

46.5.1 Distinctions beween Noether and Hamilton

Recall from Section 46.2 that we derived the Euler-Lagrange equation of motion by examining how the action changes when confronted with a functional variation of the field, $\psi \to \psi + \delta\psi$, with $\delta\psi$ vanishing along the time boundary. Setting to zero the corresponding variation of the action, $\delta\mathcal{S} = 0$, is the statement of Hamilton's principle that leads to the Euler-Lagrange equation (along with natural spatial boundary conditions) that are satisfied by the physically realized dynamical system. The variations are never physically realized. Hamilton's realized that by probing these unphysical realizations renders a novel perspective (relative to Newton) on the physically realized system.

To deduce conservation laws using Noether's theorem requires a conceptual approach that builds from that used for Hamilton's principle. For Hamilton's principle we postulate that variation of the action vanishes when considering a variation in the field in the interior of the space-time domain. For Noether's theorem we work exclusively with the physical system that satisfies the Euler-Lagrange equations that arise from invoking Hamilton's principle. Noether's theorem then exposes the differential conservation laws arising from symmetries, as probed by variations to the space-time, that leave the physically realized action unchanged (or mechanically equivalent).

46.5.2 Active transformations

There are two complementary perspectives we take when considering a transformation (and its infinitesimal version referred to as a *variation*): the *active transformation* (*active variation*) and the *passive transformation* (*passive variation*). Active transformations arise from moving the physical system through space-time, whereas a passive transformation modifies the space-time coordinates while keeping the physical system unchanged. We here discuss active transformations with Section 46.5.3 considering the passive.[9] Notably, they lead to the same mathematical result, and yet conceptually it can be useful to take one or the other perspective when studying variations to physical systems.

Active transformations and Noether's first theorem

Operationally, an active transformation arises from confronting the action with a variation of the physical fields (to probe *internal symmetries*) and/or a variation of the space-time position

[9] Chapter 3 in *José and Saletan* (1998) provides a thorough discussion of active and passive transformations.

of the system (to probe space-time symmetries). With these variations considered in their active sense, we imagine the physical system to be transformed (e.g., moved or rotated) whereas the space-time coordinate system used to describe the physical system remain unchanged. Moving an experimental apparatus from one side of the laboratory to another is an example active transformation, as is rotating the apparatus by some angle. Those active transformations that leave the action unchanged are symmetries of the physical system that directly lead to differential conservation laws. This connection between active symmetries and conservation laws constitutes *Noether's first theorem.*

Active transformations leave the coordinate system unchanged

As note above, the coordinate system used to describe the physical system is unchanged when performing an active transformation. Instead, an active transformation results in the modification to the space-time position of a point within the physical system

$$x^\alpha \to x'^\alpha = x^\alpha + \delta x^\alpha, \tag{46.90}$$

where δx^α is a tiny coordinate variation so that the space-time point, x', is very close to the point, x. Since the coordinate lines remain fixed under an active transformation, we do not introduce a new set of coordinates, which are typically expressed as $x^{\overline{\alpha}}$ in this book. Instead, we kept the same coordinates, and wrote x^α for the original space-time point and x'^α for the displaced space-time point.

Galilean space-time active transformations and Noether's first theorem

The space-time symmetries we focus on are taken from Galilean space-time, which is relevant for studies of geophysical fluid mechanics.[10] In particular, we consider a uniform space-time translation plus a rigid rotation. For a space and time coordinate translation, the new point has a coordinate position relative to the original point according to the coordinate variation

$$\delta x^\alpha = h^\alpha, \tag{46.91}$$

where h^α is a constant coordinate variation that is scaled by a tiny non-dimensional number to ensure that δx^α is tiny. To investigate spatial rotations we examine the coordinate variation determined by a small spatial rotation of the physical system as given by

$$\delta x^a = \mathcal{R}^a{}_b \, x^b \quad \text{and} \quad \delta x^0 = 0. \tag{46.92}$$

Here we introduced the anti-symmetric rotation matrix

$$\mathcal{R}^a{}_b = \epsilon^a{}_{bc} \, \Omega^c, \tag{46.93}$$

with $\boldsymbol{\Omega} = \widehat{\boldsymbol{\Omega}} \, |\boldsymbol{\Omega}|$ a vector that orients the rotation and with $|\boldsymbol{\Omega}| \ll 1$ a tiny angle. Bringing both the translation and rotation together into a single active variation leads to

$$x'^\alpha = x^\alpha + \delta x^\alpha = x^\alpha + h^\alpha + \mathcal{R}^\alpha{}_\beta \, x^\beta, \tag{46.94}$$

where $\mathcal{R}^\alpha{}_\beta = 0$ if either $\alpha = 0$ or $\beta = 0$.

[10] In other areas of physics, such as electrodynamics and quantum field theory, symmetries are examined within the Lorentzian space-time of special relativity.

Variations to the volume element under an active transformation

The spatial coordinate measure, d^3x, remains unchanged since the coordinate lines are fixed under an active transformation. However, since we are moving the physical system to a new space-time position and/or modifying its spatial orientation, the spatial metric tensor is generally modified. We here assume the metric is time independent, and consider the effects on the volume element under an active transformation. The volume element appearing within the action integral has a variation

$$\delta(g\,\mathrm{d}^3x) = \delta(g)\,\mathrm{d}^3x, \tag{46.95}$$

so we must determine a variation of the square root of the metric tensor determinant, g. It is a bit simpler to work with the determinant of the metric, g^2, which is a function only of the metric tensor elements, g_{ab}, so that

$$\delta g^2 = \frac{\partial g^2}{\partial g_{ab}}\,\delta g_{ab} = g^2\,g^{ab}\,\delta g_{ab}, \tag{46.96}$$

where the second equality follows from equation (4.75) holding for determinants.[11] We thus find that an active transformation leads to the variation of the spatial volume element

$$\delta(g\,\mathrm{d}^3x) = (g\,\mathrm{d}^3x)\,g^{ab}\,\delta g_{ab}/2 \iff \delta(\mathrm{d}V) = \mathrm{d}V\,g^{ab}\,\delta g_{ab}/2. \tag{46.97}$$

To determine the variation of the metric tensor components, we proceed much like in Section 18.8.8 where we determined the material evolution of the Cauchy-Green strain tensor, thus resulting in[12]

$$g^{ab}\,\delta g_{ab} = 2\,g^{ab}\,\nabla_a(\delta x_b) = 2\,\nabla^b(\delta x_b) = 2\,\nabla_a(\delta x^a), \tag{46.98}$$

so that

$$\delta(g\,\mathrm{d}^3x) = (g\,\mathrm{d}^3x)\,\nabla_a(\delta x^a) \iff \delta(\mathrm{d}V) = \mathrm{d}V\,\nabla_a(\delta x^a). \tag{46.99}$$

Evidently, under an active transformation, the relative variation of the volume element is determined by the covariant divergence of the coordinate variation, so that the active transformation is volume perserving if the covariant divergence vanishes

$$\nabla_a(\delta x^a) = 0 \implies \text{volume preserving active transformation.} \tag{46.100}$$

This result corresponds to that found using alternative methods in Chapters 18 and 19 when studying how fluid flow divergence affects the volume of a fluid element (e.g., see equation (19.18)). Indeed, we could have appealed to those earlier results to immediately write equation (46.99). Furthermore, we know that one physical way to alter the volume of a fluid region is to apply pressure work.

Variations to the mass element under an active transformation

In continuum mechanics we generally follow mass conserving parcels of matter. It is thus relevant to determine if the mass changes under an active transformation, in which we investigate

$$\delta(\rho\,\mathrm{d}V) = \rho\,\delta(\mathrm{d}V) + \delta\rho\,\mathrm{d}V \tag{46.101a}$$

$$= \mathrm{d}V\,(\rho\,\nabla_a(\delta x^a) + \delta x^a\,\partial_a\rho) \tag{46.101b}$$

[11] In words, equation (46.96) says that the derivative of the determinant, with respect to one of its elements (here g_{ab}), equals to the determinant times the component of the inverse matrix corresponding to the element (here g^{ab}).

[12] A more general approach makes use of *Lie derivatives* to compute the variation of the metric along the congruence of curves defined by the variation, δx^α. Here, we largely appeal to the intuition of the result (46.99). Section F.3 of *Tromp* (2025a) provides a lucid discussion of Lie derivatives.

$$= \mathrm{d}V\,(g^{-1}\,\rho\,\partial_a(g\,\delta x^a) + \delta x^a\,\partial_a\rho) \tag{46.101c}$$
$$= \mathrm{d}V\,\nabla_a(\rho\,\delta x^a). \tag{46.101d}$$

Evidently, the mass of a region of matter remains unchanged if the covariant divergence of the density weighted variation vanishes

$$\nabla_a(\rho\,\delta x^a) = 0 \Longrightarrow \text{mass preserving active transformation.} \tag{46.102}$$

This sort of transformation requires the volume of the region to reduce while the density increases, and vice versa, thus keeping the mass unchanged. Conversely, a nonzero covariant divergence, $\nabla_a(\rho\,\delta x^a) \neq 0$, is the signal of a modification to the mass of an infinitesimal region.

46.5.3 Passive transformations

A *passive transformation* keeps the physical system untouched while it alters its coordinate representation. For example, the transformation between Cartesian coordinates and spherical coordinates is passive, as is the transformation between Eulerian and Lagrangian coordinates. Passive transformations have been discussed extensively in this book in the context of tensor analysis, whereby tensors are considered objective geometric objects whose coordinate representations leave a tensor unchanged whereas the tensor's representation is changed (see Chapters 1 through 4). Equations written in a manner that remain form invariant under coordinate transformations are said to satisfy *coordinate covariance*. In the context of symmetry principles, if we can find a continuous transformation of the coordinates that leaves the physical action unchanged, then this passive transformation leads, through *Noether's second theorem*, to a local conservation law (sometimes referred to as a *Bianchi identity*). The particle relabeling symmetry detailed in Section 47.7 is an example of a passive transformation applied to fluid flow as represented using Lagrangian kinematics.

An infinitesimal passive transformation is a coordinate variation of the form

$$x^{\overline{\alpha}} = \delta^{\overline{\alpha}}{}_{\alpha}\,(x^\alpha + \delta x^\alpha), \tag{46.103}$$

which should be compared to the active variation in equation (46.90). The transformation matrix arising from the coordinate variation (46.103) is given by

$$\Lambda^{\overline{\alpha}}{}_{\beta} = \partial x^{\overline{\alpha}}/\partial x^\beta = \delta^{\overline{\alpha}}{}_{\alpha}\,[\delta^\alpha{}_\beta + \partial_\beta(\delta x^\alpha)], \tag{46.104}$$

and its Jacobian determinant is, to leading order in variation, given by

$$\det(\Lambda^{\overline{\alpha}}{}_{\beta}) \approx 1 + \partial_\alpha(\delta x^\alpha). \tag{46.105}$$

Consequently, the space-time coordinate measure transforms according to

$$\mathrm{d}^4\overline{x} = \det(\Lambda^{\overline{\alpha}}{}_{\beta})\,\mathrm{d}^4x = [1 + \partial_\alpha(\delta x^\alpha)]\,\mathrm{d}^4x \Longrightarrow \delta(\mathrm{d}^4x) = (\partial_\alpha(\delta x^\alpha)\,\mathrm{d}^4x. \tag{46.106}$$

Assuming the metric tensor is time independent, we find that the spatial volume element transforms as

$$\delta(\mathrm{d}V) = \delta(g\,\mathrm{d}^3x) = [g^{-1}\,\delta x^a\,\partial_a g + \partial_a(\delta x^a)]\,g\,\mathrm{d}^3x = (\nabla_a\delta x^a)\,\mathrm{d}V. \tag{46.107}$$

Hence, a volume conserving passive transformation arises from the same non-divergence condition (46.100) holding for the active transformation. In a similar manner, we find that the mass transforms under a passive transformation just as for the active transformation (46.101d), so that the mass is unchanged if $\nabla_a(\rho\,\delta x^a) = 0$.

46.5.4 Total variation of the field

In Section 46.2.2 we defined the functional variation of the field, $\delta\psi$. The functional variation affects a change just to the function, with the space-time point unchanged

$$\delta\psi(x^\alpha) = \psi'(x^\alpha) - \psi(x^\alpha), \tag{46.108}$$

where each term is evaluated at the same space-time point using the coordinate, x^α. This is the sort of variation considered for Hamilton's principle. Focusing here on active transformations, we find it useful to define the *total variation*, which considers both a functional change as well as a change to the space-time point, so that (dropping the α label on $\psi(x^\alpha)$ for brevity)

$$\begin{aligned}
\Delta\psi(x) &\equiv \psi'(x') - \psi(x) && \text{(46.109a)}\\
&= [\psi'(x') - \psi(x')] + [\psi(x') - \psi(x)] && \text{(46.109b)}\\
&\approx \delta\psi(x') + \delta x^\alpha\, \partial_\alpha\psi(x) && \text{(46.109c)}\\
&\approx \delta\psi(x) + \delta x^\alpha\, \partial_\alpha\psi(x). && \text{(46.109d)}
\end{aligned}$$

For the final equality we set

$$\delta\psi(x') \approx \delta[\psi(x) + \delta x^\alpha\, \partial_\alpha\psi(x)] = \delta\psi(x) + \mathcal{O}(\delta^2), \tag{46.110}$$

with second order terms ignored. Evidently, to first order in δ, the total variation of the field is given by

$$\Delta\psi(x) = (\delta + \delta x^\alpha\, \partial_\alpha)\, \psi(x). \tag{46.111}$$

The first term on the right hand side is the functional variation, $\delta\psi$, and the second term is a transport term that arises from translation and/or rotation of the coordinates, $\delta x^\alpha\, \partial_\alpha\psi$. Note that when we are just probing space-time symmetries, then $\Delta\psi = 0$ so that $\delta\psi = -\delta x^\alpha\, \partial_\alpha\psi$.

46.5.5 Variation of the action under an active transformation

We here consider the variation of the action under an active transformation

$$\delta\mathcal{S} = \mathcal{S}' - \mathcal{S} = \int_{\mathrm{R}} \mathcal{L}[\psi'(x'), \partial_\alpha\psi'(x'), x'^\alpha]\, g'\, \mathrm{d}^4x' - \int_{\mathrm{R}} \mathcal{L}[\psi(x), \partial_\alpha\psi(x), x^\alpha]\, g\, \mathrm{d}^4x. \tag{46.112}$$

Making use of equation (46.107) for the volume element renders, to first order in variation,

$$\delta\mathcal{S} = \int_{\mathrm{R}} [\delta + \nabla_\alpha(\delta x^\alpha)]\, \mathcal{L}[\psi(x), \partial_\alpha\psi(x), x^\alpha]\, g\, \mathrm{d}^4x. \tag{46.113}$$

The chain rule yields the variation

$$\begin{aligned}
\delta\mathcal{L} + \mathcal{L}\, \nabla_\alpha(\delta x^\alpha) &= \frac{\partial\mathcal{L}}{\partial\psi}\, \delta\psi + \frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\, \delta(\partial_\alpha\psi) + \frac{\partial\mathcal{L}}{\partial x^\alpha}\, \delta x^\alpha + g^{-1}\, \mathcal{L}\, \partial_\alpha(\delta x^\alpha) && \text{(46.114a)}\\
&= \frac{\partial\mathcal{L}}{\partial\psi}\, \delta\psi + \frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\, \delta(\partial_\alpha\psi) + \nabla_\alpha(\mathcal{L}\, \delta x^\alpha), && \text{(46.114b)}
\end{aligned}$$

with the Euler-Lagrange equation (46.47) substituted in for $\partial\mathcal{L}/\partial\psi$ rendering the very tidy result

$$\delta\mathcal{L} + \mathcal{L}\, \nabla_\alpha(\delta x^\alpha) = \nabla_\alpha \left[\frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\, \delta\psi + \mathcal{L}\, \delta x^\alpha \right]. \tag{46.115}$$

Now introduce the total variation, $\Delta\psi$, from equation (46.109d), and the stress-energy-momentum tensor from equation (46.73) to find

$$\delta\mathcal{L} + \mathcal{L}\,\nabla_\alpha(\delta x^\alpha) = \nabla_\alpha\left[\frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\,\Delta\psi - T^\alpha{}_\beta\,\delta x^\beta\right], \tag{46.116}$$

which then leads to the variation of the action under and active transformation

$$\delta\mathcal{S} = \int_{\mathrm{R}}[\delta + \nabla_\alpha(\delta x^\alpha)]\,\mathcal{L}\,\mathrm{d}^4x = \int_{\mathrm{R}}\nabla_\alpha J^\alpha\,g\,\mathrm{d}^4x = \int_{\partial\mathrm{R}} J^\alpha\,\hat{n}_\alpha\,\mathrm{d}\mathcal{S}, \tag{46.117}$$

where $\hat{n}_\alpha\,\mathrm{d}\mathcal{S}$ is the oriented area element on the space-time boundary, and we introduced the space-time flux[13]

$$J^\alpha \equiv \frac{\partial\mathcal{L}}{\partial(\partial_\alpha\psi)}\,\Delta\psi - T^\alpha{}_\beta\,\delta x^\beta. \tag{46.118}$$

We conclude that if the total variation, $\Delta\psi$, reflects a symmetry of the physical system, then the action must have a zero variation, in which case we have the local conservation law (continuity equation)

$$\nabla_\alpha J^\alpha = 0, \tag{46.119}$$

where J^α is given by equation (46.118). This result constitutes Noether's first theorem.

46.5.6 Angular momentum and space isotropy

In Section 46.4 we considered the space-time symmetry associated with the absence of dependence on an origin, and we assumed the total field variation vanishes,

$$\Delta\psi = \psi'(x') - \psi(x) = 0 \Longrightarrow \delta\psi = -\delta x^\alpha\,\partial_\alpha\psi. \tag{46.120}$$

In this case the conservation law reduces to a statement about the stress-energy-momentum tensor (see Section 46.4.2). Namely, if there is no special space or time origin, then linear momentum and mechanical energy are conserved. Here we display the angular momentum conservation law arising from the absence of a dependence on the orientation of the spatial coordinates. We also consider $\Delta\psi = 0$, but specify the spatial variation according to the rotation (46.93) so that the active variation is

$$\delta x^0 = 0 \quad \text{and} \quad \delta x^a = \mathcal{R}^a{}_b\,x^b = \epsilon^a{}_{bc}\,\Omega^c\,x^b, \tag{46.121}$$

where Ω^c are the components to a spatial vector whose magnitude, $|\boldsymbol{\Omega}|$, is small. The space-time flux, J^α, from equation (46.118) thus has the components

$$-J^\beta = T^\beta{}_\alpha\,\delta x^\alpha = T^\beta{}_a\,\epsilon^a{}_{bc}\,\Omega^c\,x^b. \tag{46.122}$$

At this point we assume Cartesian coordinates, so that the covariant derivative is a partial derivative, and the four-convergence of the flux is

$$-\partial_\beta J^\beta = \partial_\beta T^\beta{}_a\,\epsilon^a{}_{bc}\,\Omega^c\,x^b + T^\beta{}_a\,\epsilon^a{}_{\beta c}\,\Omega^c. \tag{46.123}$$

If the physical system has no concern for the origin of space, then we know from Section 46.4.4 that $\partial_\beta T^\beta{}_a = 0$ for each of the $a = 1, 2, 3$ spatial coordinates. If the physical system likewise has no concern for the orientation of space (i.e., it is spatially isotropic), then we must have rotational symmetry. For that property to manifest in a conservation law requires the

[13] In the quantum field theory literature, J^α is referred to as a *current*, in analog to an electrical current. Here we refer to it as a flux to correspond to the nomenclature in flud mechanics.

stress-energy-momentum tensor to be symmetric so that

$$T^{\beta}{}_{a}\,\epsilon^{a}{}_{\beta c} = 0 \Longleftrightarrow T^{\beta}{}_{a} = T_{a}{}^{\beta} = (T^{\beta}{}_{a})^{\mathrm{T}}. \tag{46.124}$$

We encountered this same condition in Section 25.4 arising from similar considerations.[14]

46.5.7 Comments

The space-time symmetries considered in this section and Section 46.4 are generally broken in realistic physical systems. For example, in Chapter 47 we study the motion of a perfect fluid moving around a rotating and gravitating planet, with spatial symmetry reduced to axial symmetry around the rotation axis (assuming a smooth planet). When considering motion of a geophysical fluid on a realistic planet with non-smooth boundaries (i.e., mountains, land-sea boundaries), we have no spatial symmetry and so no momentum conservation. Even so, by examining the properties of closed fluid systems moving in spaces of particular symmetry, we reveal the conservation laws forming the foundation for the physical theory. Doing so provides a valuable conceptual and operational baseline for then examining how processes and boundary conditions break symmetry.

We have thus far only considered space-time symmetries, so that we assumed the total field variation vanishes,

$$\Delta\psi = \psi'(x') - \psi(x) = 0 \Longrightarrow \delta\psi = -\delta x^{\alpha}\,\partial_{\alpha}\psi, \tag{46.125}$$

which means that the field is a scalar. But the formalism developed in this section also allows for probing symmetries in the space of fields, in which $\Delta\psi \neq 0$. If the action remains unchanged under a $\Delta\psi \neq 0$, then that reflects an *internal symmetry* that is not associated with space and time symmetries. Such internal symmetries are the basis for *gauge theories* of particle physics, as discussed in *Quigg* (1983), *Ryder* (1985), *Ramond* (1990), and many other texts.

46.5.8 Further study

The treatment of Noether's theorem in this section was inspired by Chapter 2 of *Quigg* (1983), Section E.1 of *Wald* (1984), Section 3.2 of *Ryder* (1985), Section 1.5 of *Ramond* (1990), and Section 2.6 of *Tromp* (2025a).

[14] There are some Lagrangian densities that do not produce a symmetric stress-energy-momentum tensor when evaluating equation (46.73). However, we can add a term, $\partial_{\lambda}F^{\lambda\alpha}{}_{\beta}$, to $T^{\alpha}{}_{\beta}$ without affecting the conservation law (46.89), so long as $F^{\lambda\alpha}{}_{\beta} = -F^{\alpha\lambda}{}_{\beta}$. This gauge degree of freedom allows us to always work with a symmetrized stress-energy-momentum tensor. See Section E.1 of *Wald* (1984) or Section 3.2 of *Ryder* (1985) for more discussion on this point, which is of particular relevance to general relativity.

Chapter 47

HAMILTON'S PRINCIPLE FOR PERFECT FLUIDS

In this chapter we derive the momentum equation (Euler equation) for a single-component perfect fluid using *Hamilton's variational principle* rather than Newton's laws. To do so, we couple the field theory of Chapter 46 with the Lagrangian kinematics of the motion field, $\boldsymbol{\varphi}(\boldsymbol{a}, T)$, thus deriving a field theory for $\boldsymbol{\varphi}$ in Lagrangian space-time. Hamilton's principle is concerned with conservative physical systems, such as a single component perfect fluid in a static gravitational field with each fluid parcel only experiencing reversible processes (i.e., no diffusion, friction, or conduction), which means that the fluid is contained within a materially and thermally closed domain. The fluid parcels feel conservative body forces from gravity, as well as, in a rotating terrestrial frame, the planetary Coriolis and planetary centrifugal forces are present. Interactions between the parcels are limited to mechanical contact forces from pressure, with pressure forces performing work on fluid parcels by modifying their volume (for non-Boussinesq fluids).

READER'S GUIDE FOR THIS CHAPTER

Mathematical elements of variational principles are presented in Chapter 10, along with a suite of examples. We make use of arbitrary material coordinates ($\boldsymbol{a}$-space), thus requiring the general tensor analysis as detailed in Chapters 3 and 4. We use general Eulerian ($\boldsymbol{x}$-space) coordinates up to the point of deriving the variation of the internal energy, at which point we assume Cartesian Eulerian coordinates. We make full use of the Lagrangian kinematics from Chapters 17, 18, and 19, and require a rudimentary understanding of thermodynamics as considered in Part IV. Development and use of Hamilton's principle are provided in Chapters 12 and 15 for discrete systems and in Chapter 46 for continuous fields.

Salmon (1988) is the canonical reference for Hamilton's principle in fluid mechanics (see also *Müller* (1995), chapter 7 in *Salmon* (1998) and *Badin and Crisciani* (2018)). *Soper* (2008) provides a treatment based on the Lorentz space-time of special relativity, though with some non-relativistic limiting cases to connect with the Galilean space-time of terrestrial motion. *Jezierski and Kijowski* (1990) and *Sieniutycz* (1994) target a unification of thermodynamics with continuum mechanics using variational methods. Our presentation makes use of general tensor notation for working in Lagrangian space-time, and offers a particular emphasis on the motion field, $\boldsymbol{\varphi}(\boldsymbol{a}, T)$, following from the treatment of continuum mechanics in Chapters 1 and 2 of *Tromp* (2025a).

47.1 Loose threads

- Referential flow and deviations from that flow
- Clean up notation and presenation, particularly in the particle relabeling Section 47.7.
- It would be nice not to need the Cartesian Eulerian assumption to compute the variation of the internal energy. Is there a simple way to generalize?

47.2 Motion and velocity

We here summarize salient points concerning the motion field studied in Chapters 17 and 18.

47.2.1 The motion field, flow map, deformation matrix, and velocity

We conceive of fluid flow as the smooth movement through space of a matter continuum, with this movement measured by the three-component *motion field*, $\boldsymbol{\varphi}$. Mathematically, the motion field provides the *flow map* that takes the matter continuum from its reference state (e.g., some spatial configuration at time $T = t_{\mathsf{R}}$) to the state at time $T > t_{\mathsf{R}}$. Assuming $\boldsymbol{x}$ is the position of a point in Euclidean space, the motion field provides a point transformation,

$$\boldsymbol{x} = \boldsymbol{\varphi}(\boldsymbol{a}, T) \quad \text{and} \quad t = T, \tag{47.1}$$

between the Eulerian ($\boldsymbol{x}$-position space) reference frame to the Lagrangian ($\boldsymbol{a}$-material space) reference frame. The motion field enables a 1-to-1 and invertible mapping (a *diffeomorphism*) between Eulerian and Lagrangian space-time. Transformation of tensors between Eulerian and Lagrangian space is provided by the *deformation matrix* (Section 18.4), with components to this matrix given by the partial derivatives

$$F^i{}_I = \frac{\partial \varphi^i}{\partial a^I} = \partial_I \varphi^i, \tag{47.2}$$

where lowercase indices are reserved for Eulerian space coordinates, x^i, and upper case for Lagrangian coordinates, a^I. The components to the inverse of the deformation matrix are written $F^I{}_i$, so that

$$F^i{}_J \, F^J{}_j = \delta^i{}_j \quad \text{and} \quad F^I{}_i F^i{}_J = \delta^I{}_J. \tag{47.3}$$

We also have use for the determinant of the transformation matrix (the Jacobian of transformation), which is written

$$\det(F^i{}_I) = \frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}} \tag{47.4}$$

Evaluating the motion field for a particular value for the material coordinate, $\boldsymbol{a}$, and allowing time to progress, provides the space-time trajectory, $\boldsymbol{X}$, of the fluid particle labeled by $\boldsymbol{a}$

$$\boldsymbol{X}(\boldsymbol{a}, T) = \boldsymbol{\varphi}(\boldsymbol{a}, T). \tag{47.5}$$

The velocity of a material fluid particle is determined by the material time derivative of the motion

$$\boldsymbol{v}^{\mathsf{L}}(\boldsymbol{a}, T) = \partial_T \boldsymbol{\varphi}(\boldsymbol{a}, T) \Longleftrightarrow (v^{\mathsf{L}})^i = \partial_T \varphi^i. \tag{47.6}$$

We include the L superscript to emphasize that $\boldsymbol{v}^{\mathsf{L}}$ is sampled on a fluid particle and so it is a function of $(\boldsymbol{a}, T)$. Consequently, we commonly refer to $\boldsymbol{v}^{\mathsf{L}}$ as the "Lagrangian velocity". Even so, we see below (equation (47.8)) another candidate for this same name that is more precise from a tensor analysis perspective. The velocity $\boldsymbol{v}^{\mathsf{L}}$ has a dual Eulerian velocity, $\boldsymbol{v}(\boldsymbol{x}, t)$, that is equal to the Lagrangian velocity for the fluid particle that passes through $\boldsymbol{x}$ at time t

$$\boldsymbol{v}(\boldsymbol{x}, t) = \boldsymbol{v}^{\mathsf{L}}(\boldsymbol{a}, T) \quad \text{for } \boldsymbol{x} = \boldsymbol{\varphi}(\boldsymbol{a}, T) \text{ and } t = T. \tag{47.7}$$

This self-evident relation is reflected in all other properties of the continuum.

The Lagrangian velocity, $\boldsymbol{v}^{\mathsf{L}}(\boldsymbol{a}, T)$, and Eulerian velocity, $\boldsymbol{v}(\boldsymbol{x}, t)$, are generally distinct functions of their respective coordinates, thus prompting use of the distinct symbols, $\boldsymbol{v}^{\mathsf{L}}$ versus $\boldsymbol{v}$. For example, we might choose one of the material coordinates to be the specific entropy since for a perfect fluid the specific entropy is constant on fluid particles. For this case it is clear that $\boldsymbol{v}^{\mathsf{L}}(\boldsymbol{a}, T)$ and $\boldsymbol{v}(\boldsymbol{x}, t)$ are distinct mathematical functions. Even so, as tensors, both $\boldsymbol{v}^{\mathsf{L}}$ and $\boldsymbol{v}$ carry Eulerian space-time indices, $(v^{\mathsf{L}})^i$ and v^i. A representation of the velocity that carries Lagrangian space-time indices is realized through use of the inverse transformation matrix,

$$v^I = F^I{}_i \, (v^{\mathsf{L}})^i. \tag{47.8}$$

We encounter this *tensorially Lagrangian* representation of the velocity when studying the fluid particle relabeling symmetry in Section 47.7.

47.2.2 Including planetary rotation

As detailed in Section 13.6, the inertial frame representation for the velocity of a fluid particle moving on the rotating planet is given by

$$\boldsymbol{v}_{\text{inertial}} = \boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}, \tag{47.9}$$

where $\boldsymbol{v}$ is the particle velocity relative to the rotating planet, $\boldsymbol{\Omega}$ is the time-independent angular velocity of the rotating planet, $\boldsymbol{x}$ is the position vector of the particle relative to an origin, and $\boldsymbol{\Omega} \times \boldsymbol{x}$ is the velocity arising from the rigid body rotation of the planetary reference frame. The corresponding Eulerian velocity field for fluid motion on a rotating planet is thus given by

$$\boldsymbol{v}_{\text{inertial}}(\boldsymbol{x}, t) = \boldsymbol{v}(\boldsymbol{x}, t) + \boldsymbol{\Omega} \times \boldsymbol{x}, \tag{47.10}$$

and the Lagrangian velocity is

$$\boldsymbol{v}^{\text{L}}_{\text{inertial}}(\boldsymbol{a}, T) = \partial_T \boldsymbol{\varphi}(\boldsymbol{a}, T) + \boldsymbol{\Omega} \times \boldsymbol{\varphi}(\boldsymbol{a}, T). \tag{47.11}$$

As studied in Chapter 13, planetary rotation gives rise to the planetary Coriolis acceleration and planetary centrifugal acceleration when describing motion in the rotating terrestrial reference frame.

47.3 Mass, density, and specific volume

We here recall elements of fluid kinematics related to the mass and volume of infinitesimal material fluid parcels, and for finite sized spatial material domains denoted by $\mathcal{R}$. Since the region is material, it is time independent when expressed in terms of Lagrangian coordinates, $\mathcal{R}(\boldsymbol{a})$, whereas it is time dependent when expressed in terms of Eulerian coordinates, $\mathcal{R}(t)$.

47.3.1 Expressions for mass over a material region

From the discussion of mass conservation in Section 19.4.4, the mass over a material region can be written in either the Eulerian or Lagrangian integral expressions

$$M = \int_{\mathcal{R}(t)} \rho(\boldsymbol{x}, t)\, g^{\text{E}}(\boldsymbol{x})\, \mathrm{d}^3 x = \int_{\mathcal{R}(\boldsymbol{a})} \rho^{\text{L}}(\boldsymbol{a}, T)\, g^{\text{L}}(\boldsymbol{a}, T)\, \mathrm{d}^3 a. \tag{47.12}$$

The first expression for mass makes use of arbitrary Eulerian coordinates and thus represents the volume integral of mass density over the moving material region. The square root of the metric determinant, $g^{\text{E}}(\boldsymbol{x})$, is independent of Eulerian time, by construction of Eulerian coordinates, whereas the Lagrangian analog, $g^{\text{L}}(\boldsymbol{a}, T)$, is generally a function of the Lagrangian time. The second expression for mass in equation (47.12) makes use of Lagrangian coordinates, with the material coordinate element given by

$$\mathrm{d}^3 a = \mathrm{d}a^1\, \mathrm{d}a^2\, \mathrm{d}a^3, \tag{47.13}$$

which has physical dimensions determined by those of the material coordinates, (a^1, a^2, a^3). The products $g^{\text{E}}(\boldsymbol{x})\, \mathrm{d}^3 x$ and $g^{\text{L}}(\boldsymbol{a}, T)\, \mathrm{d}^3 a$ have dimensions of volume (L^3), so that they are expressions for the same invariant volume element studied in Section 18.7

$$\mathrm{d}V = g^{\text{E}}(\boldsymbol{x})\, \mathrm{d}^3 x = g^{\text{L}}(\boldsymbol{a}, T)\, \mathrm{d}^3 a. \tag{47.14}$$

This equation then leads to the identity (see equation (18.45)) for the Jacobian of transformation between Eulerian and Lagrangian coordinates

$$\frac{\partial \boldsymbol{x}}{\partial \boldsymbol{a}} = \frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}} = \det(F^i{}_I) = \frac{g^{\mathsf{L}}}{g^{\mathsf{E}}}. \tag{47.15}$$

47.3.2 Constant mass fluid parcels

From Section 19.4.2, the mass of a fluid parcel remains constant when its center of mass follows a fluid particle trajectory, so that

$$\mathrm{d}M = \rho^{\mathsf{L}}(\boldsymbol{a}, T)\, g^{\mathsf{L}}(\boldsymbol{a}, T)\, \mathrm{d}^3 a \tag{47.16}$$

is a material constant. The element, $\mathrm{d}^3 a$, measures the material coordinate volume and it is fixed within material space. Hence, mass conservation for material parcels means that $\rho^{\mathsf{L}}(\boldsymbol{a}, T)\, g^{\mathsf{L}}(\boldsymbol{a}, T)$ is independent of material time,

$$\partial_T [\rho^{\mathsf{L}}(\boldsymbol{a}, T)\, g^{\mathsf{L}}(\boldsymbol{a}, T)] = 0. \tag{47.17}$$

We can thus set its value at any convenient time instance, which we choose as the $T = t_{\mathsf{R}}$ conditions and write

$$\mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\, \mathring{g}^{\mathsf{L}}(\boldsymbol{a}) = \rho^{\mathsf{L}}(\boldsymbol{a}, T = t_{\mathsf{R}})\, g^{\mathsf{L}}(\boldsymbol{a}, T = t_{\mathsf{R}}) = \rho^{\mathsf{L}}(\boldsymbol{a}, T)\, g^{\mathsf{L}}(\boldsymbol{a}, T), \tag{47.18}$$

with the corresponding mass of the material region

$$M = \int_{\mathscr{R}(\boldsymbol{a})} \mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\, \mathring{g}^{\mathsf{L}}(\boldsymbol{a})\, \mathrm{d}^3 a. \tag{47.19}$$

Evidently, $\mathring{\rho}^{\mathsf{L}}$, $\mathring{g}^{\mathsf{L}}$, and $\mathrm{d}^3 a$ are each set at the initial time, and thus are unaltered when considering the variation of trajectories when varying the action for Hamilton's principle in Section 47.5. They can be changed, however, when varying coordinates as per the discussion of particle relabeling in Section 47.7.

47.3.3 Cartesian Eulerian for when varying internal energy

We need the specific volume for working with the internal energy in Section 47.4.4, which from equations (47.18) and (47.15) yield

$$\nu_{\mathsf{s}}^{\mathsf{L}}(\boldsymbol{a}, T) = 1/\rho^{\mathsf{L}}(\boldsymbol{a}, T) = \frac{g^{\mathsf{L}}(\boldsymbol{a}, T)}{\mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\, \mathring{g}^{\mathsf{L}}(\boldsymbol{a})} = \frac{g^{\mathsf{E}}(\boldsymbol{x})}{\mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\, \mathring{g}^{\mathsf{L}}(\boldsymbol{a})} \frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial \boldsymbol{a}}. \tag{47.20}$$

When varying the internal energy, we find it convenient to choose Cartesian coordinates for describing Eulerian $\boldsymbol{x}$-space. For this case we have $g^{\mathsf{E}} = 1$ so that

$$\nu_{\mathsf{s}}^{\mathsf{L}}(\boldsymbol{a}, T) = \frac{1}{\mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\, \mathring{g}^{\mathsf{L}}(\boldsymbol{a})} \frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial \boldsymbol{a}} \Longleftarrow \text{Cartesian Eulerian coordinates with } g^{\mathsf{E}}(\boldsymbol{x}) = 1 \tag{47.21a}$$

$$\frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial \boldsymbol{a}} = g^{\mathsf{L}}(\boldsymbol{a}, T) \Longleftarrow \text{Cartesian Eulerian coordinates with } g^{\mathsf{E}}(\boldsymbol{x}) = 1. \tag{47.21b}$$

47.3.4 Concerning mass-labeling/unimodular coordinates

The material time independence of $\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}$ motivate some authors to assume the material coordinates are *unimodular*, which is also sometimes called *mass-labeling*. In this case, one sets

$$\mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\,\mathring{g}^{\mathsf{L}}(\boldsymbol{a}) = 1 \quad \text{mass-labeling (or unimodular) } \boldsymbol{a}\text{-space coordinates.} \tag{47.22}$$

These coordinates are used by, for example, *Salmon* (1988), *Jezierski and Kijowski* (1990), *Müller* (1995), and *Salmon* (1998). Furthermore, for $\boldsymbol{a}$-space mass-labeling coordinates and $\boldsymbol{x}$-space Cartesian coordinates, the specific volume from equation (47.21a) reduces to the Jacobian

$$\nu^{\mathsf{L}}_{\mathsf{s}}(\boldsymbol{a}, T) = \frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial \boldsymbol{a}} \quad \text{Cartesian } \boldsymbol{x}\text{-space and mass-labeling } \boldsymbol{a}\text{-space.} \tag{47.23}$$

Although rather convenient for many purposes, we do not choose mass-labeling $\boldsymbol{a}$-space coordinates for the following reasons. First, doing so makes it awkward to use dimensional analysis as a check on the equations.[1] Second, it hides the fundamentally non-Cartesian nature of material space coordinates by hiding $\mathring{g}^{\mathsf{L}}$. This concern is mild, since one can readily assume the initial coordinate layout sets $\mathring{g}^{\mathsf{L}} = 1$. Third, we wish to maintain a connection between the perfect fluid field theory of this chapter to the continuum mechanics of *Tromp* (2025a), as well as the scalar field theory from Chapter 46, with unimodular coordinates obscuring that connection since it absorbs the density factor into the coordinates.

47.4 Energetics and entropy

In this section we develop equations for domain integrated kinetic energy, gravitational potential energy, and internal energy for a perfect fluid in a thermally and materially closed domain, $\mathcal{R}$, and as viewed from a rotating planetary reference frame.

47.4.1 Kinetic energy

Building on the two expressions for mass in equation (47.12) leads to the corresponding expressions for the kinetic energy within the material domain, first written using Cartesian Eulerian coordinates

$$E_{\text{KE}} = \frac{1}{2}\int_{\mathcal{R}(t)} (\boldsymbol{v} + \boldsymbol{\Omega}\times\boldsymbol{x})\cdot(\boldsymbol{v} + \boldsymbol{\Omega}\times\boldsymbol{x})\,\rho\, g^{\mathsf{E}}\,\mathrm{d}^3x, \tag{47.24}$$

and with the equivalent expression using arbitrary Lagrangian coordinates

$$E_{\text{KE}} = \frac{1}{2}\int_{\mathcal{R}(\boldsymbol{a})} (\partial_T\boldsymbol{\varphi} + \boldsymbol{\Omega}\times\boldsymbol{\varphi})\cdot(\partial_T\boldsymbol{\varphi} + \boldsymbol{\Omega}\times\boldsymbol{\varphi})\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a. \tag{47.25}$$

47.4.2 Gravitational potential energy

The gravitational potential, Φ_{e}, accounts for the potential energy per mass from the earth's gravity field (Section 13.10.2). As such, its domain integral measures the total gravitational potential energy of the fluid

$$E_{\text{GPE}} = \int_{\mathcal{R}(t)} \Phi_{\mathsf{e}}(\boldsymbol{x}, t)\,\rho\, g^{\mathsf{E}}\,\mathrm{d}^3x = \int_{\mathcal{R}(\boldsymbol{a})} \Phi_{\mathsf{e}}(\boldsymbol{\varphi}, T)\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a. \tag{47.26}$$

[1] Throughout this book we exploit the dimensional nature of physical quantities to enable the use of dimensional analysis in debugging mathematical equations. Unimodular or mass-labeling coordinates make that process difficult.

For most applications in this book, we assume the gravitational potential is time independent, which is required for a mechanically closed system as assumed here.[2]

47.4.3 Specific entropy is materially constant

As seen in Section 26.6.8, the specific entropy is materially constant for a perfect fluid. Consequently, each fluid parcel has a specific entropy equal to the value at its initial condition

$$\mathcal{S}(\boldsymbol{a}, T) = \mathcal{S}(\boldsymbol{a}, T = t_{\mathsf{A}}) = \mathring{\mathcal{S}}(\boldsymbol{a}). \tag{47.27}$$

With the density satisfying equation (47.18), the constancy of specific entropy means that the entropy content of a fluid parcel can be written

$$\mathcal{S}(\boldsymbol{a}, T)\, \rho^{\mathsf{L}}(\boldsymbol{a}, T)\, g^{\mathsf{L}}(\boldsymbol{a}, T)\, \mathrm{d}^3 a = \mathring{\mathcal{S}}(\boldsymbol{a})\, \mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\, \mathring{g}^{\mathsf{L}}(\boldsymbol{a})\, \mathrm{d}^3 a. \tag{47.28}$$

When applying Hamilton's principle, the fluid particle trajectories are unaltered at their temporal boundaries. Hence, any field that is independent of time, such as the the specific entropy, $\mathring{\mathcal{S}}(\boldsymbol{a})$, has zero variation under changes to the fluid particle trajectories. However, when varying the material coordinates, such as when studying particle relabeling in Section 47.7, then we find a nonzero $\delta\mathring{\mathcal{S}}(\boldsymbol{a})$.

47.4.4 Internal energy

As encountered in the study of thermodynamics in Part IV of this book, as well as the thermohydrodynamics in Chapter 26, *internal energy* is that portion of the total energy for a region of the continuum that is not accounted for by the mechanical energy of macroscopic motion (kinetic energy) nor the mechanical energy arising from being in an external force field (gravitational potential energy). The fundamental thermodynamic relation (22.62) for a single component fluid renders the natural functional dependency of specific internal energy (dimensions of energy per mass, which equals squared length per squared time)

$$\mathcal{I} = \mathcal{I}(\mathcal{S}, \nu_{\mathsf{s}}) = \mathcal{I}(\mathring{\mathcal{S}}(\boldsymbol{a}), \nu_{\mathsf{s}}), \tag{47.29}$$

with $\mathcal{S}$ the specific entropy and $\nu_{\mathsf{s}} = 1/\rho$ the specific volume. We also made use of results from Section 47.4.3 by setting $\mathcal{S}(\boldsymbol{a}, T) = \mathring{\mathcal{S}}(\boldsymbol{a})$ since the specific entropy remains materially constant. For the specific volume we make use of equation (47.21a), which assumes the Eulerian coordinates are Cartesian. In turn, it is just the Jacobian, $\partial\boldsymbol{\varphi}(\boldsymbol{a}, T)/\partial\boldsymbol{a}$, portion of the specific volume that is affected by variations in the trajectories. Bringing the above results together renders the integrated internal energy for the material fluid domain

$$E_{\mathsf{IE}} = \int_{\mathscr{R}(t)} \mathcal{I}(\boldsymbol{x}, t)\, \rho(\boldsymbol{x}, t)\, g^{\mathsf{E}}(\boldsymbol{x})\, \mathrm{d}^3 x = \int_{\mathscr{R}(\boldsymbol{a})} \mathcal{I}[\mathring{\mathcal{S}}(\boldsymbol{a}), \nu_{\mathsf{s}}^{\mathsf{L}}(\boldsymbol{a}, T)]\, \mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\, \mathring{g}^{\mathsf{L}}(\boldsymbol{a})\, \mathrm{d}^3 a. \tag{47.30}$$

47.5 Variation of the action and Euler-Lagrange equations

The action for the perfect fluid is given by the space-time integral of the kinetic energy minus the gravitational energy and minus the internal energy[3]

$$\mathsf{S}^{\backslash} = \int_{t_{\mathcal{A}}}^{t_{\mathcal{B}}} \int_{\mathscr{R}(\boldsymbol{a})} \left[\tfrac{1}{2}\, (\partial_T \boldsymbol{\varphi} + \boldsymbol{\Omega} \times \boldsymbol{\varphi}) \cdot (\partial_T \boldsymbol{\varphi} + \boldsymbol{\Omega} \times \boldsymbol{\varphi}) - \Phi_{\mathsf{e}} - \mathcal{I}\right] \mathring{\rho}^{\mathsf{L}}\, \mathring{g}^{\mathsf{L}}\, \mathrm{d}^3 a\, \mathrm{d}T. \tag{47.31}$$

[2] One exception concerns the study of a space-time dependent gravitational acceleration in Chapter 34.

[3] We write $\mathcal{S}^{\text{action}}$ for the action to distinguish it from the specific entropy, $\mathcal{S}$. Also note that the lower time bound for the action, t_{A}, is not necessarily the same as the time bound, t_{R}, used to define the base manifold.

We here focus on the action written in terms of Lagrangian coordinates rather than the Eulerian coordinates, with functional dependencies given by

$$\boldsymbol{\varphi}(\boldsymbol{a},T) \quad \text{and} \quad \Phi(\boldsymbol{\varphi}(\boldsymbol{a},T),T) \quad \text{and} \quad \mathcal{I}(\mathring{\mathcal{S}}(\boldsymbol{a}),\nu_{\mathsf{s}}^{\mathsf{L}}(\boldsymbol{a},T)). \tag{47.32}$$

Making use of Lagrangian kinematics provides a direct link between Hamilton's principle applied here to continuum matter and Hamilton's principle applied to the discrete particle systems in Chapters 12 and 15. Namely, we here examine a variation of the continuum motion field (i.e., trajectories) that vanishes at the temporal bounds (just like we did for particle mechanics)

$$\boldsymbol{\varphi}(\boldsymbol{a},T) \to \boldsymbol{\varphi}(\boldsymbol{a},T) + \delta\boldsymbol{\varphi}(\boldsymbol{a},T) \quad \text{with} \quad \delta\boldsymbol{\varphi}(\boldsymbol{a},t_{\mathsf{A}}) = \delta\boldsymbol{\varphi}(\boldsymbol{a},t_{\mathsf{B}}) = 0. \tag{47.33}$$

Hamilton's principle says that when varying the action by varying the motion, the physically realized motion extremizes the action so that

$$\text{Hamilton's principle} \implies \delta\mathcal{S}^{\text{action}} = 0. \tag{47.34}$$

Extremizing the action leads to the *Euler-Lagrange* equation satisfied by the Lagrangian. As derived in this section, the Euler-Lagrange equation is a partial differential equation satisfied by each component, φ^i, of the motion field. That is, we derive a Lagrangian space-time field theory for the three component motion field, $\boldsymbol{\varphi}(\boldsymbol{a},T)$.

We now summarize the operational task at hand to apply Hamilton's principle to the action (47.31). First, apply the variation operator, δ, to vary the motion field and compute the variation of the action. The variation operator acts solely on the motion field via equation (47.33). Hence, δ has no affect on space and time points, which means the variation operator commutes with $(\boldsymbol{a},T)$ and its differential operators.[4] We organize the varied integrand to isolate $\delta\varphi^i$, and we do so via integrating by parts and setting $\delta\varphi^i$ to zero on the temporal boundaries. Invoking Hamilton's principle renders the Euler-Lagrange differential equations and natural boundary conditions on the material space boundaries.

47.5.1 General expression for the Euler-Lagrange equation

We here directly follow the procedure used for the scalar field theory in Section 46.2. Here we have three fields for the three components to the motion field, with these fields living in Lagrangian space time. Following the approach in Section 46.2, we find it convenient to write the action (47.31) in the form

$$\mathcal{S}^{\text{action}} = \int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}} \int_{\mathcal{R}(\boldsymbol{a})} \mathscr{L}\, \mathring{g}^{\mathsf{L}}\, \mathrm{d}^3a\, \mathrm{d}T \implies \delta\mathcal{S}^{\text{action}} = \int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}} \int_{\mathcal{R}(\boldsymbol{a})} (\delta\mathscr{L})\, \mathring{g}^{\mathsf{L}}\, \mathrm{d}^3a\, \mathrm{d}T, \tag{47.35}$$

where we defined the *Lagrangian density* (dimensions of energy per material coordinate volume, d^3a)

$$\mathscr{L}[\boldsymbol{\varphi},\partial_T\boldsymbol{\varphi},\partial_I\boldsymbol{\varphi},\boldsymbol{a},T] = \mathring{\rho}^{\mathsf{L}}\left[\tfrac{1}{2}\left(\partial_T\boldsymbol{\varphi} + \boldsymbol{\Omega}\times\boldsymbol{\varphi}\right)\cdot\left(\partial_T\boldsymbol{\varphi} + \boldsymbol{\Omega}\times\boldsymbol{\varphi}\right) - \Phi_{\mathsf{e}} - \mathcal{I}(\mathring{\mathcal{S}},\nu_{\mathsf{s}}^{\mathsf{L}})\right]. \tag{47.36}$$

Note that varying the trajectories has no affect on $\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a$ since these terms are fixed at $T = t_{\mathsf{R}}$, and the same holds for $\mathring{\rho}^{\mathsf{L}}$.

[4] This commutation property holds when applying δ to the action for Hamilton's principle. However, as seen in Section 46.5, δ affects a variation of the space-time points when developing conservation laws using the methods of Noether's theorem. We emphasized these distinct variations in Section 46.5.1.

Use of the chain rule renders a variation of the Lagrangian density[5]

$$\mathring{g}^{\mathsf{L}}\,\delta\mathscr{L} = \mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial\varphi^i}\,\delta\varphi^i + \mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_T\varphi^i)}\,\delta(\partial_T\varphi^i) + \mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\,\delta(\partial_I\varphi^i), \tag{47.37}$$

where the summation convention is followed for the motion field indices, so that repeated indices are summed over their range, $i = 1, 2, 3$. Since the variation operator, δ, commutes with $(\boldsymbol{a}, T)$ derivative operators, we can write the equivalent expression

$$\mathring{g}^{\mathsf{L}}\,\delta\mathscr{L} = \mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial\varphi^i}\,\delta\varphi^i + \mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_T\varphi^i)}\,\partial_T(\delta\varphi^i) + \mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\,\partial_I(\delta\varphi^i). \tag{47.38}$$

We now bring the time and space derivative operators onto the full term and subtract the remainder. Doing so for the time derivative leads to

$$\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_T\varphi^i)}\,\frac{\partial(\delta\varphi^i)}{\partial T} = \frac{\partial}{\partial T}\left[\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_T\varphi^i)}\,\delta\varphi^i\right] - \frac{\partial}{\partial T}\left[\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_T\varphi^i)}\right]\delta\varphi^i. \tag{47.39}$$

When plugging this term into the action variation (47.35), the total time derivative on the right hand side vanishes since we assume $\delta\varphi^i$ vanishes at temporal boundaries as per equation (47.33). Similar manipulations lead to the material space derivative expression

$$\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\,\frac{\partial(\delta\varphi^i)}{\partial a^I} = \frac{\partial}{\partial a^I}\left[\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\,\delta\varphi^i\right] - \frac{\partial}{\partial a^I}\left[\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\right]\delta\varphi^i. \tag{47.40}$$

When plugging this term into the action variation (47.35), the total space derivative term vanishes if we assume the following natural boundary condition

$$\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\,\hat{n}_I = 0 \quad \text{at material boundaries,} \tag{47.41}$$

where $\hat{n}_I$ are components to the outward normal one-form along the material boundary. We encountered a similar version of the natural boundary conditions in Section 46.3.3 when studying Hamilton's principle for a scalar field.

Bringing terms together leads to the variation of the action (47.35) taking the form

$$\delta\mathcal{S}^{\mathsf{action}} = \int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}}\int_{\mathscr{R}(\boldsymbol{a})}\left(\frac{\partial\mathscr{L}}{\partial\varphi^i} - \frac{1}{\mathring{g}^{\mathsf{L}}}\,\frac{\partial}{\partial T}\left[\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_T\varphi^i)}\right] - \frac{1}{\mathring{g}^{\mathsf{L}}}\,\frac{\partial}{\partial a^I}\left[\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\right]\right)\delta\varphi^i\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T, \tag{47.42}$$

Variation of the motion, $\delta\varphi^i$, is arbitrary everywhere except at the temporal boundaries. Setting the variation of the action to zero as per Hamilton's principle requires the Lagrangian density to satisfy the Euler-Lagrange equation as well as the natural kinematic boundary condition, with both satisfied by each of the $i = 1, 2, 3$ components of the motion field

$$\frac{\partial\mathscr{L}}{\partial\varphi^i} = \frac{1}{\mathring{g}^{\mathsf{L}}}\,\frac{\partial}{\partial T}\left[\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_T\varphi^i)}\right] + \frac{1}{\mathring{g}^{\mathsf{L}}}\,\frac{\partial}{\partial a^I}\left[\mathring{g}^{\mathsf{L}}\,\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\right] \tag{47.43a}$$

$$\frac{\partial\mathscr{L}}{\partial(\partial_I\varphi^i)}\,\hat{n}_I = 0 \quad \text{at material boundaries.} \tag{47.43b}$$

The presence of $1/\mathring{g}^{\mathsf{L}}(\boldsymbol{a})$ on the outside of the derivatives, and $\mathring{g}^{\mathsf{L}}(\boldsymbol{a})$ on the inside, allows us to identify a covariant divergence (based on $\mathring{g}^{\mathsf{L}}$) on the right hand side of the Euler-Lagrange equation (47.43a). The $\mathring{g}^{\mathsf{L}}(\boldsymbol{a})$ term cancels for the time derivative term, since $\mathring{g}^{\mathsf{L}}(\boldsymbol{a})$ is independent

[5] When integrating by parts, we must keep track of the metric tensor determinant, $\mathring{g}^{\mathsf{L}}$, since it is a function of the material coordinates. We follow the approach in Section 46.3.2.

of material time. However, it is an essential piece for the space derivative term given that Lagrangian space coordinates are not Cartesian.

The Euler-Lagrange equation (47.43a) and boundary conditions (47.43b) are identical to those derived in Section 46.2.4 when studying scalar field theory. The only operational difference is that here we have $i = 1, 2, 3$ fields whereas there we had a single scalar field. We also note that here the field theory is in Lagrangian space-time, $(\boldsymbol{a}, T)$, rather than Eulerian space-time, $(\boldsymbol{x}, t)$, and the dynamical field is the motion field, $\boldsymbol{\varphi}(\boldsymbol{a}, T)$. As noted earlier in this section, the Lagrangian kinematic formulation of Hamilton's principle is directly connected to the discrete particle mechanics treatment of Hamilton's principle. In particular, by tracking the fluid motion field (i.e., fluid particle trajectories), we are afforded a straitghtforward means to constrain variations to vanish at the temporal boundaries. An Eulerian formulation does not follow fluid particles and requires Lagrange multipliers to constrain material coordinates to remain constant along trajectories (see Section 3 of *Salmon* (1988) for details).

In the remainder of this section we derive the Euler-Lagrange equations for the perfect fluid using the Lagrangian density (47.36). Rather than compute partial derivatives of the Lagrangian density as per the Euler-Lagrange equation (47.43a), we find it slightly more pedagogical to work directly from the action variation in equation (47.35).

47.5.2 Variation of the kinetic energy

Starting with the kinetic energy appearing in the Lagrangian density (47.36), we have

$$\tfrac{1}{2}\,(\partial_T \boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})\cdot(\partial_T \boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi}) = \tfrac{1}{2}\,\partial_T\boldsymbol{\varphi}\cdot\partial_T\boldsymbol{\varphi}+\partial_T\boldsymbol{\varphi}\cdot(\boldsymbol{\Omega}\times\boldsymbol{\varphi})+\tfrac{1}{2}\,(\boldsymbol{\Omega}\cdot\boldsymbol{\Omega})\,(\boldsymbol{\varphi}\cdot\boldsymbol{\varphi})-\tfrac{1}{2}\,(\boldsymbol{\Omega}\cdot\boldsymbol{\varphi})^2, \tag{47.44}$$

which made use of the identity (1.73c). Use of the chain rule leads to the variation

$$\begin{aligned}&\delta\,[\tfrac{1}{2}\,(\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})\cdot(\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})]\\ &\qquad = \partial_T(\delta\boldsymbol{\varphi})\cdot(\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})+\partial_T\boldsymbol{\varphi}\cdot(\boldsymbol{\Omega}\times\delta\boldsymbol{\varphi})+\Omega^2\,\boldsymbol{\varphi}\cdot\delta\boldsymbol{\varphi}-(\boldsymbol{\Omega}\cdot\boldsymbol{\varphi})\,(\boldsymbol{\Omega}\cdot\delta\boldsymbol{\varphi}),\end{aligned} \tag{47.45}$$

which can be rearranged to

$$\begin{aligned}&\delta\,[\tfrac{1}{2}\,(\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})\cdot(\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})]\\ &\qquad = \partial_T[(\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})\cdot\delta\boldsymbol{\varphi}]-[\partial_{TT}\boldsymbol{\varphi}+2\,\boldsymbol{\Omega}\times\partial_T\boldsymbol{\varphi}-\Omega^2\,\boldsymbol{\varphi}+(\boldsymbol{\Omega}\cdot\boldsymbol{\varphi})\,\boldsymbol{\Omega}]\cdot\delta\boldsymbol{\varphi}.\end{aligned} \tag{47.46}$$

Since the variations, $\delta\boldsymbol{\varphi}$, vanish at the initial and final times, as per equation (47.33), the total time derivative in equation (47.46) drops out when integrated over time as part of the action. We are thus left with the kinetic energy variation

$$\begin{aligned}&\tfrac{1}{2}\,\delta\int_{t_\mathsf{A}}^{t_\mathsf{B}}\int_{\mathcal{R}(\boldsymbol{a})}(\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})\cdot(\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times\boldsymbol{\varphi})\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T\\ &\qquad = -\int_{t_\mathsf{A}}^{t_\mathsf{B}}\int_{\mathcal{R}(\boldsymbol{a})}[\partial_{TT}\boldsymbol{\varphi}+2\,\boldsymbol{\Omega}\times\partial_T\boldsymbol{\varphi}+\boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\boldsymbol{\varphi})]\cdot\delta\boldsymbol{\varphi}\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T,\end{aligned} \tag{47.47}$$

where we used equation (1.71g) to write

$$\boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\boldsymbol{\varphi}) = -\Omega^2\,\boldsymbol{\varphi}+(\boldsymbol{\Omega}\cdot\boldsymbol{\varphi})\,\boldsymbol{\Omega}. \tag{47.48}$$

Variation of the kinetic energy in equation (47.47) reveals the material acceleration, $\partial_{TT}\boldsymbol{\varphi}$, plus contributions from the planetary Coriolis and planetary centrifugal accelerations.

47.5.3 Variation of the gravitational potential energy

The gravitational potential energy (47.26) depends on the motion field, so that its variation follows from the chain rule

$$\delta\Phi_{\mathsf{e}} = \frac{\partial\Phi_{\mathsf{e}}}{\partial\varphi^i}\,\delta\varphi^i. \tag{47.49}$$

We thus have variation of the gravitational potential energy

$$\delta\int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}}\int_{\mathcal{R}(\boldsymbol{a})}\Phi_{\mathsf{e}}\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T = \int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}}\int_{\mathcal{R}(\boldsymbol{a})}\frac{\partial\Phi_{\mathsf{e}}}{\partial\varphi^i}\,\delta\varphi^i\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T. \tag{47.50}$$

47.5.4 Variation of the specific internal energy

As seen by equation (47.29), the specific internal energy is a function of the specific entropy and specific volume

$$\mathcal{I} = \mathcal{I}[\mathring{\mathcal{S}}(\boldsymbol{a}), \nu_{\mathsf{s}}^{\mathsf{L}}(\boldsymbol{a}, T)], \tag{47.51}$$

where $\mathring{\mathcal{S}}(\boldsymbol{a})$ is the specific entropy set by the initial conditions, and $\nu_{\mathsf{s}}^{\mathsf{L}}(\boldsymbol{a}, T)$ is related to the Jacobian of transformation between the Eulerian and Lagrangian coordinates, as given by equation (47.21a). It is through dependence on $\nu_{\mathsf{s}}^{\mathsf{L}}(\boldsymbol{a}, T)$ that the specific internal energy is a function of $\partial_I\varphi^i$, so that variation of the internal energy portion of the action is

$$\int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}}\int_{\mathcal{R}(\boldsymbol{a})}\delta\mathcal{I}\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T = \int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}}\int_{\mathcal{R}(\boldsymbol{a})} -p^{\mathsf{L}}\,(\delta\nu_{\mathsf{s}}^{\mathsf{L}})\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T, \tag{47.52}$$

where $p^{\mathsf{L}}(\boldsymbol{a}, T)$ is the pressure written as a function of the Lagrangian space-time coordinates, and it is related to the specific internal energy via the thermodynamic identity (22.64)

$$\delta\mathcal{I} = \left[\frac{\partial\mathcal{I}}{\partial\nu_{\mathsf{s}}}\right]_{\mathcal{S}}\delta\nu_{\mathsf{s}}^{\mathsf{L}} = -p^{\mathsf{L}}\,\delta\nu_{\mathsf{s}}^{\mathsf{L}}. \tag{47.53}$$

From equation (47.21a) we have

$$\nu_{\mathsf{s}}^{\mathsf{L}}\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}} = \partial\boldsymbol{\varphi}/\partial\boldsymbol{a} = \det(F^i{}_I) \tag{47.54}$$

so that

$$\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\delta\nu_{\mathsf{s}}^{\mathsf{L}} = \delta(\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\nu_{\mathsf{s}}^{\mathsf{L}}) = \delta(\partial\boldsymbol{\varphi}/\partial\boldsymbol{a}) = \delta\det(F^i{}_I). \tag{47.55}$$

We thus need to determine how the Jacobian varies when changing trajectories.

Since the Jacobian is only a function of the deformation matrix elements, $F^i{}_I = \partial_I\varphi^i$, the chain rule gives

$$\delta\det(F^i{}_I) = \frac{\partial\det(F^i{}_I)}{\partial F^l{}_L}\,\delta F^l{}_L = \frac{\partial\det(F^i{}_I)}{\partial F^l{}_L}\,\partial_L(\delta\varphi^l), \tag{47.56}$$

where the second equality noted that the trajectory variation operator commutes with the partial derivative operator. We now make use of the identity (4.75) to write the derivative of the Jacobian with respect to an element of the transformation matrix

$$\delta[\det(F^i{}_I)] = \det(F^i{}_I)\,F^L{}_l\,\partial_L(\delta\varphi^l) = \det(F^i{}_I)\,\partial_l(\delta\varphi^l), \tag{47.57}$$

where the final equality transformed from a Lagrangian partial derivative to an Eulerian partial derivative via

$$F^L{}_l\,\partial_L = \partial_l. \tag{47.58}$$

At the end of this chapter, we present an alternative derivation of equation (47.57) that does not make use of the identity (4.75). That derivation is far more tedious than the one presented

here, and yet it is presented for those wishing further exposure to index gymnastics.

Equation (47.57) says that the relative variation of the Jacobian determinant is directly determined by the $\boldsymbol{x}$-space divergence of the motion field's variation. This result is analogous to equation (18.148) that expresses the material time evolution of the Jacobian. We can understand its kinematical content by observing that an $\boldsymbol{x}$-space divergence of $\delta\boldsymbol{\varphi}$ leads to a variation in the $\boldsymbol{x}$-space volume of a fluid parcel, and thus to a variation in the Jacobian. Making use of the variation (47.57) in equation (47.52) yields the internal energy variation

$$\int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}} \int_{\mathscr{R}(\boldsymbol{a})} \delta\mathcal{I}\, \mathring{\rho}^{\mathsf{L}}\, \mathring{g}^{\mathsf{L}}\, \mathrm{d}^3a\, \mathrm{d}T = -\int_{t_{\mathsf{A}}}^{t_{\mathsf{B}}} \int_{\mathscr{R}(\boldsymbol{a})} p^{\mathsf{L}}\, \frac{\partial(\delta\varphi^i)}{\partial x^i}\, \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}}\, \mathrm{d}^3a\, \mathrm{d}T. \tag{47.59}$$

47.5.5 How the pressure gradient appears

We now present two related methods for for how the pressure gradient appears within the integral (47.59).

Method I

Making use of the relations in Section 47.3 allows us to convert the right hand side of equation (47.59) to Cartesian Eulerian coordinates so that

$$\int_{\mathscr{R}(\boldsymbol{a})} p^{\mathsf{L}}\, \frac{\partial(\delta\varphi^i)}{\partial x^i}\, \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}}\, \mathrm{d}^3a = \int_{\mathscr{R}(t)} p\, \frac{\partial(\delta\varphi^i)}{\partial x^i}\, \mathrm{d}^3x, \tag{47.60}$$

with integration by parts yielding

$$\int_{\mathscr{R}(t)} p\, \frac{\partial(\delta\varphi^i)}{\partial x^i}\, \mathrm{d}^3x = \int_{\mathscr{R}(t)} \frac{\partial(p\,\delta\varphi^i)}{\partial x^i}\, \mathrm{d}^3x - \int_{\mathscr{R}(t)} \frac{\partial p}{\partial x^i}\, \delta\varphi^i\, \mathrm{d}^3x. \tag{47.61}$$

Assuming either zero mechanical forcing at the boundaries (e.g., free boundary with $p = 0$), or assuming $\delta\boldsymbol{\varphi}\cdot\hat{\boldsymbol{n}} = 0$ at the boundaries (i.e., rigid solid-earth boundary), allows us to drop the boundary term. We are thus left with the internal energy variation

$$\int_{\mathscr{R}(\boldsymbol{a})} \delta\mathcal{I}\, \mathring{\rho}^{\mathsf{L}}\, \mathring{g}^{\mathsf{L}}\, \mathrm{d}^3a = \int_{\mathscr{R}(t)} \frac{1}{\rho}\frac{\partial p}{\partial x^i}\, \delta\varphi^i\, \rho\, \mathrm{d}^3x = \int_{\mathscr{R}(\boldsymbol{a})} \frac{1}{\rho^{\mathsf{L}}}\frac{\partial p^{\mathsf{L}}}{\partial\varphi^i}\, \delta\varphi^i\, \mathring{\rho}^{\mathsf{L}}\, \mathring{g}^{\mathsf{L}}\, \mathrm{d}^3a, \tag{47.62}$$

with the final equality converting back to Lagrangian coordinates and making use of equation (47.18) for the density, $\mathring{\rho}^{\mathsf{L}}\, \mathring{g}^{\mathsf{L}}$.

Method II

Rather than convert to Cartesian Eulerian coordinates at the point done in equation (47.60), we write

$$p^{\mathsf{L}}\, \frac{\partial(\delta\varphi^i)}{\partial x^i}\, \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}} = p^{\mathsf{L}}\, \frac{\partial(\delta\varphi^i)}{\partial a^I}\, \frac{\partial a^I}{\partial x^i}\, \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}} = \frac{\partial}{\partial a^I}\left[p^{\mathsf{L}}\, \delta\varphi^i\, \frac{\partial a^I}{\partial x^i}\, \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}}\right] - \delta\varphi^i\, \frac{\partial}{\partial a^I}\left[p^{\mathsf{L}}\, \frac{\partial a^I}{\partial x^i}\, \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}}\right], \tag{47.63}$$

where the first equality made use of the chain rule and the second equality used the product rule. For the final term note that

$$\frac{\partial}{\partial a^I}\left[F^I{}_i\, \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}}\right] = \frac{\partial}{\partial a^I}\left[\frac{\partial a^I}{\partial x^i}\, \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}}\right] = 0, \tag{47.64}$$

which follows from the determinant identity (4.73) in which

$$\frac{\partial a^I}{\partial x^i}\,\frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}} = \frac{1}{2}\,\epsilon^{IJK}\,\epsilon_{ijk}\,\frac{\partial \varphi^j}{\partial a^J}\,\frac{\partial \varphi^k}{\partial a^K}, \tag{47.65}$$

thus yielding equation (47.64) through anti-symmetry of ϵ^{IJK} and symmetry of the second partial derivatives ∂_{IK} and ∂_{IJ}. These results then bring equation (47.63) into the form

$$p^{\text{L}}\,\frac{\partial(\delta\varphi^i)}{\partial x^i}\,\frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}} = \frac{\partial}{\partial a^I}\left[p^{\text{L}}\,\delta\varphi^i\,\frac{\partial a^I}{\partial x^i}\,\frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}}\right] - \delta\varphi^i\,\frac{\partial p^{\text{L}}}{\partial a^I}\,\frac{\partial a^I}{\partial x^i}\,\frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}}. \tag{47.66}$$

When integrated over the material domain, the ∂_I divergence term drops out due to the material boundary conditions. We are thus led to

$$\int_{\mathcal{R}(\boldsymbol{a})} \delta\mathcal{I}\,\mathring{\rho}^{\text{L}}\,\mathring{g}^{\text{L}}\,\mathrm{d}^3a = \int_{\mathcal{R}(\boldsymbol{a})} \frac{\partial p^{\text{L}}}{\partial a^I}\,\frac{\partial a^I}{\partial \varphi^i}\,\frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}}\,\delta\varphi^i\,\mathrm{d}^3a \quad \text{equations (47.59) and (47.66)} \tag{47.67a}$$

$$= \int_{\mathcal{R}(\boldsymbol{a})} \frac{1}{\rho^{\text{L}}}\,\frac{\partial p^{\text{L}}}{\partial x^i}\,\delta\varphi^i\,\mathring{\rho}^{\text{L}}\,\mathring{g}^{\text{L}}\,\mathrm{d}^3a \quad \text{chain rule and equation (47.54)}, \tag{47.67b}$$

which agrees with equation (47.62).

47.5.6 The perfect fluid Euler-Lagrange equation

Making use of the variation of the kinetic energy portion of the action (47.47), the gravitational potential energy portion (47.50), and the internal energy portion (47.62), leads us to the variation of the action under variations in the trajectories that are fixed at the temporal boundaries

$$\delta\mathsf{S}^{\text{action}} = -\int_{t_{\text{A}}}^{t_{\text{B}}}\int_{\mathcal{R}(\boldsymbol{a})}\left[\partial_{TT}\boldsymbol{\varphi} + 2\,\boldsymbol{\Omega}\times\partial_T\boldsymbol{\varphi} + \boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\boldsymbol{\varphi}) + \frac{\partial\Phi_{\text{e}}}{\partial\boldsymbol{\varphi}} + \frac{1}{\rho^{\text{L}}}\frac{\partial p^{\text{L}}}{\partial\boldsymbol{\varphi}}\right]\cdot\delta\boldsymbol{\varphi}\,\mathring{\rho}^{\text{L}}\,\mathring{g}^{\text{L}}\,\mathrm{d}^3a\,\mathrm{d}T. \tag{47.68}$$

Hamilton's principle says that the physically realized action is stationary under variations to the motion, with that motion fixed at the temporal boundaries. Invoking this principle then leads to the Euler-Lagrange equation

$$\partial_{TT}\boldsymbol{\varphi} + 2\,\boldsymbol{\Omega}\times\partial_T\boldsymbol{\varphi} = -\frac{1}{\rho^{\text{L}}}\frac{\partial p^{\text{L}}}{\partial\boldsymbol{\varphi}} - \frac{\partial\Phi}{\partial\boldsymbol{\varphi}} \iff \partial_T\boldsymbol{v}^{\text{L}} + 2\,\boldsymbol{\Omega}\times\boldsymbol{v}^{\text{L}} = -\frac{1}{\rho^{\text{L}}}\frac{\partial p^{\text{L}}}{\partial\boldsymbol{\varphi}} - \frac{\partial\Phi}{\partial\boldsymbol{\varphi}}, \tag{47.69}$$

where we introduced the velocity in the rotating reference frame

$$\boldsymbol{v}^{\text{L}} = \partial_T\boldsymbol{\varphi}, \tag{47.70}$$

and the geopotential

$$\Phi = \Phi_{\text{e}} - (\boldsymbol{\Omega}\times\boldsymbol{\varphi})^2/2, \tag{47.71}$$

which is the sum of the gravitational potential and the planetary centrifugal potential (see Section 13.10.4).

The Euler-Lagrange equation (47.69) is written with spatial derivatives taken with respect to the motion field, $\boldsymbol{\varphi}$, and time derivatives with respect to Lagrangian time, T. Transforming this equation to an Eulerian perspective leads to the rotating perfect fluid Euler equation derived in Section 24.2.4. It is particularly notable that this transformation is rather trivial, simply requiring a swap of the motion field for an Eulerian position, $\boldsymbol{x}$. This transformation to the Eulerian reference frame removes all remnants of the motion field from the equations. A key reason for this rather simple result arises from the form of the internal energy, whose dependence on trajectories arises only via the Jacobian, $\partial\boldsymbol{\varphi}/\partial\boldsymbol{a}$. Different forms of the internal energy arise

in other areas of continuum mechanics, thus making the translation to an Eulerian perspective less convenient than found here for the perfect fluid.

47.5.7 Comments

Based on our experience with particle mechanics in Chapters 12 and 15, we expected to realize the same equations using Hamilton's principle as those found through Newton's laws. Even so, it is a remarkable result given the fundamentally distinct conceptual and operational perspectives. This agreement offers further confidence that the theoretical construct of continuum mechanics has a robust foundation beyond that afforded by the work of Euler and Cauchy in their applications of Newton's laws to the continuum.

47.6 Perfect fluid Hamiltonian continuity equation

As a means to illustrate the connection between symmetry and conservation within the perfect fluid, note that the Lagrangian density in equation (47.36) has no explicit dependence on time

$$\left[\frac{\partial \mathscr{L}}{\partial T}\right]_{\varphi^i,\partial_T\varphi^i,\partial_I\varphi^i,a^I} = 0, \tag{47.72}$$

where the subscripts on the derivative denote those terms that are held fixed in computing the partial derivative. According to the discussion of Noether's theorem in Sections 46.4 and 46.5, we know that the Hamiltonian density, $\mathscr{H}$, satisfies the Lagrangian space-time continuity equation (46.67)

$$\partial_T \mathscr{H} + \mathring{\nabla}_I \mathscr{F}^I = 0, \tag{47.73}$$

where

$$\mathring{\nabla}_I \mathscr{F}^I = (1/\mathring{g}^{\text{L}})\, \partial_I (\mathring{g}^{\text{L}}\, \mathscr{F}^I) \tag{47.74}$$

is the covariant divergence as defined by the geometry of the reference manifold at $T = t_{\text{R}}$.

The canonical momentum, Hamiltonian density, and the energy flux are given in equation (46.64) for the scalar field are generalized to the φ^i field theory of a perfect fluid

$$\mathscr{P}_i \equiv \frac{\partial \mathscr{L}}{\partial(\partial_T \varphi^i)} \quad \text{and} \quad \mathscr{H} = \mathscr{P}_i\, \partial_T \varphi^i - \mathscr{L} \quad \text{and} \quad \mathscr{F}^I = \frac{\partial \mathscr{L}}{\partial(\partial_I \varphi^i)}\, \frac{\partial \varphi^i}{\partial T}, \tag{47.75}$$

where the implied summation over the i index is the only distinction from the scalar field in considered in Section 46.4. We now determine an expression of this continuity equation for the perfect fluid. Doing so provides useful experience with the variety of tensor manipulations arising from this formalism.

47.6.1 Canonical momentum and Hamiltonian density

Making use of the perfect fluid Lagrangian density (47.36) renders the canonical momentum

$$\mathscr{P}_j = \mathring{\rho}^{\text{L}}\, [\partial_T \varphi^i + (\boldsymbol{\Omega} \times \boldsymbol{\varphi})^i]\, \delta_{ij}, \tag{47.76}$$

so that the Hamiltonian density is

$$\mathscr{H} = \mathring{\rho}^{\mathcal{L}}\, [\partial_T \varphi^i + (\boldsymbol{\Omega} \times \boldsymbol{\varphi})^i]\, \delta_{ij}\, \partial_T \varphi^j - \mathscr{L} = \mathring{\rho}^{\mathcal{L}}\, (\partial_T \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi}/2 + \Phi + \mathcal{I}), \tag{47.77}$$

where we introduced the geopotential from equation (47.71). Evidently, the Hamiltonian density is the sum of the kinetic energy plus geopotential plus internal energy.

47.6.2 Energy flux and the covariant flux divergence

For the energy flux we need the derivative of the Lagrangian density with respect to the deformation matrix components, $F^i{}_I = \partial_I \varphi^i$, which appear only within the specific internal energy

$$\begin{aligned}
\frac{\partial \mathcal{L}}{\partial F^i{}_I} &= -\mathring{\rho}^{\text{L}} \frac{\partial \mathcal{I}}{\partial \nu_{\text{s}}} \frac{\partial \nu_{\text{s}}}{\partial F^i{}_I} && \text{chain rule with } \mathcal{I} = \mathcal{I}(\mathring{\mathcal{S}}, \nu_{\text{s}}) \text{ and } \mathring{\mathcal{S}} = \mathring{\mathcal{S}}(\boldsymbol{a}) && \text{(47.78a)}\\
&= \mathring{\rho}^{\text{L}}\, p^{\text{L}} \frac{\partial \nu_{\text{s}}}{\partial F^i{}_I} && \text{thermodynamic identity (47.53)} && \text{(47.78b)}\\
&= \frac{p^{\text{L}}}{\mathring{g}^{\text{L}}} \frac{\partial (\mathring{\rho}^{\text{L}}\, \mathring{g}^{\text{L}}\, \nu_{\text{s}}))}{\partial F^i{}_I} && \partial(\mathring{\rho}^{\text{L}}\, \mathring{g}^{\text{L}})/\partial F^i{}_I = 0 && \text{(47.78c)}\\
&= \frac{p^{\text{L}}}{\mathring{g}^{\text{L}}} \frac{\partial \det(F^i{}_I)}{\partial F^i{}_I} && \mathring{\rho}^{\text{L}}\, \mathring{g}^{\text{L}}\, \nu_{\text{s}} = \det(F^i{}_I) \text{ from equation (47.54)} && \text{(47.78d)}\\
&= (p^{\text{L}}/\mathring{g}^{\text{L}})\, \det(F^i{}_I)\, F^I{}_i && \text{determinant identity (4.75),} && \text{(47.78e)}
\end{aligned}$$

which yields the energy flux

$$\mathcal{F}^I = \frac{\partial \mathcal{L}}{\partial F^i{}_I} \frac{\partial \varphi^i}{\partial T} = (p^{\text{L}}/\mathring{g}^{\text{L}})\, \det(F^i{}_I)\, F^I{}_i\, \partial_T \varphi^i. \tag{47.79}$$

Making use of equation (4.134) for the covariant divergence, we have the $\boldsymbol{a}$-space covariant flux divergence

$$\mathring{\nabla}_I [\det(F^i{}_I)\, F^I{}_i\, (p^{\text{L}}/\mathring{g}^{\text{L}})\, \partial_T \varphi^i] = (1/\mathring{g}^{\text{L}})\, \partial_I [\det(F^i{}_I)\, F^I{}_i\, p^{\text{L}}\, \partial_T \varphi^i]. \tag{47.80}$$

The identity (47.64) says that $\partial_I [\det(F^i{}_I)\, F^I{}_i] = 0$, so that the covariant flux divergence is

$$\mathring{\nabla}_I [\det(F^i{}_I)\, F^I{}_i\, (p^{\text{L}}/\mathring{g}^{\text{L}})\, \partial_T \varphi^i] = (1/\mathring{g}^{\text{L}})\, \det(F^i{}_I)\, F^I{}_i\, \partial_I (p^{\text{L}}\, \partial_T \varphi^i). \tag{47.81}$$

Finally, we convert the $\boldsymbol{a}$-space derivative to an $\boldsymbol{x}$-space derivative using the deformation matrix

$$F^I{}_i\, \partial_I = \partial_i, \tag{47.82}$$

so that

$$\mathring{\nabla}_I [\det(F^i{}_I)\, F^I{}_i\, (p^{\text{L}}/\mathring{g}^{\text{L}})\, \partial_T \varphi^i] = (1/\mathring{g}^{\text{L}})\, \det(F^i{}_I)\, \partial_i (p^{\text{L}}\, \partial_T \varphi^i) = \mathring{\rho}^{\text{L}}\, \nu_{\text{s}}^{\text{L}}\, \partial_i (p^{\text{L}}\, \partial_T \varphi^i), \tag{47.83}$$

where the second equality used the determinant identity (47.21a) that says $\det(F^i{}_I) = \nu_{\text{s}}^{\text{L}}\, \mathring{\rho}^{\text{L}}\, \mathring{g}^{\text{L}}$.

47.6.3 Lagrangian and Eulerian Hamiltonian continuity equations

Bringing the pieces together leads the Hamiltonian density continuity equation (47.73) taking the following perfect fluid expression

$$\partial_T \left[\mathring{\rho}^{\mathcal{L}}\, (\partial_T \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi}/2 + \Phi + \mathcal{I})\right] + \mathring{\rho}^{\text{L}}\, \nu_{\text{s}}^{\text{L}}\, \partial_i (p^{\text{L}}\, \partial_T \varphi^i) = 0. \tag{47.84}$$

The density $\mathring{\rho}^{\text{L}} = \mathring{\rho}^{\text{L}}(\boldsymbol{a})$ cancels from both terms, so that

$$\rho^{\mathcal{L}}\, \partial_T (\partial_T \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi}/2 + \Phi + \mathcal{I}) + \partial_i (p^{\text{L}}\, \partial_T \varphi^i) = 0, \tag{47.85}$$

which has a corresponding Eulerian expression[6]

$$\rho \frac{\mathrm{D}(\boldsymbol{v}\cdot\boldsymbol{v}/2+\Phi+\mathcal{I})}{\mathrm{D}t} + \nabla\cdot(p\,\boldsymbol{v}) = 0. \tag{47.86}$$

This equation accords with the perfect fluid total energy budget equation (26.91) derived using very different methods. This agreement lends further confidence to our use of Hamilton's principle with Lagrangian kinematics for the perfect fluid.

47.7 Particle relabeling symmetry and potential vorticity

In this chapter we are working with a Lagrangian space-time field theory for the perfect fluid motion field, $\boldsymbol{\varphi}(\boldsymbol{a}, T)$. Hence, as just seen in Section 47.6 for the Hamiltonian density, space-time symmetries leading to conservation laws in the perfect fluid arise from variations in the position within the Lagrangian space-time. For the usual momentum conservation laws corresponding to spatial symmetry, we take the material coordinates equal to the Cartesian coordinates at some reference time. For a perfect geophysical fluid in motion around a rotating and gravitating planet, we no longer have the full symmetry of empty space considered in Chapter 46. Instead, we have axial symmetry around the planetary rotational axis. As a result, perfect planetary fluid motion only realizes differential conservation laws for axial angular momentum conservation along with the energy conservation of Section 47.6.

For momentum conservation, the *active transformation* (Section 46.5.2) is realized by shifting the material spatial position of each fluid particle by the same constant, and for energy each fluid particle has its material time shifted by the same constant. Here we examine whether there is a nontrivial *passive transformation* that leaves the action invariant. Recall from our discussion in Section 46.5.3, a passive transformation only affects a variation to the coordinate representation of a physical system. *Noether's second theorem* says that each passive symmetry gives rise to a *Bianchi identity* that corresponds to a local conservation law. Here we consider *particle relabeling* symmetry and the corresponding local (in $\boldsymbol{a}$-space) conservation of potential vorticity. Our presentation is inspired by *Salmon* (1988), *Müller* (1995), *Padhye and Morrison* (1996), and Chapter 7 of *Salmon* (1998).

47.7.1 Passive transformation of Lagrangian space coordinates

Consider a time dependent coordinate transformation of the material spatial coordinates

$$\boldsymbol{a}' = \boldsymbol{a}'(\boldsymbol{a}, T), \tag{47.87}$$

with an infinitesimal version of this transformation

$$\boldsymbol{a}' = \boldsymbol{a} + \delta\boldsymbol{a}(\boldsymbol{a}, T). \tag{47.88}$$

In this manner, each fluid particle experiences a distinct variation of its material coordinate. The transformation is passive (only affects coordinates) and so the fluid particle trajectories are unchanged. We do not expect particle labels to affect our ability to describe the physically realized trajectories, and this expectation is given the name *particle relabeling symmetry* (*Salmon*, 1988).

We consider a particular form of coordinate transformation that is assumed to vanish at the material space and time bounds. Furthermore, we assume that the coordinate transformation respects the constraint of mass conservation holding for each fluid parcel. As shown in Sections 46.5.2 and 46.5.3, a mass conserving transformation, δa^I, as a zero density weighted covariant

[6] Recall we are assuming Cartesian coordinates for $\boldsymbol{x}$-space.

divergence. Since the material coordinates, a^I, are set at the reference time, $T = t_{\mathsf{R}}$, the relevant density at that time is $\mathring{\rho}^{\mathsf{L}} = \rho^{\mathsf{L}}(\boldsymbol{a}, T = t_{\mathsf{R}})$, as is the metric determinant, $\mathring{g}^{\mathsf{L}}(\boldsymbol{a}) = g^{\mathsf{L}}(\boldsymbol{a}, T = t_{\mathsf{R}})$. Hence, the particular form of coordinate variation relevant to particle relabeling is given by

$$\delta\boldsymbol{a} = 0 \quad \text{at material space-time boundaries} \quad \text{and} \quad \mathring{\nabla}_I(\mathring{\rho}^{\mathsf{L}}\,\delta a^I) = 0. \tag{47.89}$$

Since δa^I is time dependent, trajectories have their material coordinate modified at each point that is not on the material space-time boundary, with the modification constrained by assuming that the mass of each fluid parcel is invariant.

To deduce the conservation resulting from particle relabeling symmetry, and to expose the key aspects of the derivation, it is sufficient to study flow in a non-rotating reference frame. Generalization to a rotating reference frame is straightforward. We thus consider the following perfect fluid action

$$\mathsf{S}^{\backslash} = \int_{t_{\mathcal{A}}}^{t_{\mathcal{B}}} \int_{\mathcal{R}(\boldsymbol{a})} \left(\tfrac{1}{2}\,\partial_T\boldsymbol{\varphi}\cdot\partial_T\boldsymbol{\varphi} - \Phi_{\mathsf{e}} - \mathcal{I}\right)\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T. \tag{47.90}$$

47.7.2 Constraints from mass conservation

The spatial region where the fluid flows, $\mathcal{R}$, is material and each fluid parcel is material. Consequently, if particle relabeling is to render an equivalent description of the fluid, then the measurement of mass must remain unchanged using the new set of coordinates. Globally, mass conservation means that

$$\int_{\mathcal{R}(\boldsymbol{a})} \mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a = \int_{\mathcal{R}'(\boldsymbol{a}')} \mathring{\rho}'^{\mathsf{L}}\,\mathring{g}'^{\mathsf{L}}\,\mathrm{d}^3a', \tag{47.91}$$

where $\mathcal{R}'(\boldsymbol{a}')$ is the functional expression for the domain when written in terms of the varied coordinates. Since the domain is not changed by the coordinate variation, we must have the functional expression for the domain when using coordinates $\boldsymbol{a}'$ equal to the functional expression for the domain when using coordinates $\boldsymbol{a}$, which is succinctly expressed as

$$\mathcal{R}'(\boldsymbol{a}') = \mathcal{R}(\boldsymbol{a}). \tag{47.92}$$

Likewise, since the mass of a fluid parcel is unchanged we have

$$\mathrm{d}M(\boldsymbol{a}) = \mathrm{d}M'(\boldsymbol{a}') \implies \mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\,\mathring{g}^{\mathsf{L}}(\boldsymbol{a})\,\mathrm{d}^3a = \mathring{\rho}'^{\mathsf{L}}(\boldsymbol{a}')\,\mathring{g}'^{\mathsf{L}}(\boldsymbol{a}')\,\mathrm{d}^3a'. \tag{47.93}$$

This result then means that the Jacobian of transformation between the two material coordinates is given by the volume ratio

$$\frac{\partial\boldsymbol{a}'}{\partial\boldsymbol{a}} = \frac{\mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\,\mathring{g}^{\mathsf{L}}(\boldsymbol{a})}{\mathring{\rho}'^{\mathsf{L}}(\boldsymbol{a}')\,\mathring{g}'^{\mathsf{L}}(\boldsymbol{a}')}, \tag{47.94}$$

which is a familiar result from coordinate transformations discussed in Section 18.7.

Specific volume is invariant

Making use of equation (47.21a) for the specific volume along with the mass conservation identity (47.94), we find

$$\nu_{\mathsf{s}}^{\mathsf{L}'}(\boldsymbol{a}', T) = \frac{1}{\mathring{\rho}'^{\mathsf{L}}(\boldsymbol{a}')\,\mathring{g}'^{\mathsf{L}}(\boldsymbol{a}')}\frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}'} = \frac{1}{\mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\,\mathring{g}^{\mathsf{L}}(\boldsymbol{a})}\frac{\partial\boldsymbol{a}'}{\partial\boldsymbol{a}}\frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}'} = \frac{1}{\mathring{\rho}^{\mathsf{L}}(\boldsymbol{a})\,\mathring{g}^{\mathsf{L}}(\boldsymbol{a})}\frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}} = \nu_{\mathsf{s}}^{\mathsf{L}}(\boldsymbol{a}, T), \tag{47.95}$$

where the third equality made use of the chain rule identity (4.78) holding for determinants

$$\frac{\partial \boldsymbol{a}'}{\partial \boldsymbol{a}} \frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}'} = \frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}}. \tag{47.96}$$

Evidently, so long as the coordinate transformation from $\boldsymbol{a}$ to $\boldsymbol{a}'$ leaves the mass of a fluid parcel unchanged as per equation (47.93), then it also leaves its specific volume unchanged as per equation (47.95).

Zero covariant divergence of density weighted coordinate variation

So far we have only assumed the coordinate transformation is mass preserving. To determine a differential expression of that property, we make use of the discussion in Section 46.5.3 for infinitesimal coordinate transformations. Evidently, the mass conservation identity (47.93) means that, to second order in variation, the density weighted coordinate variation has a zero covariant divergence

$$\mathring{\nabla}_I(\mathring{\rho}^{\text{L}}\,\delta a^I) = (1/\mathring{g}^{\text{L}})\,\partial_I(\mathring{g}^{\text{L}}\,\mathring{\rho}^{\text{L}}\,\delta a^I) = 0. \tag{47.97}$$

This constraint is satisfied by setting $\mathring{\rho}^{\text{L}}\,\delta\boldsymbol{a}$ equal to the covariant curl of an arbitrary vector (see equation (4.146) in Section 4.18)

$$\mathring{\rho}^{\text{L}}\,\delta\boldsymbol{a} = \mathring{\text{curl}}(\boldsymbol{W}) \Longleftrightarrow \mathring{\rho}^{\text{L}}\,\delta a^I = \mathring{\varepsilon}^{IJK}\,\partial_J W_K = (1/\mathring{g}^{\text{L}})\,\epsilon^{IJK}\,\partial_J W_K, \tag{47.98}$$

where

$$\mathring{\varepsilon}^{IJK} = (1/\mathring{g}^{\text{L}})\,\epsilon^{IJK} \tag{47.99}$$

is the coordinate covariant Levi-Civita tensor discussed in Section 4.7.1, and $\boldsymbol{W} = \boldsymbol{W}(\boldsymbol{a}, T)$ is an arbitrary vector that parameterizates the coordinate variation.[7]

Summary from mass conservation

In summary, there are three conditions resulting from the constraint that mass remains invariant when performing a variation of the Lagrangian space coordinates: (1) we only need to vary the energy terms in the action, (2) the specific volume is invariant, and (3) the density weighted coordinate variation is a total curl

$$\delta\mathcal{S}^{\text{action}} = \int_{t_{\text{A}}}^{t_{\text{B}}} \int_{\mathcal{R}(\boldsymbol{a})} \delta\left(\tfrac{1}{2}\,\partial_T\boldsymbol{\varphi}\cdot\partial_T\boldsymbol{\varphi} - \Phi_{\text{e}} - \mathcal{I}\right)\mathring{\rho}^{\text{L}}\,\mathring{g}^{\text{L}}\,\mathrm{d}^3a\,\mathrm{d}T \tag{47.100a}$$

$$\delta\nu_{\text{s}}^{\text{L}} = 0 \tag{47.100b}$$

$$\mathring{\rho}^{\text{L}}\,\delta\boldsymbol{a} = \text{curl}(\boldsymbol{W}). \tag{47.100c}$$

47.7.3 The motion field is a scalar

The gravitational potential is a function of the spatial position as determined by the motion field

$$\Phi_{\text{e}} = \Phi_{\text{e}}(\boldsymbol{\varphi}), \tag{47.101}$$

so that the gravitational potential has a functional dependence

$$\Phi_{\text{e}} = \Phi_{\text{e}}[\boldsymbol{\varphi}(\boldsymbol{a}, T)]. \tag{47.102}$$

[7] Note that $W_K = \mathfrak{g}_{KL}\,W^L$, where $\mathfrak{g}_{KL} = F^k{}_K\,F^l{}_L\,g_{kl}$ is the Lagrangian representation of the metric tensor whereas g_{kl} is the Eulerian representation. Choosing Cartesian Eulerian coordinates so that $g_{kl} = \delta_{kl}$ means that $\mathfrak{g}_{KL}$ is the Cauchy-Green strain tensor (18.41).

For the coordinate variation (47.88) to keep the geopotential invariant requires the motion field to satisfy[8]

$$\boldsymbol{\varphi}'(\boldsymbol{a}', T) = \boldsymbol{\varphi}(\boldsymbol{a}, T). \tag{47.103}$$

This equality means that the motion field, $\boldsymbol{\varphi}'(\boldsymbol{a}', T)$, points to the same fluid particle as the motion field, $\boldsymbol{\varphi}(\boldsymbol{a}, T)$. This condition is consistent with the concept of a passive transformation. From the discussion in Section 1.5.1, we conclude that each component of the motion field transforms as a scalar (zeroth order tensor) under the particle relabeling coordinate transformation, so that the total variation (see Section 46.5.4) of each component vanishes

$$\Delta\boldsymbol{\varphi} = \boldsymbol{\varphi}'(\boldsymbol{a}', T) - \boldsymbol{\varphi}(\boldsymbol{a}, T) = 0. \tag{47.104}$$

47.7.4 The specific internal energy is a scalar

To retain the same specific internal energy, $\mathcal{I}$, when affecting the passive variation requires $\mathcal{I}$ to be a scalar under particle relabeling so that

$$\mathcal{I} = \mathcal{I}(\mathring{\mathcal{S}}(\boldsymbol{a}), \nu_{\mathsf{s}}) = \mathcal{I}'(\mathring{\mathcal{S}}'(\boldsymbol{a}'), \nu'_{\mathsf{s}}). \tag{47.105}$$

We already saw that mass conservation ensures that the specific volume remains a scalar under particle relabeling as per equation (47.100b). In order for relabeling to keep the specific entropy unchanged we must have

$$\mathring{\mathcal{S}}'(\boldsymbol{a}') = \mathring{\mathcal{S}}(\boldsymbol{a}). \tag{47.106}$$

To realize this symmetry requires the coordinate variation to be orthogonal to the $\boldsymbol{a}$-space gradient of the specific entropy

$$\delta\boldsymbol{a}^I\, \partial_I \mathring{\mathcal{S}} = \delta\boldsymbol{a} \cdot \nabla_{\boldsymbol{a}} \mathring{\mathcal{S}} = 0. \tag{47.107}$$

Namely, the relabeling must remain on a constant specific entropy surface. This condition reduces the coordinate variation to two degrees of freedom, and the constraint (47.107) can be readily realized by setting one of the material coordinates equal to the specific entropy. Alternatively, the constraint can be satisfied by writing the coordinate variation as

$$\mathring{\rho}^{\text{L}}\, \delta\boldsymbol{a} = \mathring{\text{curl}}(\boldsymbol{W}) = \mathring{\text{curl}}(A\, \nabla_{\boldsymbol{a}} \mathring{\mathcal{S}}) \iff \mathring{\rho}^{\text{L}}\, \delta a^I = \mathring{\varepsilon}^{IJK}\, \partial_J W_K = \mathring{\varepsilon}^{IJK}\, \partial_J (A\, \partial_K \mathring{\mathcal{S}}). \tag{47.108}$$

We have thus specified the particle relabeling variation up to an arbitrary function, $A(\boldsymbol{a}, T)$.

47.7.5 Coordinate variation of the kinetic energy

The coordinate variation of the kinetic energy per mass is

$$\delta(\partial_T \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi}/2) = \partial_T \boldsymbol{\varphi} \cdot \delta(\partial_T \boldsymbol{\varphi}), \tag{47.109}$$

where the variation of the velocity is given by

$$\delta(\partial_T \boldsymbol{\varphi}) = \left.\frac{\partial \boldsymbol{\varphi}'(\boldsymbol{a}', T)}{\partial T}\right|_{\boldsymbol{a}'} - \left.\frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial T}\right|_{\boldsymbol{a}}. \tag{47.110}$$

Note the distinct time derivatives on the right hand side, as per the need to hold distinct space coordinates fixed while computing the time derivatives. This derivative, to first order in variation,

[8] The geopotential arising in a rotating reference frame is the sum of the gravitational potential plus the planetary centrifugal potential (see equation (47.69)) $\Phi(\boldsymbol{\varphi}) = \Phi_{\mathsf{e}}(\boldsymbol{\varphi}) - (\boldsymbol{\Omega} \times \boldsymbol{\varphi})^2/2$. So if the motion field is a scalar under the coordinate variation as per equation (47.103), then so is the geopotential.

is given by

$$\left.\frac{\partial \boldsymbol{\varphi}'(\boldsymbol{a}', T)}{\partial T}\right|_{\boldsymbol{a}'} = \left.\frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial T}\right|_{\boldsymbol{a}'} = \left.\frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial T}\right|_{\boldsymbol{a}} + \left.\frac{\partial a^I}{\partial T}\right|_{\boldsymbol{a}'} \frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial a^I}, \tag{47.111}$$

where the first equality follows from $\boldsymbol{\varphi}'(\boldsymbol{a}', T) = \boldsymbol{\varphi}(\boldsymbol{a}, T)$ as per equation (47.103), and the second equality follows from the chain rule. Next, make use of the coordinate variation (47.88) to write

$$\left.\frac{\partial a^I}{\partial T}\right|_{\boldsymbol{a}'} = \left.\frac{\partial (a'^I - \delta a^I)}{\partial T}\right|_{\boldsymbol{a}'} = -\left.\frac{\partial (\delta a^I)}{\partial T}\right|_{\boldsymbol{a}'} = -\left.\frac{\partial (\delta a^I)}{\partial T}\right|_{\boldsymbol{a}}, \tag{47.112}$$

where the second equality follows since the time derivative is computed with $\boldsymbol{a}'$ fixed, and the third equality drops terms that are second order in the coordinate variation. This result thus brings the velocity variation in equation (47.111) to

$$\delta(\partial_T \boldsymbol{\varphi}) = \left.\frac{\partial \boldsymbol{\varphi}'(\boldsymbol{a}', T)}{\partial T}\right|_{\boldsymbol{a}'} - \left.\frac{\partial \boldsymbol{\varphi}(\boldsymbol{a}, T)}{\partial T}\right|_{\boldsymbol{a}} = -\left.\frac{\partial (\delta a^I)}{\partial T}\right|_{\boldsymbol{a}} \frac{\partial \boldsymbol{\varphi}}{\partial a^I}, \tag{47.113}$$

so that

$$\delta(\partial_T \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi}/2) = \partial_T \boldsymbol{\varphi} \cdot \delta(\partial_T \boldsymbol{\varphi}) = -\partial_T(\delta a^I)\, \partial_I \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi} = -\partial_T(\delta a^I)\, v_I, \tag{47.114}$$

where every term is evaluated at the Lagrangian space-time point $(\boldsymbol{a}, T)$, and where we introduced the covariant expression for the Lagrangian velocity[9]

$$v_I = \partial_I \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi} = F^i{}_I\, \delta_{ij}\, \partial_T \varphi^j = F^i{}_I\, v^{\text{L}}_i, \tag{47.115}$$

with Eulerian coordinates assumed Cartesian so that $\delta_{ij}\, (v^{\text{L}})^j = v^{\text{L}}_i$.

47.7.6 Lagrangian expression for the potential vorticity

As this point, the action (47.90) has a variation given only through variations in the kinetic energy as per equation (47.114)

$$\delta \mathcal{S}^{\text{action}} = -\int_{t_{\text{A}}}^{t_{\text{B}}} \int_{\mathcal{R}(\boldsymbol{a})} \partial_T(\delta a^I)\, v_I\, \mathring{\rho}^{\text{L}}\, \mathring{g}^{\text{L}}\, \mathrm{d}^3 a\, \mathrm{d}T = \int_{t_{\text{A}}}^{t_{\text{B}}} \int_{\mathcal{R}(\boldsymbol{a})} \delta a^I\, (\partial_T v_I)\, \mathring{\rho}^{\text{L}}\, \mathring{g}^{\text{L}}\, \mathrm{d}^3 a\, \mathrm{d}T, \tag{47.116}$$

where we assumed the coordinate variation vanishes at the temporal bounds

$$\delta a^I = 0 \quad \text{for } T = t_{\text{A}} \text{ and } T = t_{\text{B}}. \tag{47.117}$$

We next introduce equation (47.108) for the non-divergent coordinate variation, and use equation (47.99) to relate the Levi-Civita tensor to the permutation symbol, so that

$$\mathring{\rho}^{\text{L}}\, \mathring{g}^{\text{L}}\, \delta a^I = \epsilon^{IJK}\, \partial_J W_K, \tag{47.118}$$

which brings the action variation to

$$\delta \mathcal{S}^{\text{action}} = \int_{t_{\text{A}}}^{t_{\text{B}}} \int_{\mathcal{R}(\boldsymbol{a})} \epsilon^{IJK}\, \partial_J W_K\, \partial_T v_I\, \mathrm{d}^3 a\, \mathrm{d}T. \tag{47.119}$$

[9] Recall that equation (47.8) introduced the contravariant Lagrangian representation of the velocity, $v^I = F^I{}_i\, (v^{\text{L}})^i$.

Integrating by parts on the spatial derivative leads to

$$\delta\mathcal{S}^{\text{action}} = -\int_{t_A}^{t_B}\int_{\mathcal{R}(\boldsymbol{a})} \epsilon^{IJK}\, W_K\, \partial_J \partial_T v_I \,\mathrm{d}^3a\,\mathrm{d}T, \tag{47.120}$$

where we assumed the coordinate variation vanishes at the material boundaries

$$\delta a^I = 0 \quad \text{for } \boldsymbol{a} \in \partial\mathcal{R}(\boldsymbol{a}). \tag{47.121}$$

The time and space derivatives commute in equation (47.120), and the permutation symbol, ϵ^{IJK}, and specific entropy, $\mathring{\mathcal{S}}$, are both independent of material time so that (with $W_K = A\,\partial_K\mathring{\mathcal{S}}$)

$$\begin{aligned}
\delta\mathcal{S}^{\text{action}} &= -\int_{t_A}^{t_B}\int_{\mathcal{R}(\boldsymbol{a})} W_K\, \partial_T(\epsilon^{IJK}\,\partial_J v_I)\,\mathrm{d}^3a\,\mathrm{d}T && \text{(47.122a)}\\
&= -\int_{t_A}^{t_B}\int_{\mathcal{R}(\boldsymbol{a})} A\,\partial_T(\partial_K\mathring{\mathcal{S}}\,\epsilon^{IJK}\,\partial_J v_I)\,\mathrm{d}^3a\,\mathrm{d}T. && \text{(47.122b)}\\
&= -\int_{t_A}^{t_B}\int_{\mathcal{R}(\boldsymbol{a})} A\,\partial_T[(1/\mathring{\rho}^{\mathsf{L}})\,\partial_K\mathring{\mathcal{S}}\,\mathring{\varepsilon}^{IJK}\,\partial_J v_I]\,\mathring{\rho}^{\mathsf{L}}\,\mathring{g}^{\mathsf{L}}\,\mathrm{d}^3a\,\mathrm{d}T. && \text{(47.122c)}
\end{aligned}$$

At this point we assert that particle relabeling symmetry holds, so that the action has zero variation.[10] For a zero variation to be realized with an arbitrary A requires the material time invariance of the Lagrangian expression of *Ertel potential vorticity* (Section 41.1)

$$Q \equiv \frac{\nabla_{\boldsymbol{a}}\mathring{\mathcal{S}}\cdot\mathring{\mathrm{curl}}(\boldsymbol{v})}{\mathring{\rho}^{\mathsf{L}}} = \frac{\partial_K\mathring{\mathcal{S}}\,\mathring{\varepsilon}^{IJK}\,\partial_J v_I}{\mathring{\rho}^{\mathsf{L}}} = \frac{\partial_K\mathring{\mathcal{S}}\,\epsilon^{IJK}\,\partial_J v_I}{\mathring{g}^{\mathsf{L}}\,\mathring{\rho}^{\mathsf{L}}}. \tag{47.123}$$

47.7.7 Eulerian expression for the potential vorticity

Transforming the Lagrangian expression (47.7) of the potential vorticity into its Eulerian form offers useful experience with index gymnastics. First we transform the Lagrangian gradient of the specific entropy into its Eulerian gradient using the chain rule with the transformation matrix (47.2)

$$\partial_K\mathring{\mathcal{S}} = F^k{}_K\,\partial_k\mathcal{S}, \tag{47.124}$$

where $\mathcal{S} = \mathcal{S}(\boldsymbol{x},t)$ is the Eulerian expression for the specific entropy. Next, expand the Lagrangian expression of the relative vorticity according to (recall the Eulerian coordinates are Cartesian)

$$\begin{aligned}
\epsilon^{IJK}\,\partial_J v_I &= \epsilon^{IJK}\,\partial_J(F^i{}_I\,\partial_T\varphi^j\,\delta_{ij}) && \text{(47.125a)}\\
&= \epsilon^{IJK}\,\partial_J(\partial_I\varphi^i\,\partial_T\varphi^j\,\delta_{ij}) && \text{(47.125b)}\\
&= \epsilon^{IJK}\,\partial_I\varphi^i\,\partial_T\partial_J\varphi^j\,\delta_{ij} && \text{(47.125c)}\\
&= \epsilon^{IJK}\,F^i{}_I\,\partial_T F^j{}_J\,\delta_{ij} && \text{(47.125d)}\\
&= \epsilon^{IJK}\,F^i{}_I\,F^m{}_J\,\partial_m v^j\,\delta_{ij}, && \text{(47.125e)}
\end{aligned}$$

where we used equation (18.108) to write the material time evolution of the transformation matrix in terms of the Eulerian expression for the velocity gradient tensor

$$\partial_T F^j{}_J = F^m{}_J\,\partial_m v^j. \tag{47.126}$$

[10] A vanishing action variation is here not a result of invoking Hamilton's principle. Rather, it results from insisting that particle relabeling symmetry holds.

Now contract the relative vorticity (47.125e) with the gradient of the specific entropy

$$\partial_K \mathring{\mathcal{S}}\, \epsilon^{IJK}\, \partial_J v_I = \partial_k \mathcal{S}\, \epsilon^{IJK}\, F^i{}_I\, F^m{}_J\, F^k{}_K\, \partial_m v^j\, \delta_{ij}. \tag{47.127}$$

We can make this expression a bit more tidy through use of equation (4.71) for the determinant

$$\partial_K \mathring{\mathcal{S}}\, \epsilon^{IJK}\, \partial_J v_I = \partial_k \mathring{\mathcal{S}}\, \epsilon^{imk}\, \frac{\partial \boldsymbol{\varphi}}{\partial \boldsymbol{a}}\, \partial_m v^j\, \delta_{ij}. \tag{47.128}$$

Finally, using equation (47.21a) for the specific volume renders

$$\partial_K \mathring{\mathcal{S}}\, \epsilon^{IJK}\, \partial_J v_I = \partial_k \mathcal{S}\, \epsilon^{ijk}\, \partial_j(\delta_{im}\, v^m) = \mathring{g}^{\text{L}}\, \mathring{\rho}^{\text{L}}\, \frac{\nabla_{\boldsymbol{x}} \mathcal{S} \cdot \operatorname{curl}(\boldsymbol{v})}{\rho}, \tag{47.129}$$

which then leads us to the expected Eulerian expression for the potential vorticity, written entirely in terms of Eulerian quantities

$$Q = \frac{\nabla_{\boldsymbol{x}} \mathcal{S} \cdot \operatorname{curl}(\boldsymbol{v})}{\rho}. \tag{47.130}$$

47.7.8 Global versus local conservation

Space-time symmetries leading to the conservation of momentum and energy lead to differential conservation laws in the form of a continuity equation, such as equation (47.73) for the Hamiltonian density. A global spatial integration of the continuity equation leads to a constant of the motion (e.g., the globally integrated energy) in cases where the normal component of the corresponding fluxes vanish on the boundaries. Such differential conservation laws operationally arise when an active variation leads to a mechanically equivalent action, such as discussed in Section 46.4.4 for constant space-time shifts.

Rather than a mechanically equivalent Lagrangian, are there symmetries related to coordinate transformations (passive variations) that lead to unaltered actions? If so, then the corresponding Noether theorem conservation law does not appear as a continuity equation. Instead, it appears as a property that is a temporal constant everywhere in Lagrangian space-time. That is, it leads to a *local conservation law* rather than a *global conservation law*. As seen in this section, the material time independence of potential vorticity is just that local conservation law for a perfect fluid. That is, potential vorticity is constant for each point in the Lagrangian (material) space-time.

A more tedious calculation of the Jacobian variation (47.57)

To derive the variation of the Jacobian in equation (47.57), we made use of the identity (4.75) for the derivative of the Jacobian with respect to an element of the matrix. For fun, we here derive equation (47.57) yet do not make use of equation (4.75). The calculation is more tedious but it does serve to further our experience with index gymnastics, and is thus of use for those wishing to garner practice.

The first step makes use of the product rule

$$\delta\left[\frac{\partial \varphi^m}{\partial a^I}\,\frac{\partial \varphi^n}{\partial a^J}\,\frac{\partial \varphi^p}{\partial a^K}\right] = \frac{\partial(\delta\varphi^m)}{\partial a^I}\,\frac{\partial \varphi^n}{\partial a^J}\,\frac{\partial \varphi^p}{\partial a^K} + \frac{\partial(\delta\varphi^n)}{\partial a^J}\,\frac{\partial \varphi^m}{\partial a^I}\,\frac{\partial \varphi^p}{\partial a^K} + \frac{\partial(\delta\varphi^p)}{\partial a^K}\,\frac{\partial \varphi^m}{\partial a^I}\,\frac{\partial \varphi^n}{\partial a^J}. \tag{47.131}$$

We now introduce $\boldsymbol{x}$-space derivatives rather than sticking solely with $\boldsymbol{a}$-space derivatives, and

for this purpose we make use of the chain rule to write[11]

$$\frac{\partial(\delta\varphi^m)}{\partial a^I} = \frac{\partial(\delta\varphi^m)}{\partial x^q}\,\frac{\partial\varphi^q}{\partial a^I}, \qquad \frac{\partial(\delta\varphi^n)}{\partial a^J} = \frac{\partial(\delta\varphi^n)}{\partial x^q}\,\frac{\partial\varphi^q}{\partial a^J}, \qquad \frac{\partial(\delta\varphi^p)}{\partial a^K} = \frac{\partial(\delta\varphi^p)}{\partial x^q}\,\frac{\partial\varphi^q}{\partial a^K}, \tag{47.132}$$

where the $\boldsymbol{x}$-space derivatives of the variation, $\delta\boldsymbol{\varphi}$, are computed at the point $\boldsymbol{x} = \boldsymbol{\varphi}(\boldsymbol{a}, T)$. Making use of equations (47.132) renders the variation

$$\begin{aligned}\delta&\left[\frac{\partial\varphi^m}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K}\right]\\ &= \frac{\partial(\delta\varphi^m)}{\partial x^q}\,\frac{\partial\varphi^q}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K} + \frac{\partial(\delta\varphi^n)}{\partial x^q}\,\frac{\partial\varphi^q}{\partial a^J}\,\frac{\partial\varphi^m}{\partial a^I}\,\frac{\partial\varphi^p}{\partial a^K} + \frac{\partial(\delta\varphi^p)}{\partial x^q}\,\frac{\partial\varphi^q}{\partial a^K}\,\frac{\partial\varphi^m}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}.\end{aligned} \tag{47.133}$$

Now reintroduce the permutation symbols to yield

$$\begin{aligned}\delta&\left[\frac{1}{3!}\,\epsilon_{mnp}\,\epsilon^{IJK}\,\frac{\partial\varphi^m}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K}\right]\\ &= \frac{1}{3!}\,\epsilon_{mnp}\,\epsilon^{IJK}\,\frac{\partial(\delta\varphi^m)}{\partial x^q}\left(\frac{\partial\varphi^q}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K} - \frac{\partial\varphi^q}{\partial a^J}\,\frac{\partial\varphi^n}{\partial a^I}\,\frac{\partial\varphi^p}{\partial a^K} - \frac{\partial\varphi^q}{\partial a^K}\,\frac{\partial\varphi^p}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\right),\end{aligned} \tag{47.134}$$

which can be simplified to

$$\delta\left[\frac{1}{3!}\,\epsilon_{mnp}\,\epsilon^{IJK}\,\frac{\partial\varphi^m}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K}\right] = \frac{1}{2}\,\epsilon_{mnp}\,\epsilon^{IJK}\,\frac{\partial(\delta\varphi^m)}{\partial x^q}\left(\frac{\partial\varphi^q}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K}\right). \tag{47.135}$$

The right hand side vanishes unless $m = q$, which can be seen by expanding the terms. The case with $m = q = 1$ is given by

$$\begin{aligned}\frac{1}{2}\,\epsilon_{1np}\,\epsilon^{IJK}\,\frac{\partial(\delta\varphi^1)}{\partial x^1}&\left(\frac{\partial\varphi^1}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K}\right)\\ &= \frac{1}{2}\,\epsilon_{123}\,\epsilon^{IJK}\,\frac{\partial(\delta\varphi^1)}{\partial x^1}\left(\frac{\partial\varphi^1}{\partial a^I}\,\frac{\partial\varphi^2}{\partial a^J}\,\frac{\partial\varphi^3}{\partial a^K} - \frac{\partial\varphi^1}{\partial a^I}\,\frac{\partial\varphi^3}{\partial a^J}\,\frac{\partial\varphi^2}{\partial a^K}\right),\end{aligned} \tag{47.136}$$

which can be simplified to

$$\frac{1}{2}\,\epsilon_{1np}\,\epsilon^{IJK}\,\frac{\partial(\delta\varphi^1)}{\partial x^1}\left(\frac{\partial\varphi^1}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K}\right) = \epsilon^{IJK}\,\frac{\partial(\delta\varphi^1)}{\partial x^1}\left(\frac{\partial\varphi^1}{\partial a^I}\,\frac{\partial\varphi^2}{\partial a^J}\,\frac{\partial\varphi^3}{\partial a^K}\right). \tag{47.137}$$

The cases $m = 2$ and $m = 3$ lead to corresponding results, in which case we are led to

$$\delta\left[\frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}}\right] = \frac{\partial(\delta\varphi^i)}{\partial x^i}\,\epsilon^{IJK}\left(\frac{\partial\varphi^1}{\partial a^I}\,\frac{\partial\varphi^2}{\partial a^J}\,\frac{\partial\varphi^3}{\partial a^K}\right) \tag{47.138a}$$

$$= \frac{\partial(\delta\varphi^i)}{\partial x^i}\,\frac{1}{3!}\,\epsilon_{mnp}\,\epsilon^{IJK}\,\frac{\partial\varphi^m}{\partial a^I}\,\frac{\partial\varphi^n}{\partial a^J}\,\frac{\partial\varphi^p}{\partial a^K} \tag{47.138b}$$

$$= \frac{\partial(\delta\varphi^i)}{\partial x^i}\,\frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{a}}, \tag{47.138c}$$

which is equation (47.57).

[11] At this point, it can be useful to be reminded of the notational conventions detailed in Section 18.4.

Chapter 48

Approximate theories from Hamilton's principle

In this chapter we derive some approximate theories for perfect fluids using *Hamilton's variational principle*.

READER'S GUIDE FOR THIS CHAPTER

This chapter is a direct follow-on from Chapter 47 that considered Hamilton's principle for a perfect fluid.

48.1 Loose threads

- Adiabatic Boussinesq in buoyancy coordinates
- Quasi-geostrophy
- Semi-geostrophy
- shallow water

48.2 Boussinesq ocean

We studied the Boussinesq ocean in Chapter 29, and here establish the Boussinesq equations of motion via Hamilton's principle. There are some novel conceptual and technical points to raise here relative to the non-Boussinesq fluid considered in Chapter 47, thus warranting a full discussion of the Boussinesq case.

48.2.1 Unit Jacobian for non-divergent flow

Following the approach earlier in this chapter, we use Cartesian Eulerian coordinates so that $\boldsymbol{x} = \boldsymbol{\varphi}(\boldsymbol{a}, T)$ provides the instantaneous Cartesian position of a fluid particle with material label, $\boldsymbol{a}$, and material time, T. Additionally, we here assume material coordinates are given by the

Cartesian initial positions of fluid particles, in which case the Jacobian is unity at the initial condition

$$\boldsymbol{a} = \mathring{\boldsymbol{x}} \implies \frac{\partial \boldsymbol{\varphi}}{\partial \mathring{\boldsymbol{x}}} = 1 \quad \text{at } T = t_0. \tag{48.1}$$

With this choice for the Eulerian and material coordinates, equation (18.77) means that the Jacobian is the ratio of the present fluid parcel volume to the initial parcel volume

$$\frac{\partial \boldsymbol{\varphi}}{\partial \mathring{\boldsymbol{x}}} = \frac{\mathrm{d}^3 x}{\mathrm{d}^3 \mathring{x}}. \tag{48.2}$$

From our study in Chapter 21, we know that non-divergent flows keep the volume of fluid parcels constant while following fluid particle trajectories, so that the Jacobian is a material constant

$$\partial_T (\partial \boldsymbol{\varphi} / \partial \mathring{\boldsymbol{x}}) = 0. \tag{48.3}$$

A unit initial value as per equation (48.1) along material constancy means that the Jacobian retains its unity value along each particle trajectory for all time

$$\partial \boldsymbol{\varphi} / \partial \mathring{\boldsymbol{x}} = 1 \; \forall \; T. \tag{48.4}$$

48.2.2 Boussinesq energetics

As described in Section 29.1.8, the Boussinesq ocean does not respect the principle of equivalence, since the mass used for the kinetic energy (inertial mass) is based on a constant reference density, $\rho_\circ$, whereas the mass used for the gravitational potential energy (gravitational mass) uses the *in situ* density, ρ. A constant reference density for kinetic energy means that the flow is non-divergent, whereas the *in situ* density for potential energy allows for buoyancy to affect motion via density gradients.

Now recall from Section 47.4.3 that the specific internal energy is a function of the specific entropy and specific volume. For the perfect fluid the specific entropy is a material constant. Equation (48.4) implies that the specific volume is also a material constant. Consequently, the specific internal energy for the Boussinesq ocean is a material constant. Evidently, there is a disconnect between between pressure and internal energy for the Boussinesq ocean. Stated otherwise, we know that in the absence of flow divergence, there can be no pressure work on a fluid parcel. Hence, pressure in the Boussinesq ocean has no thermodynamic connection to internal energy. Pressure instead plays a purely mechanical role, which we see in Section 48.2.3 via its role as a Lagrange multiplier that constrains the flow to remain non-divergent. We already described pressure as a constraint in Section 29.3, with the present discussion furthering that understanding through Hamilton's principle.

48.2.3 Action for the Boussinesq ocean

We follow the approach in Sections 13.11.3 and 15.5.2 by absorbing the centrifugal potential into the geopotential, thus writing

$$\Phi = g\, z. \tag{48.5}$$

In this manner we are led to the action for a Boussinesq ocean (recall that $\boldsymbol{a} = \mathring{\boldsymbol{x}}$)

$$\begin{aligned} \mathsf{S}^{\text{action}} = \int_{T_{\text{init}}}^{T_{\text{final}}} \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} \left[\tfrac{1}{2}\, \partial_T \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi} + \partial_T \boldsymbol{\varphi} \cdot (\boldsymbol{\Omega} \times \boldsymbol{\varphi}) \right] \rho_\circ \, \mathrm{d}^3 \mathring{x} \, \mathrm{d}T - \int_{T_{\text{init}}}^{T_{\text{final}}} \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} \Phi \, \mathring{\rho} \, \mathrm{d}^3 \mathring{x} \, \mathrm{d}T \\ + \int_{T_{\text{init}}}^{T_{\text{final}}} \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} p \, (\partial \boldsymbol{\varphi} / \partial \mathring{\boldsymbol{x}} - 1) \, \mathrm{d}^3 \mathring{x} \, \mathrm{d}T, \end{aligned} \tag{48.6}$$

where p is a Lagrange multiplier that plays the role of mechanical pressure. Notice that we used the constant Boussinesq reference density, $\rho_\circ$, for computing the kinetic energy, whereas the geopotential uses $\mathring{\rho}$. The use of distinct densities arises since the Boussinesq ocean does not respect the principle of equivalance.

48.2.4 Boussinesq Euler-Lagrange equation

We now vary the Boussinesq action (48.6) by independently varying the trajectories as well as the Lagrange multiplier, p. Varying the Lagrange multipler leads, as expected, to the non-divergence constraint (48.4)

$$\delta_p \mathcal{S}^{\text{act}} = 0 \Longrightarrow \partial\boldsymbol{\varphi}/\partial\mathring{\boldsymbol{x}} = 1. \tag{48.7}$$

We now detail results from varying the trajectories.

Kinetic energy variation arising from variation of the trajectories

Following the steps in Section 47.5.2, only now with density set to the constant reference density, $\rho_\circ$, leads to variation of the kinetic energy contribution to the action

$$\begin{aligned}\delta \int_{T_{\text{init}}}^{T_{\text{final}}} \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} [\tfrac{1}{2}\, \partial_T \boldsymbol{\varphi} \cdot \partial_T \boldsymbol{\varphi} + \partial_T \boldsymbol{\varphi} \cdot (\boldsymbol{\Omega} \times \boldsymbol{\varphi})]\, \rho_\circ \, \mathrm{d}^3\mathring{x}\, \mathrm{d}T \\ = - \int_{T_{\text{init}}}^{T_{\text{final}}} \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} [\partial_{TT} \boldsymbol{\varphi} + 2\, \boldsymbol{\Omega} \times \partial_T \boldsymbol{\varphi}] \cdot \delta\boldsymbol{\varphi}\, \rho_\circ \, \mathrm{d}^3\mathring{x}\, \mathrm{d}T.\end{aligned} \tag{48.8}$$

Geopotential energy variation arising from variation of the trajectories

The chain rule leads to variation of the integrated geopotential

$$\delta \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} \Phi\, \mathring{\rho}\, \mathrm{d}^3\mathring{x} = \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} \frac{\partial \Phi}{\partial \varphi^i}\, \delta\varphi^i\, \mathring{\rho}\, \mathrm{d}^3\mathring{x} = \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} \frac{\partial \Phi}{\partial \varphi^i}\, \delta\varphi^i\, \rho^{\text{L}}\, \mathrm{d}^3\mathring{x}, \tag{48.9}$$

where the final equality made use of the identity (47.18) with a unit Jacobian

$$\mathring{\rho} = \rho^{\text{L}}\, \partial\boldsymbol{\varphi}/\partial\mathring{\boldsymbol{x}} = \rho^{\text{L}}. \tag{48.10}$$

Constraint variation arising from variation of the trajectories

Varying the trajectories leads to variation of the constraint

$$\int_{\mathscr{R}(\mathring{\boldsymbol{x}})} p\, \delta(\partial\boldsymbol{\varphi}/\partial\mathring{\boldsymbol{x}})\, \mathrm{d}^3\mathring{x} = \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} p\, \frac{\partial(\delta\varphi^i)}{\partial x^i}\, \mathrm{d}^3\mathring{x} = - \int_{\mathscr{R}(\mathring{\boldsymbol{x}})} \frac{\partial p}{\partial x^i}\, \delta\varphi^i\, \mathrm{d}^3\mathring{x}, \tag{48.11}$$

where we used equation (47.138c) for the Jacobian variation in the presence of a unit Jacobian

$$\delta \left[\frac{\partial\boldsymbol{\varphi}}{\partial\mathring{\boldsymbol{x}}}\right] = \frac{\partial(\delta\varphi^i)}{\partial x^i}\, \frac{\partial\boldsymbol{\varphi}}{\partial\mathring{\boldsymbol{x}}} = \frac{\partial(\delta\varphi^i)}{\partial x^i}, \tag{48.12}$$

and assumed zero mechanical forcing at the domain boundaries.

The Euler-Lagrange equation for the Boussinesq ocean

Bringing terms together leads to the action variation under variation of the trajectories

$$\delta_{\boldsymbol{\varphi}} \mathcal{S}^{\text{act}} = -\int_{T_{\text{init}}}^{T_{\text{final}}} \int_{\mathcal{R}(\mathring{\boldsymbol{x}})} [\partial_{TT} \boldsymbol{\varphi} + 2\,\boldsymbol{\Omega} \times \partial_T \boldsymbol{\varphi}] \cdot \delta\boldsymbol{\varphi}\, \rho_{\circ}\, \mathrm{d}^3\mathring{x}\, \mathrm{d}T - \int_{T_{\text{init}}}^{T_{\text{final}}} \int_{\mathcal{R}(\mathring{\boldsymbol{x}})} \frac{\partial \Phi}{\partial \varphi^i}\, \delta\varphi^i\, \rho^{\text{L}}\, \mathrm{d}^3\mathring{x}\, \mathrm{d}T - \int_{T_{\text{init}}}^{T_{\text{final}}} \int_{\mathcal{R}(\mathring{\boldsymbol{x}})} \frac{\partial p}{\partial x^i}\, \delta\varphi^i\, \mathrm{d}^3\mathring{x}\, \mathrm{d}T. \quad (48.13)$$

Setting the variation to zero leads to the Boussinesq Euler-Lagrange equations

$$\partial_T \boldsymbol{v}^{\text{L}} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v}^{\text{L}} = -\frac{1}{\rho_{\circ}} \frac{\partial p}{\partial \boldsymbol{\varphi}} - \frac{\rho^{\text{L}}}{\rho_{\circ}} \frac{\partial \Phi}{\partial \boldsymbol{\varphi}}, \quad (48.14)$$

which agrees with the perfect fluid Boussinesq ocean equations derived in Section 29.1.7 using Newtonian methods.

48.2.5 Comments

Absence of an equivalence principle for the Boussinesq ocean prompts a careful treatment of the density factors. Furthermore, note how the pressure, here appearing as a Lagrange multiplier, corresponds directly to the thermodynamic pressure for the non-Boussinesq fluid in Section 47.5. That correspondence is not a coincidence, with the sign of the constraint as written in equation (48.6) chosen to facilitate the agreement.

Part X

Linear wave mechanics

Waves and the central role of a dispersion relation

In this part of the book, we study the mechanics of non-dissipative linear waves appearing in geophysical fluids. This study of *wave mechanics* forms a key part of geophysical fluid mechanics in part since so much of the observed geophysical flows manifest waves in one form or another.[1] Waves in fluids manifest as fluctuations of fluid particles and associated fluid properties, with the fluctuations possessing coherency in both space and time. Linear waves exist dynamically due to a restoring force that provides the means for fluid particles to undergo simple harmonic oscillations. Kinematically, linear waves arise when a symmetry is mildly broken, with coherent fluctuations the collective response to the symmetry breaking. This *wave mechanics* forms a key part of observed geophysical fluid phenomena.[2]

Linear waves have spatial and temporal properties that are closely linked. This linkage relates the angular frequency, ω, which measures the temporal structure of a wave, to the wavevector, $\boldsymbol{k}$, which measures the spatial structure of a wave. The *dispersion relation* is the mathematical equation that specifies the linkage between ω and $\boldsymbol{k}$. Details of the dispersion relation are determined by the physical forces that give rise to the wave, such as compressibility for acoustic waves (Chapter 51), surface tension for capillary waves (Chapter 52), gravitational acceleration for gravity waves (Chapters 52, 55, and 57), the Coriolis acceleration for inertial waves (Chapters 53 and 55) and differential rotation (beta effect) for planetary Rossby waves (Chapters 54 and 55).

Linear waves satisfy the *superposition principle* that is generally respected by linear physical phenomena. As a result, interactions between linear waves are reversible, and consist of constructive and destructive *interferences*.[3] The superposition principle allows for the solution of a linear wave equation to be constructed from constituent elementary pieces. Linear superposition is the fundamental reason we can usefully examine properties of waves by examining the behavior of a single traveling wave. We use this property of linearity when deriving the dispersion relation for waves, and, in Part XI of this book, for determining stability properties.

Linearization to derive the wave equations

Derivation of a wave equation and corresponding dispersion relation requires us to linearize the nonlinear governing equations of fluid motion. After deriving the linearized equations, we study their salient properties to help understand the mechanics of their linear wave solutions and dispersion relations. Each wave system has unique properties depending on the underlying dynamical forces. Even so, many kinematical properties transcend details of the dynamics, with kinematics forming the focus for Chapters 49 and 50.

Wave energy transport versus matter transport

The movement of fluid particles within a fluid is associated with the movement of matter, including tracers, as well as other properties such as momentum, vorticity, enthalpy, entropy, etc. Although waves can lead to a net transfer of matter, through a process known as *Stokes drift*, the transfer of wave energy and momentum generally occurs without any net movement of fluid particles, where "net movement" refers to a time average over a wave period (i.e., the *phase average* from Section 8.1.2). As such, wave energy propagates at speeds that are unconstrained by fluid particle speeds. Indeed, wave energy in linear waves is generally transmitted many times

[1] "Wave mechanics" sometimes refers to that part of quantum mechanics based on Schrödinger's equation. We are instead here concerned with waves that occur in classical geophysical fluids.

[2] "Wave mechanics" sometimes refers to that part of quantum mechanics based on Schrödinger's equation. We are instead here concerned with waves that occur in classical geophysical fluids.

[3] Some authors prefer to consider reversible interactions as the absence of any interaction, since one can exactly distinguish individual linear waves through the Fourier decomposition of a wave field comprised of multiple waves.

faster than matter. We thus conceive of waves as organized disturbances on a background fluid state (sometimes called the base state or equilibrium state) that transmit energy from one part of the media to another. The speed and direction of wave energy is determined by the dispersion relation, thus making the dispersion relation a central feature of wave mechanics.

The scope of our study

The study of wave mechanics forms a central part of physics, engineering, and applied mathematics. We target the reader aiming to learn wave mechanics for the first time, while also providing selected material for the experienced physicist interested in geophysical fluid wave mechanics. For these purposes, we survey a suite of geophysical fluid waves and dive deep into particular special topics to support understanding and to develop mathematical methods. To help simplify the maths, we restrict attention to Cartesian waves (i.e., plane waves), leaving the geophysically relevant topic of spherical waves for more specialized treatments. Our presentation is not comprehensive. Instead, we aim to offer an intellectual platform for further study and research. Insights and skills working with waves requires practice, and we get plenty from the wide variety of geophysical fluid waves considered here.

Chapter 49

PLANE WAVES AND WAVE PACKETS

Forces acting in a fluid determine the *dispersion relation* satisfied by linear waves, with the dispersion relation connecting the wave angular frequency, ω, to the *wavevector*, $\boldsymbol{k}$. We write this relation in the functional form[1]

$$\omega = \varpi(\boldsymbol{k}), \tag{49.1}$$

where ϖ is generally a nonlinear function of the wavevector. The dispersion relation couples the space and time structure of a wave: once a wavevector is chosen then the angular frequency is specified. In this chapter we develop the foundations for *wave kinematics*, which focuses on wave properties arising from the existence of a dispersion relation yet is unconcerned with the forces that determine this relation.

The *wave function* plays a fundamental role in describing waves. Example wave functions include the velocity potential (acoustic and surface waves), the streamfunction (Rossby waves), and free surface height (shallow water waves). All other dynamical fields can be generated from the wave function, thus allowing us to focus on characterizing how the wave appears through study of the wave function. The wave function has both an $\boldsymbol{x}$-space (geographic/height space) representation as well as a $\boldsymbol{k}$-space (wavevector space) representation. These two representations offer complementary characterizations of wave properties, with the transformation between these representations provided by Fourier's integral theorem from Section 8.3.1. One of the more remarkable aspects of this complementarity arises through the *uncertainty relation*, which states that it is not possible to simultaneously specify the position of a wave packet with arbitrary precision in both $\boldsymbol{x}$-space and $\boldsymbol{k}$-space. That is, precision in one space corresponds to imprecision in the other. We derive this uncertainty relation through the study of Gaussian wave packets.

READER'S GUIDE TO THIS CHAPTER

We focus on plane waves in this chapter and so make use of Cartesian coordinates and Cartesian tensors (Chapters 1 and 2). Furthermore, we assume familiarity with the use of complex variables as well as Fourier transforms, both reviewed in Chapter 8. We restrict attention to a homogeneous background/base state upon which waves are supported. A homogeneous base state is rarely realized in geophysics, and yet it serves our pedagogical needs prior to moving onto the more realistic, and mathematically complex, case of an inhomogeneous base state in Chapter 50.

The presentation shares much with books and reviews covering topics in linear wave mechanics, such as *Bretherton* (1971), chapter 3 of *Acheson* (1990), chapters 1 and 2 of *Pedlosky* (2003), chapter 6 of *Olbers et al.* (2012), chapter 1 of *Sutherland* (2010), chapter 7 of *Thorne and Blandford* (2017), and chapter 6 of *Vallis* (2017). However, be mindful that not all authors agree on the conventions followed here and as summarized in Section 49.2.

[1] For waves moving on a space and time dependent background, the dispersion relation picks up space and time dependence. This topic is the focus of Chapter 50.

49.1 Loose threads

- Figures

- More on wave packets and Green's functions. Derive the Green's function equation from the packet equation plus the dispersion relation.

49.2 Nomenclature and conventions

Many readers have encountered wave kinematics in prior studies. Yet some of the conventions are not universal, so that it is useful to summarize salient points to expose the choices made in this book.

49.2.1 Types of waves

Table 49.1 summarizes the various types of waves considered in this book. We mostly encounter plane traveling waves, though also make use of standing waves (as for waves within a bounded domain) and stationary waves (when a wave has only spatial periodicity and no time dependence). The wave patterns in Table 49.1 can arise from any conceivable context, physical or otherwise (e.g., the wave produced by spectators in a large sporting event). The specifics of a physical system arises when enforcing that a wave function, Φ, satisfies a linear partial differential equation, and it is through this equation that we derive the dispersion relation.

We wish to emphasize the above points in a bit more mundane manner. Namely, there are many mathematical functions that give rise to oscillating patterns. However, these patterns correspond to particular solutions to a physical system only when they satisfy a partial differential equation such as equation (6.65). That is, there are more mathematial wave-like patterns than there are physical waves. For example, consider the function

$$\Phi(x,y,t) = A\cos(k_x\,x - \omega\,t)\cos(\omega\,t) = (A/2)\,[\cos(k_x\,x - 2\,\omega\,t) + \cos(k_x x)], \tag{49.2}$$

where A is a constant amplitude. The second expression reveals the sum of a traveling plane wave plus a stationary wave. It is notable that this function is *not* in the form of a Fourier component that constitutes the wave patterns in Table 49.1. Rather, it is simply the sum of two trigonometric functions having a particular space and time structure. Is this function a particular solution to the classic wave equation with operator $\partial_{tt} - c^2\,\partial_{xx}$? A quick calculation reveals that it is *not* a solution since

$$\partial_{tt}\Phi = -2\,A\,\omega^2\cos(k_x\,x - 2\,\omega\,t) \tag{49.3a}$$

$$\partial_{xx}\Phi = -k_x^2\,\Phi = -(k_x^2\,A/2)[\cos(k_x\,x - 2\,\omega\,t) + \cos(k_x x)], \tag{49.3b}$$

revealing that there is no way to relate $\partial_{tt}\Phi$ and $c^2\,\partial_{xx}\Phi$ at arbitrary space and time points. In turn, this function is *not* a suitable wave function ansatz for deriving a dispersion relation.[2]

NAME	SPACE-TIME STRUCTURE
monochromatic	$\mathrm{Re}[\Phi_0\,\mathrm{e}^{-\mathrm{i}\,\omega\,t}]$
traveling	$\mathrm{Re}[\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}]$
standing	$\mathrm{Re}[\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}]\cos(\omega t)$
stationary	$\mathrm{Re}[\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}]$

TABLE 49.1: Summarizing the variety of waves encountered in this book, with distinctions based on their space-time structure. The operator, Re, extracts the real part of its argument, so that, for example, $\mathrm{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}] = \cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)$. The first three patterns are monochromatic, which means they oscillate coherently with a single period, $2\pi/\omega$, where $\omega \geq 0$ is the angular frequency. However, note that $\mathrm{Re}[\Phi_0\,\mathrm{e}^{-\mathrm{i}\,\omega\,t}]$ is monochromatic and yet we cannot conclude whether it is a wave until we have further information about its spatial structure. Spatial dependence is introduced in the form $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}$, where $\boldsymbol{k}$ is the wavevector that determines the direction of the wave and its wavelength. For a plane wave in three-dimensional space, $\boldsymbol{k}\cdot\boldsymbol{x} = k_x\,x + k_y\,y + k_z\,z$, whereas a plane wave in two dimensions has wavevector $\boldsymbol{k}\cdot\boldsymbol{x} = k_x\,x + k_y\,y$. Standing waves do not travel in space but oscillate in place. A stationary wave has an oscillatory spatial pattern but has no time dependence and so is static. The final three waves are *harmonic* since they have a regular spatial pattern.

[2] See Section 49.5.5 for a discussion of wave *ansatz*.

49.2.2 Types of dispersion relations

The dispersion relation (49.1) is the root of all wave properties since it links the space and time structure of the wave. Some waves encountered in this book have a dispersion relation in the slightly more restricted form

$$\omega = \varpi(|\boldsymbol{k}|), \tag{49.4}$$

where $|\boldsymbol{k}|$ is the *wavenumber*. Evidently, these waves have their angular frequency independent of the wave direction. Examples include acoustic waves (Chapter 51) and surface waves (Chapter 52). Inertial waves from Chapter 53 and internal gravity waves from Chapter 57 are the complement, with their dispersion relation independent of the wavenumber yet dependent on the wave direction,

$$\omega = \varpi(\hat{\boldsymbol{k}}) \quad \text{with} \quad \hat{\boldsymbol{k}} = \boldsymbol{k}/|\boldsymbol{k}|. \tag{49.5}$$

Finally, the Rossby waves introduced in Chapters 54 and 55 have a dispersion relation that depends on both the wavenumber and wave direction; i.e., on the wavevector, $\boldsymbol{k}$.

49.2.3 Conventions for space-time description of waves

The suite of dispersion relations encountered in geophysical fluids motivates the following conventions that form the basis for our space-time description of waves. Readers should be aware that certain of these conventions are not universally followed in the literature.

- ANGULAR FREQUENCY: Following *Bretherton* (1971), the angular frequency of a stable linear wave that results from the dispersion relation, $\omega = \varpi(\boldsymbol{k})$, is chosen as a non-negative real number,

  $$\omega \geq 0, \tag{49.6}$$

  so that the wave period, $2\pi/\omega$, is also a non-negative number and the wave advances forward in time with the wave direction determined by the wavevector.

  This convention is not universally followed in the literature. One reason to allow for a negative angular frequency is that dispersion relations typically lead to quadratic equations that have a positive and a negative root. For example, the one-dimensional acoustic wave equation has

  $$\omega^2(\boldsymbol{k}) = c_{\mathrm{s}}^2\, \boldsymbol{k}^2, \tag{49.7}$$

  which has roots $\omega = \pm c_{\mathrm{s}}|\boldsymbol{k}|$ (c_{s} is the acoustic wave speed; Section 51.5.1). When choosing both roots, one interprets them as representing oppositely moving waves. Even so, we follow a convention that always chooses the positive root, so that the wave direction is determined by the wavevector (see next point) rather than the sign of the angular frequency. Additionally, we are not generally interested in waves traveling backward in time, which is sometimes used to interpret waves with $\omega < 0$.

  One encounters a negative angular frequency when conducting time-frequency Fourier analysis in the complex plane, as in Section 8.4. In that context, the negative frequency is not physical, but instead is a mathematical expedient that allows one to work with a complex Fourier transform. There is nothing physical associated with the negative frequency in this context, since one could equivalently work with real Fourier sine and cosine transforms where the angular frequency is non-negative. See Section 8.4.1 for more discussion. Furthermore, if using complex Fourier analysis, then switching the sign of the angular frequency and the wavevector merely leads to the complex conjugate wave function. Since the physical wave is real in classical physics, the complex conjugate wave function is the same wave.

- WAVE DIRECTION: The direction of a wave is specified by the wavevector, $\boldsymbol{k}$ (Section 49.5), and its wavelength is $2\pi/|\boldsymbol{k}|$, where $|\boldsymbol{k}| \geq 0$ is the wavenumber.
- PHASE SPEED: The phase speed, C_p, is a non-negative number. It is not a vector so that we do not consider components to the phase speed. Rather, we consider components to the phase velocity vector, which is a vector whose direction is given by the wavevector and whose non-negative magnitude, along with the angular frequency, determine the phase speed (Section 49.5.2).

49.3 Two classes of linear waves

We distinguish two types of linear wave phenomena: non-dispersive waves and dispersive waves. In this section we present a mathematical overview of these waves, offering examples of each type of wave along with pointers to the physics and maths to come later.[3]

49.3.1 Non-dispersive waves

The canonical non-dispersive wave phenomena is described by "the" wave equation

$$(\partial_{tt} - c^2 \nabla^2)\Phi = 0, \tag{49.8}$$

where Φ is a wave function (e.g., velocity potential, streamfunction, surface height), and $c^2 > 0$ is the squared wave speed. As discussed in Section 6.7, this wave equation is hyperbolic and its wave solutions all transmit signals with speed, $c > 0$, without distortion. That is, waves satisfying equation (49.8) of arbitrary wavelengths travel at the same speed so that there is no mixing across the spectrum of wavevectors. We find that for non-dispersive waves the angular frequency divided by the wavenumber equals to a constant phase speed shared by all waves. The acoustic waves of Chapter 51 and the shallow water gravity waves of Chapter 55 are example non-dispersive waves considered in this book.

To expose some of the mathematical details, consider the wave equation (49.8) in one space dimension and written in the factored form

$$(\partial_t - c\,\partial_x)\,(\partial_t + c\,\partial_x)\Phi = 0. \tag{49.9}$$

As discussed in Section 6.7, the solution to this hyperbolic partial differential equation takes the form of two signals moving in opposite directions

$$\Phi(x,t) = F(x - c\,t) + G(x + c\,t), \tag{49.10}$$

where the functions F and G are specified by boundary and initial conditions. Their respectiive functional dependencies, $x \pm c\,t$, determine the propagation direction of the signal, with $F(x - c\,t)$ a signal propagating in the $+\hat{\boldsymbol{x}}$ direction whereas $G(x + c\,t)$ is a signal propagating in the $-\hat{\boldsymbol{x}}$ direction. A key point is that the signals all move with the same speed, with F and G arbitrary functions that may be built from a single linear wave or any number of waves (including an infinity of waves). Also note that the wave equation (49.9) has been factored into the product of two linear operators, so that a simpler hyperbolic wave equation is either of the two first order equations

$$(\partial_t \pm c\,\partial_x)\Phi = 0. \tag{49.11}$$

In other parts of this book this equation is referred to as the *advection equation* for a one-dimensional signal with constant advection velocity (e.g., see Sections 69.3 and 69.4).

[3] Chapter 1 of *Whitham* (1974) provides a thorough mathematical introduction to the variety of linear and nonlinear waves.

It is common to be introduced to wave physics through solutions to the hyperbolic wave equations (49.8) or (49.11). Correspondingly, much of our experience with waves is based on the non-dispersive nature of these waves. For example, when listening to a symphony, we hear the sounds from various instruments "in concert". That is, the speed that the acoustic waves propagate are independent of the wavelength. Indeed, imagine how difficult it would be for an audience spread throughout a concert hall to equally appreciate a symphonic performance if acoustic waves were dispersive!

49.3.2 Dispersive waves

Upon studying geophysical waves, we soon realize that non-dispersive waves are the exception rather than the norm. That is, most waves in geophysical fluids are dispersive, with their governing wave equations sometimes mathematically classified as hyperbolic though many are not. A dispersive wave is one that admits solutions of the form

$$\Phi(\boldsymbol{x}, t) = A\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \varpi\, t)} = A\, \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x} - \hat{\boldsymbol{k}}\, C_{\mathrm{p}}\, t)} \tag{49.12}$$

where the speed of a surface with constant phase,

$$C_{\mathrm{p}} = \varpi(\boldsymbol{k})/|\boldsymbol{k}|, \tag{49.13}$$

is a function of the wavevector. As such, the movement of the dispersive wave signal (i.e., the *phase velocity*) depends on the wavelength of the wave. For example, if we prepare a packet of dispersive waves with a particular shape in space, the evolution of the packet is characterized by the dispersion of the packet.

Waves visible by eye on the surface of a pond or surface of the ocean offer a canonical example of dispersive waves. As explored in Section 52.5.3, long surface gravity waves (which also have low frequency) travel faster than short and high frequency surface gravity waves. Indeed, it is this dispersion for surface gravity waves that surfers appreciate when assessing the suitability of coastal surf conditions following an offshore storm.[4]

49.3.3 Comments about time derivatives

As noted when discussing the non-dispersive wave equation (49.9), the presence of two time derivatives provides the means for two wave signals to arise from solutions to this equation, where the waves move in opposite directions. This case occurs for acoustic waves, gravity waves, and inertial waves. It manifests as a dispersion relation written for the squared angular frequency. In contrast, when there is only one time derivative in the wave equation, then the dispersion relation is written for the angular frequency rather than its square. Furthermore, the system chooses a preferred direction for the wave signal, with the Rossby wave offering the canonical example of such anisotropic waves. Rossby waves also offer a clear example of how the non-negative angular frequency convention (Section 49.2.3) helps to understand the phase velocity.

49.4 Monochromatic patterns

A *monochromatic pattern* is a feature characterized by having all points maintain the same time periodic motion with single angular frequency, ω. Hence, all points within a *monochromatic wave* have the same angular frequency. The trigonometric functions, $\cos(\omega\, t)$ and $\sin(\omega\, t)$, both exhibit time periodic behavior, which explains the factors of 2π appearing throughout wave

[4] See *Butt et al.* (2004) for a scientific view on surface ocean waves geared towards surfing.

physics. As noted in Section 49.2.3, we choose the convention in which the angular frequency is a non-negative number, $\omega \geq 0$, so that the period of the oscillation is $2\pi/\omega$.

It is often convenient to make use of the *Euler identity*

$$\mathrm{e}^{-\mathrm{i}\,\omega\,t} = \cos(\omega\,t) - \mathrm{i}\,\sin(\omega\,t), \tag{49.14}$$

to thus write a time periodic *wave function* as[5]

$$\Phi = \mathrm{Re}[\Phi_0\,\mathrm{e}^{-\mathrm{i}\,\omega\,t}], \tag{49.15}$$

where Φ_0 is a complex function further specified below, and Re[ ] is an operator that returns the real part of its argument (see Section 8.1). For linear calculations we can safely omit the Re operation until the end of the calculations. However, for products of wave fields, such as when performing energetic analyses, more care is needed, with details given in Section 8.1.[6]

49.5 Free plane waves

Plane waves are characterized by a single wavevector and single angular frequency, with the wave exhibiting symmetry in directions perpendicular to the propagation direction (hence the "plane" in its name). Any linear wave, be it acoustic, gravity, Rossby, etc., can be decomposed into a sum or integral of plane waves with a suite of frequencies and wavevectors, and with modulation by an amplitude function.

The general form of a stationary plane wave function is given by

$$\Phi_0 = \mathscr{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}, \tag{49.16}$$

where $\mathscr{A}(\boldsymbol{k})$ is a complex wave amplitude and $\boldsymbol{k}$ is the *wavevector* or *wavenumber vector*. The wavevector has dimensions of inverse length and it characterizes the wavelength of the wave as well as the spatial direction of the wave propagation (as per travelling plane waves in Section 49.5.1). The magnitude of the wavevector, $|\boldsymbol{k}|$, is referred to as the *wavenumber* as it measures 2π times the number of waves per unit length (we further discuss this notion in Section 49.5.2). We allow the wave amplitude, $\mathscr{A}(\boldsymbol{k})$, to be a function of wavevector so that different plane waves can have distinct amplitudes. We also allow for $\mathscr{A}(\boldsymbol{k})$ to be complex so that different plane waves can have their phases shifted relative to one another (we discuss phases in Section 49.5.1).

Given that the plane wave possesses symmetry in planes perpendicular to $\boldsymbol{k}$, it is spatially dependent only on the direction parallel to the wavevector,[7]

$$\boldsymbol{k} = |\boldsymbol{k}|\,\hat{\boldsymbol{k}}. \tag{49.17}$$

We say that the plane wave function (49.16) is *free* since it exists throughout all of space and is unaffected by boundaries. Furthermore, we are uninterested in how the plane wave was formed. Indeed, since it is present throughout all of space, we imagine that the plane wave has existed for all time. Clearly these notions are not physically realizable. Even so, the mathematical simplicity of the plane wave, along with the superposition principle, affords it a central role in the study of wave mechanics. Furthermore, through the construct of wave packets studied in Sections 49.6 and 49.7, which are built via the superposition of plane waves, we can build wave

[5]The minus sign is motivated by convenience for when we consider a traveling wave and the phase velocity in Section 49.5.2. See in particular Figure 49.1.

[6]As noted when developing the basics of Fourier analysis in Chapter 8, we use complex variables solely for mathematical convenience, with all physical fields producing real numbers in this book.

[7]Caution: many authors write $\hat{\boldsymbol{k}}$ for the unit vertical direction, whereas in this book we write $\hat{\boldsymbol{z}}$ for the unit vertical direction whereas $\hat{\boldsymbol{k}}$ is the direction of a wave.

forms that are spatially and temporally localized and are thus physically realizable.

49.5.1 Traveling plane wave

Allowing for time to evolve renders the traveling monochromatic plane wave function

$$\Phi = \mathrm{Re}[\Phi_0\, \mathrm{e}^{-\mathrm{i}\,\omega\, t}] = \mathrm{Re}[\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t)}] = |\mathcal{A}(\boldsymbol{k})|\, \mathrm{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t+\alpha)}]. \tag{49.18}$$

We here wrote complex wave amplitude according to a real amplitude and a phase shift

$$\mathcal{A}(\boldsymbol{k}) = |\mathcal{A}(\boldsymbol{k})|\, \mathrm{e}^{\mathrm{i}\,\alpha} \quad \text{with} \quad \tan\alpha = \mathrm{Im}[\mathcal{A}(\boldsymbol{k})]/\,\mathrm{Re}[\mathcal{A}(\boldsymbol{k})]. \tag{49.19}$$

The traveling plane wave *phase* function is given by

$$\mathcal{P} = \boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \alpha, \tag{49.20}$$

so that

$$\Phi = |\mathcal{A}(\boldsymbol{k})|\, \mathrm{Re}[\mathrm{e}^{\mathrm{i}\,\mathcal{P}}] = |\mathcal{A}(\boldsymbol{k})|\cos\mathcal{P}. \tag{49.21}$$

The traveling plane wave function, Φ, depends on the wavevector as well as the space and time point. It is also a function of the angular frequency, ω. However, recall that for the study of waves realized by a physical system, once the wavevector is known then the angular frequency is specified through the dispersion relation (49.1).

The phase factor on the wave amplitude in equation (49.19) is generally a function of wavevector, $\alpha = \alpha(\boldsymbol{k})$. However, for most applications it is taken as a constant, in which case it is referred to as the *standard phase*.

49.5.2 Characterizing the wave

Wave period

The wave function (49.18) for the traveling plane wave takes on the same value for all space and time points with a phase, $\mathcal{P}$, that is shifted by any integer multiple of 2π. By fixing a point in space, the plane wave is identical for all times, t_n, satisfying

$$\omega\, t_n = \omega\, t + 2\,\pi\, n = \omega\,(t + 2\,\pi\, n/\omega). \tag{49.22}$$

Hence, the wave period is given by

$$\text{wave period} = 2\,\pi/\omega. \tag{49.23}$$

Wavelength

By fixing time, we see that the plane wave is identical for all space points, $\boldsymbol{x}_n$, satisfying

$$\boldsymbol{k}\cdot\boldsymbol{x}_n = \boldsymbol{k}\cdot\boldsymbol{x} + 2\,\pi\, n = |\boldsymbol{k}|\,(\boldsymbol{x}\cdot\hat{\boldsymbol{k}} + 2\,\pi\, n/|\boldsymbol{k}|), \tag{49.24}$$

which allows us to identify $2\,\pi/|\boldsymbol{k}|$ as the *wavelength*, which we write as[8]

$$\Lambda = 2\,\pi/|\boldsymbol{k}| \Longrightarrow \boldsymbol{k} = 2\,\pi\,\hat{\boldsymbol{k}}/\Lambda. \tag{49.25}$$

Figure 49.1 provides an example cosine wave in one-dimension, illustrating the wavelength and traveling nature of the wave.

[8] We choose the uppercase, Λ, to denote wavelength rather than the more commonly used λ. We do so in order to distinguish the wavelength, Λ, from the longitude, λ, that commonly appears in this book.

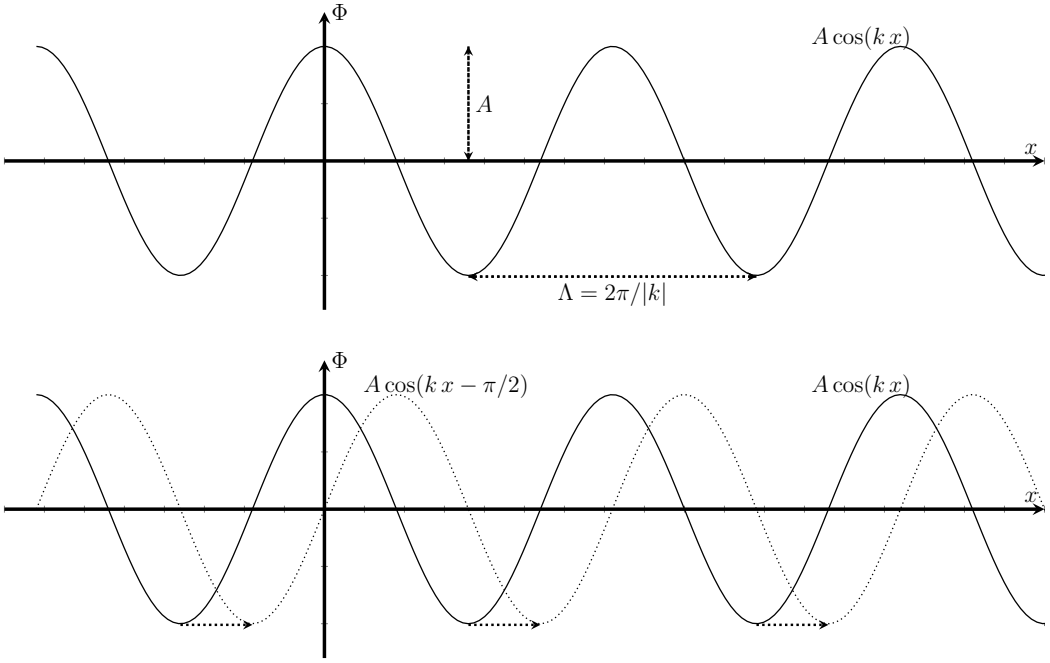

FIGURE 49.1: Top panel: a cosine wave, $\Phi = A\cos(k\,x - \omega\,t)$, along the x-axis at $t = 0$, with wavelength $\Lambda = 2\pi/|k|$, wavevector $\boldsymbol{k} = k\,\hat{\boldsymbol{x}}$, and real amplitude, A. Lower panel: two snapshots of a traveling cosine wave, one shown at $t = 0$ as in the top panel, and another shown a quarter period later, at $\omega\,t = \pi/2$. With $k > 0$ and $\omega\,t > 0$, as shown in this figure, a point with constant phase moves in the $+\hat{\boldsymbol{x}}$ direction. Correspondingly, as the phase becomes more negative (as time increases), the wave form moves to the right, in the direction of the wave propagation. If $k < 0$ then the phase propagates in the $-\hat{\boldsymbol{x}}$ direction.

Phase velocity and phase speed

When observing a traveling plane wave from a fixed point in space, one wavelength passes by the point within a single wave period. We refer to the *phase velocity*, $\boldsymbol{c}_{\text{p}}$, as the velocity of a point fixed on a phase surface and traveling in the direction of the wavevector. Its magnitude is the *phase speed*, C_{p}, which is the speed that the phase moves in the direction of the wavevector,

$$\boldsymbol{c}_{\text{p}} = C_{\text{p}}\,\hat{\boldsymbol{k}} = (\omega/|\boldsymbol{k}|)\,\hat{\boldsymbol{k}} \Longrightarrow C_{\text{p}} = \boldsymbol{c}_{\text{p}} \cdot \hat{\boldsymbol{k}} = (2\pi/|\boldsymbol{k}|)/(2\pi/\omega) = \omega/|\boldsymbol{k}| \geq 0, \tag{49.26}$$

which allows us to write the angular frequency as

$$\omega = \boldsymbol{c}_{\text{p}} \cdot \boldsymbol{k} = C_{\text{p}}\,|\boldsymbol{k}|. \tag{49.27}$$

Figure 49.2 provides an illustration of the phase velocity and phase speed.

An equivalent means to understand the phase velocity is to consider the time derivative, $\text{D}_{\text{p}}/\text{D}t$, defined to measure time changes within the reference frame of a point on a constant phase surface

$$\frac{\text{D}_{\text{p}}\mathcal{P}}{\text{D}t} \equiv \partial_t + \boldsymbol{c}_{\text{p}} \cdot \nabla, \tag{49.28}$$

in which case

$$\frac{\text{D}_{\text{p}}\mathcal{P}}{\text{D}t} = (\partial_t + \boldsymbol{c}_{\text{p}} \cdot \nabla)(\boldsymbol{x} \cdot \boldsymbol{k} - \omega\,t) = \boldsymbol{c}_{\text{p}} \cdot \boldsymbol{k} - \omega = 0. \tag{49.29}$$

We are thus led to the expression for the phase speed and angular frequency

$$C_{\mathrm{p}} = \hat{\boldsymbol{k}} \cdot \frac{\mathrm{D}_{\mathrm{p}}\boldsymbol{x}}{\mathrm{D}t} \quad \text{and} \quad \omega = \boldsymbol{c}_{\mathrm{p}} \cdot \boldsymbol{k} = \boldsymbol{k} \cdot \frac{\mathrm{D}_{\mathrm{p}}\boldsymbol{x}}{\mathrm{D}t}. \tag{49.30}$$

The wave phase time derivative (49.28) is directly analogous to the material time derivative,

$$\frac{\mathrm{D}}{\mathrm{D}t} = \partial_t + \boldsymbol{v} \cdot \nabla, \tag{49.31}$$

defined in the reference frame following the velocity of a fluid particle (Section 17.4). Likewise, in Section 50.3.2 we define the time derivative following the group velocity, $\boldsymbol{c}_{\mathrm{g}}$, in which case $\boldsymbol{c}_{\mathrm{p}}$ in equation (49.28) is replaced by $\boldsymbol{c}_{\mathrm{g}}$.

Phase distance

We can define the phase speed in another manner by introducing the projection of the position vector along the direction of the wavevector

$$S_{\hat{\boldsymbol{k}}} \equiv \hat{\boldsymbol{k}} \cdot \boldsymbol{x}, \tag{49.32}$$

which we refer to as the *phase distance*. Note that $S_{\hat{\boldsymbol{k}}}$ can be positive or negative, depending on the direction of the wavevector. The wavelength as defined by equation (49.24) takes on the form

$$\boldsymbol{k} \cdot \boldsymbol{x}_n = \boldsymbol{k} \cdot \boldsymbol{x} + 2\,\pi\,n = |\boldsymbol{k}|\,(S_{\hat{\boldsymbol{k}}} + 2\,\pi\,n/|\boldsymbol{k}|). \tag{49.33}$$

As such, the phase speed is the change in the position of the constant phase lines in the direction of the wavevector, so that

$$C_{\mathrm{p}} = \left[\frac{\partial S_{\hat{\boldsymbol{k}}}}{\partial t}\right]_{\mathcal{P}} = -\frac{\partial \mathcal{P}/\partial t}{\partial \mathcal{P}/\partial S_{\hat{\boldsymbol{k}}}} = \omega/|\boldsymbol{k}|. \tag{49.34}$$

For this equation we made use of some basic mathematics of generalized surfaces as detailed in Section 63.12.2. Finally, this notation allows us to write the phase function as

$$\mathcal{P} = \boldsymbol{k} \cdot \boldsymbol{x} - \omega\,t + \alpha = |\boldsymbol{k}|\,(S_{\hat{\boldsymbol{k}}} - C_{\mathrm{p}}\,t) + \alpha. \tag{49.35}$$

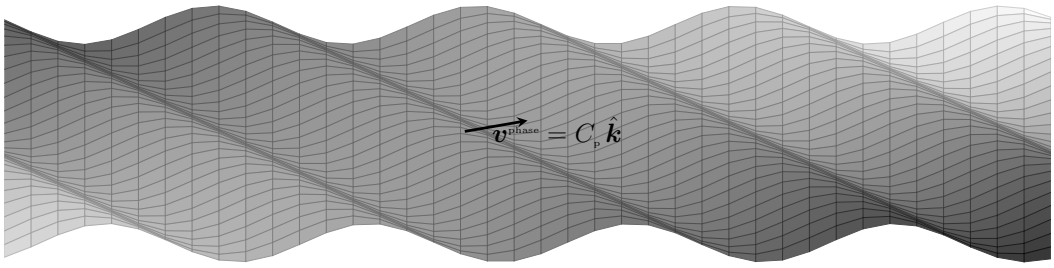

FIGURE 49.2: A mesh plot of a plane wave with phase velocity, $\boldsymbol{c}_{\mathrm{p}} = C_{\mathrm{p}}\,\hat{\boldsymbol{k}} = (\omega/|\boldsymbol{k}|)\,\hat{\boldsymbol{k}}$, pointing perpendicular to surfaces of constant phase.

49.5.3 Wavenumber and factors of 2π

The magnitude of the wavevector, $|\boldsymbol{k}|$, appears in many places in wave kinematics, such as in the definition (49.25) of the wavelength. As a shorthand terminology, we refer to $|\boldsymbol{k}|$ as the

wavenumber, with the wavenumber related to the wavelength via

$$|\boldsymbol{k}| = 2\pi/\Lambda. \tag{49.36}$$

The wavenumber measures 2π times the number of waves per unit length, so that the wavenumber measures the *spatial angular frequency* of a wave. In some contexts it is useful to introduce the *reduced wavelength*

$$\lambda\!\!\!^{-} = \Lambda/2\pi, \tag{49.37}$$

so that the wavenumber is given by the inverse reduced wavelength

$$|\boldsymbol{k}| = \lambda\!\!\!^{-1}. \tag{49.38}$$

Alternatively, it is sometimes convenient to work with the *reduced wavenumber* as introduced in Section 8.3.7 when discussing Fourier transforms

$$\bar{k} = |\boldsymbol{k}|/2\pi. \tag{49.39}$$

Hence, the reduced wavenumber is the inverse wavelength

$$\bar{k} = 1/\Lambda \tag{49.40}$$

so that $\bar{k}$ measures the number of waves per unit length.

In Section 8.3.7 we raised some issues about various conventions for placing 2π factors in Fourier analysis. We further those concerns by noting that the 2π factor associated with wavenumbers can be unclear in the literature. The ambiguity occurs when a particular length scale, L, is considered, yet it is not specified whether the length scale refers to a wavelength, in which case the corresponding wavenumber is $|\boldsymbol{k}| = 2\pi/L$, or to a reduced wavelength, in which case the corresponding wavenumber is $|\boldsymbol{k}| = 1/L$. The bottomline is that care is necessary to ensure the proper usage.

49.5.4 Superposition of plane waves

Through the principle of superposition respected by linear waves, realistic linear waves can be decomposed into the sum or integral of modulated plane waves. Indeed, this decomposition forms the mathematical basis for *Fourier analysis* detailed in Chapter 8. We here offer an illustration of this decomposition by considering how two plane waves combine, and then how three plane waves combine.

Consider the sum of two plane waves, each with same real amplitude of unity (in arbitrary units), and with distinct (but close) wavevectors and angular frequencies

$$\boldsymbol{k}_\pm = \boldsymbol{k} \pm \Delta\boldsymbol{k} \quad \text{and} \quad \omega_\pm = \omega \pm \Delta\omega \quad \text{with} \quad |\Delta\boldsymbol{k}|/|\boldsymbol{k}| \ll 1 \quad \text{and} \quad |\Delta\omega/\omega| \ll 1. \tag{49.41}$$

The resulting superposition of the two waves is given by

$$\text{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k}_+ - t\,\omega_+)} + \mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k}_- - t\,\omega_-)}] = 2\cos(\Delta\boldsymbol{k}\cdot\boldsymbol{x} - \Delta\omega\,t)\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t). \tag{49.42}$$

The $\cos(\Delta\boldsymbol{k}\cdot\boldsymbol{x} - \Delta\omega\,t)$ factor acts as a low wavenumber and low frequency modulation of the second factor, $\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)$, which is much more rapidly varying in space and time. We illustrate this superposition of two plane waves in Figure 49.3 for time $t = 0$. Adding a third wave, also with unit amplitude, $\exp[\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)]$, renders the superposition

$$\text{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k}_+ - t\,\omega_+)} + \mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k} - t\,\omega)} + \mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k}_- - t\,\omega_-)}] \;=\; 4\cos^2[(\Delta\boldsymbol{k}\cdot\boldsymbol{x} - \Delta\omega\,t)/2]\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t). \tag{49.43}$$

The third wave serves to double the amplitude through constructive interference, while also broadening the width of the low amplitude destructive interference region. Additionally, the modulation function, $\cos^2[(\Delta \boldsymbol{k} \cdot \boldsymbol{x} - \Delta\omega\, t)/2]$, is rendered non-negative when adding the third wave. We also illustrate this superposition in Figure 49.3.

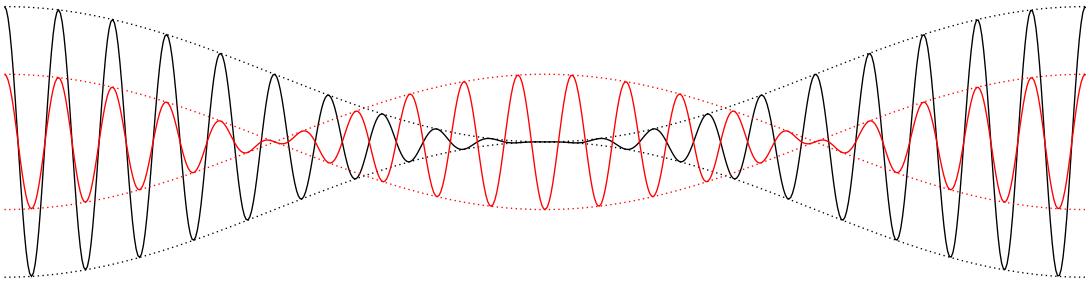

FIGURE 49.3: Superposition of two plane waves (red lines; equation (49.42)) and three plane waves (black lines; equation (49.43)), with all plane waves having equal real amplitudes and here shown for time $t = 0$. Notice how in both cases, a high wavenumber wave (short wave) is modulated by a low wavenumber wave (long wave). The units in this figure are arbitrary.

49.5.5 Wave ansatz

The principle of superposition allows us to study properties of a linear wave equation, in particular the dispersion relation, by inserting a single plane wave into the wave equation. In this manner we refer to the plane wave as an *ansatz*, which is a German word meaning "educated guess".

49.5.6 Summary of kinematic wave properties

In Table 49.2, we summarize the variety of kinematic properties of waves. In this book we work mostly with the angular frequency, ω, the wavevector, $\boldsymbol{k}$, and the wavenumber, $|\boldsymbol{k}|$. Even so, it is useful to be versed in the alternative choices.

NAME	MATH SYMBOL	DIMENSIONS	MATH RELATION
period	τ_{period}	T	$\tau_{\text{period}} = 2\pi/\omega$
angular frequency	ω	T^{-1}	$\omega = 2\pi/\tau_{\text{period}}$
frequency	f	T^{-1}	$f = \omega/2\pi = 1/\tau_{\text{period}}$
wavenumber	$\lvert\boldsymbol{k}\rvert$	L^{-1}	$\lvert\boldsymbol{k}\rvert = 2\pi/\Lambda$
wavevector	$\boldsymbol{k}$	L^{-1}	$\boldsymbol{k} = \lvert\boldsymbol{k}\rvert\, \hat{\boldsymbol{k}}$
reduced wavevector	$\bar{\boldsymbol{k}}$	L^{-1}	$\bar{\boldsymbol{k}} = \boldsymbol{k}/2\pi$
wavelength	Λ	L	$\Lambda = 2\pi/\lvert\boldsymbol{k}\rvert = 1/\lvert\bar{\boldsymbol{k}}\rvert$
reduced wavelength	$\lambda\!\!\!^{-}$	L	$\lambda\!\!\!^{-} = \Lambda/2\pi = 1/\lvert\boldsymbol{k}\rvert$

TABLE 49.2: Summarizing the variety of terms used to kinematically describe waves. In this book we mostly use the angular frequency, $\omega \geq 0$, the wavevector, $\boldsymbol{k}$, and the wavenumber, $|\boldsymbol{k}|$.

49.6 Free wave packets

The modulation of waves in Figure 49.3 serve to organize waves into $\boldsymbol{x}$-space regions known as *wave trains*. A *wave packet* is a train of free waves that are organized into a localized (and moving) region of $\boldsymbol{x}$-space. Localization is enabled by a *modulation function* and the plane wave

modes that are organized within the packet are known as *carrier waves*.[9] Wave trains and wave packets are generated by a *wavemaker*. For example, consider a wavemaker oscillating at a known frequency, ω_0. Ramping up the wavemaker amplitude for a period of time, and then ramping it down towards zero, then produces a group of waves that are localized in time and have angular frequency and wavenumber centered on ω_0 and $\boldsymbol{k}_0$, where $\boldsymbol{k}_0$ is determined by the dispersion relation given ω_0. In the laboratory, the wavemaker might be an oscillating piston placed in a tank of water, such as considered for acoustic waves in Section 51.8. In the natural environment, a wavemaker might be a storm that passes over the ocean and generates surface gravity waves, or an atmospheric convective event that generates atmospheric internal gravity waves.

Mathematically, wave packets are described by complementary wave functions in $\boldsymbol{k}$-space and $\boldsymbol{x}$-space. The $\boldsymbol{k}$-space representation, $\mathcal{A}(\boldsymbol{k}, t)$, is also called the amplitude function for the $\boldsymbol{x}$-space wave function, $\Phi(\boldsymbol{x}, t)$. In the world of mathematical abstraction, we prepare wave packets with a specified $\boldsymbol{k}$-space initial condition, $\mathcal{A}(\boldsymbol{k}, t = 0)$, that has a corresponding $\boldsymbol{x}$-space initial condition, $\Phi(\boldsymbol{x}, t = 0)$, determined by the inverse Fourier transform. Upon initializing the packets we study their evolution. Since the packets are constructed by linear plane waves, their evolution is determined by the superposed and evolving constituent plane waves. What distinguishes a packet of acoustic waves from a packet of gravity waves, for example, is the dispersion relation, which is specific to the physics describing the particular waves.

49.6.1 Phase velocity, group velocity, and the dispersion relation

Examination of Figure 49.3 suggests that the velocity of a wave packet's center is not directly related to the phase velocity of the constituent plane waves. Rather, it is determined by motion of the modulation function. For the one-dimensional examples of Figure 49.3, the packet motion is determined by $\Delta\omega/\Delta k$. In this section we generalize this result to the *group velocity* determined by[10]

$$\boldsymbol{c}_{\text{g}} = \nabla_{\boldsymbol{k}} \varpi(\boldsymbol{k}). \tag{49.44}$$

In this equation, we introduced the wave dispersion relation (49.1) that specifies how the angular frequency is functionally connected to the wavevector. We see that the group velocity is determined by the gradient of the dispersion relation in wavevector space, which prompted us to expose a wavevector subscript on the gradient operator. As defined, the group velocity points in the $\boldsymbol{k}$-space direction of maximum increase for the angular frequency. Figure 49.4 illustrates two dispersion relations for a one-dimensional wave.

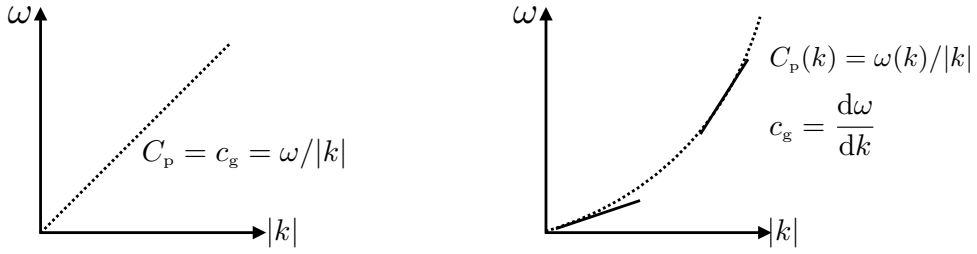

FIGURE 49.4: Example dispersion relations for one-dimensional waves. Left panel: a non-dispersive wave has a phase speed, C_{p}, that is a constant so that all waves, regardless their wavelength or angular frequency, move at the same speed. Right panel: a dispersive wave, here shown for a wave whose phase speed increases as the wave number increases, as does the group velocity.

[9] From an engineering perspective, the carrier wave carries the most useful information contained in the wave packet signal, hence the name.

[10] Many dispersion relations are naturally written as ω^2, in which case it is simpler to compute the group velocity according to $\nabla_{\boldsymbol{k}} \omega^2 = 2\,\omega\,\boldsymbol{c}_{\text{g}}$.

The dispersion relation for non-dispersive waves results in phase speeds that are independent of the wavenumber so that

$$\varpi = C_{\mathsf{p}} \, |\boldsymbol{k}|, \tag{49.45}$$

where $C_{\mathsf{p}} > 0$ is the constant phase speed. Evidently, the angular frequency is identical for all waves having the same wavenumber. That is, the angular frequency only cares about the wavelength of the non-dispersive wave and not about its direction. Furthermore, we see that the continuum of wavenumbers results in a continuum of angular frequencies, with higher wavenumbers rendering higher angular frequencies. This behavior is familiar for both electromagnetic and acoustic waves, which are both non-dispersive, in which waves of smaller wavelength (higher wavenumber) have higher frequencies. We depict this sort of dispersion relation in the left panel of Figure 49.4.

Dispersive waves are characterized by a dispersion relation with the phase speed a function of the wavevector

$$\varpi = C_{\mathsf{p}}(\boldsymbol{k}) \, |\boldsymbol{k}| > 0. \tag{49.46}$$

Again, the phase speed and angular frequency are positive, but now we find the phase speed depends on the wavenumber and possibly the wave direction. We provide an example for this sort of dispersion relation in the right panel of Figure 49.4.

49.6.2 A continuum of traveling plane waves

Consider the superposition of a continuum of traveling plane waves given by the integral expression for the wave function

$$\Phi(\boldsymbol{x}, t) = \frac{1}{(2\pi)^3} \int \mathscr{A}(\boldsymbol{k}) \, \mathrm{e}^{\mathrm{i} \, (\boldsymbol{k} \cdot \boldsymbol{x} - \varpi(\boldsymbol{k}) \, t)} \, \mathrm{d}\boldsymbol{k}. \tag{49.47}$$

The wave function, $\Phi(\boldsymbol{x}, t)$, is constructed through combining a continuum of traveling plane waves, with the amplitude function, $\mathscr{A}(\boldsymbol{k})$, determining which wavevectors contribute to the packet and by how much they contribute. The integral in equation (49.47) is computed over all the three-dimensional wavevector space ($\boldsymbol{k}$-space). For example, a Cartesian representation of a wavevector volume element is written

$$\mathrm{d}\boldsymbol{k} = \mathrm{d}k_x \, \mathrm{d}k_y \, \mathrm{d}k_z, \tag{49.48}$$

with the integration limits $k_x, k_y, k_z \in (-\infty, \infty)$, corresponding to waves traveling in all directions and spanning all wavenumbers. Furthermore, the angular frequency in equation (49.47) is specified by the dispersion relation,

$$\omega = \varpi(\boldsymbol{k}) \geq 0, \tag{49.49}$$

so that the wave function (49.47) is built from a continuum of wavevectors with corresponding angular frequencies.

49.6.3 The wave function is real

For brevity we often drop the Re operator on the wave function (49.47). Even so, it is critical to note that the wave function is real, which has implications for how we compute the $\boldsymbol{k}$-space amplitude function, $\mathscr{A}(\boldsymbol{k})$. For example, if the amplitude function is real[11]

$$\mathscr{A}(\boldsymbol{k}) = A(\boldsymbol{k}) = A^*(\boldsymbol{k}), \tag{49.50}$$

[11] The star is the complex conjugate operator.

then the wave function takes the form

$$\Phi(\boldsymbol{x},t) = \frac{1}{(2\pi)^3}\int A(\boldsymbol{k})\cos[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t]\,\mathrm{d}\boldsymbol{k}. \tag{49.51}$$

However, there are cases where we need the extra phase degree of freedom afforded by a complex amplitude function, in which case the real part of equation (49.47) leads to

$$\Phi(\boldsymbol{x},t) = \mathrm{Re}\left[\frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)}\,\mathrm{d}\boldsymbol{k}\right] \tag{49.52a}$$

$$= \frac{1}{2\,(2\pi)^3}\int \left[\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)} + \mathcal{A}^*(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)}\right]\mathrm{d}\boldsymbol{k}. \tag{49.52b}$$

Since the integral is over all of $\boldsymbol{k}$-space, we can write

$$\int \mathcal{A}^*(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)}\,\mathrm{d}\boldsymbol{k} = \int \mathcal{A}^*(-\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}+\varpi(-\boldsymbol{k})\,t)}\,\mathrm{d}\boldsymbol{k}, \tag{49.53}$$

in which case the wavefunction takes the form

$$\Phi(\boldsymbol{x},t) = \frac{1}{2\,(2\pi)^3}\int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,[\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} + \mathcal{A}^*(-\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,\varpi(-\boldsymbol{k})\,t}]\,\mathrm{d}\boldsymbol{k}, \tag{49.54}$$

and its time tendency is

$$\partial_t\Phi(\boldsymbol{x},t) = \frac{\mathrm{i}}{2\,(2\pi)^3}\int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,[-\varpi(\boldsymbol{k})\,\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} + \varpi(-\boldsymbol{k})\,\mathcal{A}^*(-\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,\varpi(-\boldsymbol{k})\,t}]\,\mathrm{d}\boldsymbol{k}. \tag{49.55}$$

49.6.4 Initializing the wave packet

We often consider wave packets in the context of initial value problems, whereby the packet is initialized according to some process such as described at the start of this section. We are concerned with freely moving wave packets, so that boundary conditions are not considered here. Thus, we consider three possibilities: initializing the packet's wave function, initializing its time tendency, or initializing both the wave function and its time tendency. To describe these initial conditions requires the use of complex $\boldsymbol{k}$-space amplitudes. Setting $t = 0$ in equation (49.54) for the wave function and equation (49.55) for the time tendency leads to

$$\Phi_0(\boldsymbol{x}) \equiv \Phi(\boldsymbol{x},0) = \frac{1}{2\,(2\pi)^3}\int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,[\mathcal{A}(\boldsymbol{k}) + \mathcal{A}^*(-\boldsymbol{k})]\,\mathrm{d}\boldsymbol{k} \tag{49.56a}$$

$$\dot{\Phi}_0(\boldsymbol{x}) \equiv \partial_t\Phi(\boldsymbol{x},0) = \frac{\mathrm{i}}{2\,(2\pi)^3}\int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,[-\varpi(\boldsymbol{k})\,\mathcal{A}(\boldsymbol{k}) + \varpi(-\boldsymbol{k})\,\mathcal{A}^*(-\boldsymbol{k})]\,\mathrm{d}\boldsymbol{k}. \tag{49.56b}$$

Inverting the Fourier transform for the initial condition (49.56a) and the initial tendency (49.56b) renders

$$\mathcal{A}(\boldsymbol{k}) + \mathcal{A}^*(-\boldsymbol{k}) = 2\int \Phi_0(\boldsymbol{x})\,\mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{x} \tag{49.57a}$$

$$-\varpi(\boldsymbol{k})\,\mathcal{A}(\boldsymbol{k}) + \varpi(-\boldsymbol{k})\,\mathcal{A}^*(-\boldsymbol{k}) = -2\,\mathrm{i}\int \dot{\Phi}_0(\boldsymbol{x})\,\mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{x}, \tag{49.57b}$$

which then leads to the $\boldsymbol{k}$-space amplitude

$$\mathcal{A}(\boldsymbol{k}) = \frac{2}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\int [\varpi(-\boldsymbol{k})\,\Phi_0(\boldsymbol{x}) + \mathrm{i}\,\dot{\Phi}_0(\boldsymbol{x})]\,\mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{x} \tag{49.58a}$$

$$\mathcal{A}^*(-\boldsymbol{k}) = \frac{2}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})} \int [\varpi(\boldsymbol{k})\, \Phi_0(\boldsymbol{x}) - \mathrm{i}\, \dot{\Phi}_0(\boldsymbol{x})]\, \mathrm{e}^{-\mathrm{i}\, \boldsymbol{k}\cdot\boldsymbol{x}}\, \mathrm{d}\boldsymbol{x}. \tag{49.58b}$$

Notice that

$$\mathcal{A}(\boldsymbol{k}) = \mathcal{A}^*(-\boldsymbol{k}) \quad \text{if } \dot{\Phi}_0 = 0, \tag{49.59}$$

which is referred to as *conjugate symmetry* when studying Fourier transforms in Section 8.3.2, whereas

$$\mathcal{A}(\boldsymbol{k}) = -\mathcal{A}^*(-\boldsymbol{k}) \quad \text{if } \Phi_0 = 0, \tag{49.60}$$

which we refer to as *conjugate anti-symmetry*.

Now substitute the amplitude functions (49.58a) and (49.58b) into the wave function (49.55), and rearrange to find

$$\begin{aligned}\Phi(\boldsymbol{x}, t) = \frac{1}{(2\pi)^3} \int \left[\int \frac{\mathrm{e}^{\mathrm{i}\, \boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{\xi})}\, [\varpi(-\boldsymbol{k})\, \mathrm{e}^{-\mathrm{i}\, \varpi(\boldsymbol{k})\, t} + \varpi(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\, \varpi(-\boldsymbol{k})\, t}]}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\, \mathrm{d}\boldsymbol{k} \right] \Phi_0(\boldsymbol{\xi})\, \mathrm{d}\boldsymbol{\xi} \\ + \frac{\mathrm{i}}{(2\pi)^3} \int \left[\int \frac{\mathrm{e}^{\mathrm{i}\, \boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{\xi})}\, [\mathrm{e}^{-\mathrm{i}\, \varpi(\boldsymbol{k})\, t} - \mathrm{e}^{\mathrm{i}\, \varpi(-\boldsymbol{k})\, t}]}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\, \mathrm{d}\boldsymbol{k} \right] \dot{\Phi}_0(\boldsymbol{\xi})\, \mathrm{d}\boldsymbol{\xi}.\end{aligned} \tag{49.61}$$

This equation can be written as the convolution of the initial conditions with two kernel functions

$$\Phi(\boldsymbol{x}, t) = \int [\dot{G}(\boldsymbol{x} - \boldsymbol{\xi}, t)\, \Phi_0(\boldsymbol{\xi}) + G(\boldsymbol{x} - \boldsymbol{\xi}, t)\, \dot{\Phi}_0(\boldsymbol{\xi})]\, \mathrm{d}\boldsymbol{\xi}, \tag{49.62}$$

where the kernels are

$$G(\boldsymbol{x}, t) \equiv \frac{\mathrm{i}}{(2\pi)^3} \int \frac{\mathrm{e}^{\mathrm{i}\, \boldsymbol{k}\cdot\boldsymbol{x}}\, [\mathrm{e}^{-\mathrm{i}\, \varpi(\boldsymbol{k})\, t} - \mathrm{e}^{\mathrm{i}\, \varpi(-\boldsymbol{k})\, t}]}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\, \mathrm{d}\boldsymbol{k} \tag{49.63a}$$

$$\dot{G}(\boldsymbol{x}, t) \equiv \frac{1}{(2\pi)^3} \int \frac{\mathrm{e}^{\mathrm{i}\, \boldsymbol{k}\cdot\boldsymbol{x}}\, [\varpi(-\boldsymbol{k})\, \mathrm{e}^{-\mathrm{i}\, \varpi(\boldsymbol{k})\, t} + \varpi(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\, \varpi(-\boldsymbol{k})\, t}]}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\, \mathrm{d}\boldsymbol{k}. \tag{49.63b}$$

In fact, the kernels are related by a time derivative, which can be seen by writing them in the following form[12]

$$G(\boldsymbol{x}, t) = -\frac{2}{(2\pi)^3} \int \frac{\sin[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\, t]}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\, \mathrm{d}\boldsymbol{k} \tag{49.64a}$$

$$\dot{G}(\boldsymbol{x}, t) = \frac{2}{(2\pi)^3} \int \frac{\varpi(\boldsymbol{k}) \cos[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\, t)]}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\, \mathrm{d}\boldsymbol{k} = \partial_t G(\boldsymbol{x}, t). \tag{49.64b}$$

Evidently, the kernels provide a wave mechanism to propagate information about the initial conditions outward in space as time moves forward. In this manner, these functions are *Green's functions* such as those studied in Chapter 9. Indeed, the solution (49.64b) corresponds to the Green's function (9.232), which was derived for the initial-boundary value problem with non-dispersive waves. Here, we are just concerned with the initial condition problem for free wave packets where the waves can be either non-dispersive or dispersive. It is satisfying that even dispersive waves allow us to write the wave packet evolution in terms of Green's functions as in equation (49.62).

49.6.5 The case of non-dispersive waves

To help further understand the nature of the wave packet equation (49.62), and to connect it to the non-dispersive Green's function (9.232), consider a packet of non-dispersive waves for $t \geq 0$

[12] To derive equation (49.64b), recall that the integral is over all of $\boldsymbol{k}$-space.

and in one space dimension.[13] For this case the dispersion relation takes the form

$$\varpi(\boldsymbol{k}) = C_{\mathsf{p}}\,|k| \implies \boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t = k\,x - C_{\mathsf{p}}\,|k|\,t, \tag{49.65}$$

where $C_{\mathsf{p}} > 0$ is the constant phase speed. In this case we make use of the Dirac delta expression (8.113) in the form

$$\delta(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k = \frac{2}{2\pi}\int_{0}^{\infty} \cos(k\,x)\,\mathrm{d}k, \tag{49.66}$$

so that

$$\begin{aligned}
\dot{G}(x,t) &= \frac{1}{2\pi}\int_{-\infty}^{\infty} \cos(k\,x - C_{\mathsf{p}}\,|k|\,t)\,\mathrm{d}k && \text{(49.67a)}\\
&= \frac{1}{2\pi}\int_{-\infty}^{0} \cos(k\,x + C_{\mathsf{p}}\,k\,t)\,\mathrm{d}k + \frac{1}{2\pi}\int_{0}^{\infty} \cos(k\,x - C_{\mathsf{p}}\,k\,t)\,\mathrm{d}k && \text{(49.67b)}\\
&= \frac{1}{2\pi}\int_{0}^{\infty} \cos(k\,x + C_{\mathsf{p}}\,k\,t)\,\mathrm{d}k + \frac{1}{2\pi}\int_{0}^{\infty} \cos(k\,x - C_{\mathsf{p}}\,k\,t)\,\mathrm{d}k && \text{(49.67c)}\\
&= [\delta(x + C_{\mathsf{p}}\,t) + \delta(x - C_{\mathsf{p}}\,t)]/2. && \text{(49.67d)}\\
&= \delta(C_{\mathsf{p}}\,t - |x|)/2. && \text{(49.67e)}
\end{aligned}$$

Hence, $\dot{G}$ is built from two Dirac delta wave fronts that move in opposite directions at speed C_{p}. Its time integral leads to the Green's function as a Heaviside step function (see Section 7.5)

$$G(x,t) = \mathcal{H}(C_{\mathsf{p}}\,t - |x|)/(2\,C_{\mathsf{p}}). \tag{49.68}$$

To within a constant factor, the Green's function (49.68) is the causal free space Green's function (9.220a) derived for the one dimensional non-dispersive waves. Making use of these results in the wave packet equation (49.64b) leads to

$$\begin{aligned}
\Phi(x,t) &= \frac{1}{2}\int_{-\infty}^{\infty} \delta(C_{\mathsf{p}}\,t - |x-\xi|)\,\Phi_0(\xi)\,\mathrm{d}\xi + \frac{1}{2\,C_{\mathsf{p}}}\int_{-\infty}^{\infty} \mathcal{H}(C_{\mathsf{p}}\,t - |x-\xi|)\,\dot{\Phi}_0(\xi)\,\mathrm{d}\xi && \text{(49.69a)}\\
&= [\Phi_0(x - C_{\mathsf{p}}\,t) + \Phi_0(x + C_{\mathsf{p}}\,t)]/2 + \frac{1}{2\,C_{\mathsf{p}}}\int_{x-C_{\mathsf{p}}\,t}^{x+C_{\mathsf{p}}\,t} \dot{\Phi}_0(\xi)\,\mathrm{d}\xi. && \text{(49.69b)}
\end{aligned}$$

For the second equality we used

$$\begin{aligned}
\int_{-\infty}^{\infty} \mathcal{H}(C_{\mathsf{p}}\,t - |x-\xi|)\,\dot{\Phi}_0(\xi)\,\mathrm{d}\xi &= \int_{-\infty}^{\infty} \mathcal{H}(C_{\mathsf{p}}\,t - |y|)\,\dot{\Phi}_0(x+y)\,\mathrm{d}y && \text{(49.70a)}\\
&= \int_{-C_{\mathsf{p}}\,t}^{C_{\mathsf{p}}\,t} \dot{\Phi}_0(x+y)\,\mathrm{d}y && \text{(49.70b)}\\
&= \int_{x-C_{\mathsf{p}}\,t}^{x+C_{\mathsf{p}}\,t} \dot{\Phi}_0(\xi)\,\mathrm{d}\xi. && \text{(49.70c)}
\end{aligned}$$

Evidently, for non-dispersive waves the initial condition, $\Phi_0(x)$, splits in half as two signals that propagate without distortion in opposite directions, whereas the initial tendency, $\dot{\Phi}_0(x)$, contributes via an integral over the *domain of influence*, which is given by the spatial region $[x - C_{\mathsf{p}}\,t, x + C_{\mathsf{p}}\,t]$ (see Figure 6.3 for a discussion of the domain of influence).

[13] This case corresponds to the infinite string discussed in Section 7.8 of *Stakgold* (2000b). We also consider packets of non-dispersive waves in Section 49.7.7, with a focus on Gaussian packets.

49.6.6 Wave trains and wave packets

Consider a wave train initialized according to[14]

$$\Phi_0(\boldsymbol{x}) = \mathrm{Re}[a(\epsilon\,\boldsymbol{x})\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}_0\cdot\boldsymbol{x}}] = a(\epsilon\,\boldsymbol{x})\cos(\boldsymbol{k}_0\cdot\boldsymbol{x}), \tag{49.71}$$

where a is a real $\boldsymbol{x}$-space modulation function and ϵ^{-1}, is a length scale that is large relative to the wavelength of the carrier wave; i.e., $\epsilon^{-1} \ll |\boldsymbol{k}_0|$. Figure 49.5 provides an example of such a wave train. A further modulation of the $\boldsymbol{x}$-space wave train into a wave packet can be realized by an amplitude that sets $\Phi_0(\boldsymbol{x})$ to zero (or exponentially close to zero) for length scales larger than ϵ^{-1}.

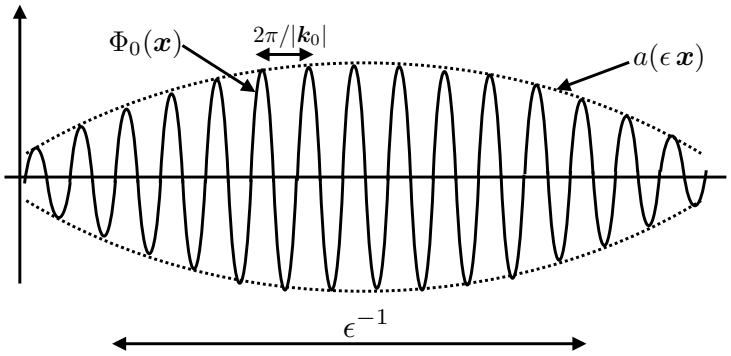

FIGURE 49.5: Example of a wave train comprised of a modulated amplitude function, $a(\epsilon\,\boldsymbol{x})$, acting on a carrier wave, $\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}_0\cdot\boldsymbol{x}}$. The modulation function has a scale ϵ^{-1}, which is large relative to that of the wave length, $2\pi/|\boldsymbol{k}_0|$, so that $2\pi/\epsilon \ll |\boldsymbol{k}_0|$.

For either a wave train or wave packet to be dominated by a single carrier wave of wavenumber $\boldsymbol{k}_0$, the $\boldsymbol{k}$-space wave amplitude must vanish for wavevectors outside of an ϵ range of $\boldsymbol{k}_0$

$$|\mathcal{A}(\boldsymbol{k})| \approx 0 \quad \text{for } |\boldsymbol{k}-\boldsymbol{k}_0| > \epsilon. \tag{49.72}$$

As a result, evolution of the $\boldsymbol{x}$-space wave packet (49.47) is dominated by the dispersion relation centerd on $\boldsymbol{k}_0$, thus motivating a Taylor series

$$\begin{aligned}\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t &\approx \boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k}_0)\,t - (k_a - k_{0a})\,[\partial_{k_a} + (1/2)\,(k_b - k_{0b})\,\partial_{k_a}\partial_{k_b}]\,\varpi(\boldsymbol{k}_0)\,t &\text{(49.73a)}\\ &= \boldsymbol{k}_0\cdot\boldsymbol{x} - \omega_0\,t + (\boldsymbol{k}-\boldsymbol{k}_0)\cdot[\boldsymbol{x} - \boldsymbol{c}_{\mathrm{g}}\,t - (t/2)\,(k_b - k_{0b})\,\partial_{k_b}\boldsymbol{c}_{\mathrm{g}}], &\text{(49.73b)}\end{aligned}$$

where we made use of the summation convention[15] and introduced the angular frequency, ω_0, and group velocity, $\boldsymbol{c}_{\mathrm{g}}$, as defined by the dispersion relation evaluated at $\boldsymbol{k}_0$

$$\omega_0 = \varpi(\boldsymbol{k}_0) \quad \text{and} \quad \boldsymbol{c}_{\mathrm{g}} = \nabla_{\boldsymbol{k}}\varpi(\boldsymbol{k}_0). \tag{49.74}$$

Plugging the Taylor expansion (49.73b) into the wave packet (49.47) renders

$$\Phi(\boldsymbol{x},t) = \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_0\cdot\boldsymbol{x}-\omega_0\,t)}\,\frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}-\boldsymbol{k}_0)\cdot\tilde{\boldsymbol{x}}}\,\mathrm{d}\boldsymbol{k} = \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_0\cdot\boldsymbol{x}-\omega_0\,t)}\,\mathcal{M}(\boldsymbol{x},t). \tag{49.75}$$

In this equation we introduced the moving position determined by the group velocity and its

[14] Note that the real operator, Re, will henceforth be dropped for brevity.

[15] We use the Cartesian version of the summation convention so there is no distinction between upstairs and downstairs indices.

derivative

$$\tilde{\boldsymbol{x}} = \boldsymbol{x} - \boldsymbol{c}_{\mathrm{g}}\, t - (t/2)\,(k_b - k_{0b})\,\partial_{k_b}\boldsymbol{c}_{\mathrm{g}} \Longleftrightarrow \tilde{x}^a = x^a - t\,\frac{\partial \varpi}{\partial k_a} - (t/2)\,(k_b - k_{0b})\,\frac{\partial^2 \varpi}{\partial_{k_a}\partial_{k_b}}. \tag{49.76}$$

The evolving packet in equation (49.75) represents a traveling plane carrier wave, $\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_0\cdot\boldsymbol{x} - \omega_0\, t)}$, with the integral term providing a moving modulation function

$$\mathcal{M}(\boldsymbol{x}, t) \equiv \frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}-\boldsymbol{k}_0)\cdot\tilde{\boldsymbol{x}}}\,\mathrm{d}\boldsymbol{k}. \tag{49.77}$$

We follow this discussion in Section 49.7 by studying one-dimensional Gaussian wave packets, where we explicitly compute the $\boldsymbol{x}$-space modulation function, and find that it is peaked at a point following the group velocity,

$$\boldsymbol{x}_{\mathrm{peak}} = \boldsymbol{x} - \boldsymbol{c}_{\mathrm{g}}\, t, \tag{49.78}$$

whereas the term, $\partial_{k_j}\boldsymbol{c}_{\mathrm{g}}$, appearing in equation (49.76) gives rise to a spread or *dispersion* of the $\boldsymbol{x}$-space packet.

49.6.7 PDE for the wave packet modulation function

To further an understanding of wave packet evolution, we derive the partial differential equation satisfied by the modulation function. For this purpose, take the space and time derivatives of $\mathcal{M}(\boldsymbol{x}, t)$ from equation (49.77) to find

$$\frac{\partial \mathcal{M}}{\partial t} = \frac{-\mathrm{i}}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,(k_a - k_{0a})\,(\partial_{k_a}\varpi + (1/2)\,(k_b - k_{0b})\,\partial_{k_b}\partial_{k_a}\varpi)\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}-\boldsymbol{k}_0)\cdot\tilde{\boldsymbol{x}}}\,\mathrm{d}\boldsymbol{k} \tag{49.79a}$$

$$\frac{\partial \mathcal{M}}{\partial x^a} = \frac{\mathrm{i}}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,(k_a - k_{0a})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}-\boldsymbol{k}_0)\cdot\tilde{\boldsymbol{x}}}\,\mathrm{d}\boldsymbol{k} \tag{49.79b}$$

$$\frac{\partial^2 \mathcal{M}}{\partial x^a \partial x^b} = -\frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,(k_a - k_{0a})\,(k_b - k_{0b})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}-\boldsymbol{k}_0)\cdot\tilde{\boldsymbol{x}}}\,\mathrm{d}\boldsymbol{k}, \tag{49.79c}$$

which then leads to

$$(\partial_t + \boldsymbol{c}_{\mathrm{g}}\cdot\nabla)\,\mathcal{M} = \frac{\mathrm{i}}{2}\,\frac{\partial^2 \varpi}{\partial k_a \partial k_b}\,\frac{\partial^2 \mathcal{M}}{\partial x^a \partial x^b}. \tag{49.80}$$

The left hand side reveals the time evolution of the modulation function following the group velocity, with the group velocity evaluated at the carrier wavevector, $\boldsymbol{k}_0$. The right hand side is a phase shifted (by $\pi/2$) transport of the modulation function by the *dispersion tensor*, $\mathbb{K}$, with the dispersion tensor determined by the second derivative of the dispersion relation evaluated at the carrier wavevector, $\boldsymbol{k}_0$

$$\mathbb{K}^{ab} = \left.\frac{\partial^2 \varpi}{\partial k_a \partial k_b}\right|_{\boldsymbol{k}=\boldsymbol{k}_0}. \tag{49.81}$$

The dispersion tensor is symmetric, as appropriate for a diffusion tensor (Chapter 69). However, there is no guarantee that it is positive-definite. Hence, dispersion can both broaden (as for diffusion) or sharpen (as for anti-diffusion) the wave packet.

It is important to emphasize that dispersion is distinct from dissipation. Indeed, dissipation is absent from this chapter. Evidently, modification of the modulation function arises from the dependence of the phase velocity on the wavevector, hence the name "dispersion." Dispersion is a property inherent in the waves and has nothing to do with dissipation.

49.6.8 Wave packets of non-dispersive waves

Much of the "interesting" behavior of wave packets appears for dispersive waves. Indeed, as we here show, packets of non-dispersive waves propagate their initial condition without modification, thus retaining their initial structure. We can understand this result by recalling that all waves comprising the packet move with the same phase velocity, so that the group and phase velocities are identical and constant. Hence, the packet maintains its initial organization of its waves as the packet evolves.

A vanishing dispersion tensor (49.81) is one signature that the wave packet moves coherently and without modification. As a result, the packet modulation function remains constant following the group velocity,

$$(\partial_t + \boldsymbol{c}_{\mathrm{g}} \cdot \nabla)\, \mathcal{M} = 0 \qquad \text{non-dispersive waves.} \tag{49.82}$$

The modulation function is given by equation (49.77) with a constant phase velocity

$$\mathcal{M}(\boldsymbol{x}, t) = \frac{1}{(2\pi)^3} \int \mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}-\boldsymbol{k}_0)\cdot(\boldsymbol{x}-\boldsymbol{c}_{\mathrm{g}}\,t)}\, \mathrm{d}\boldsymbol{k} = \mathcal{M}(\boldsymbol{x} - \boldsymbol{c}_{\mathrm{g}}\, t), \tag{49.83}$$

which means that the wave packet (49.75) evolves according to

$$\Phi(\boldsymbol{x}, t) = \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_0\cdot\boldsymbol{x}-\omega_0\,t)}\, \mathcal{M}(\boldsymbol{x} - \boldsymbol{c}_{\mathrm{g}}\, t). \tag{49.84}$$

Indeed, returning to the original form (49.75) of the wave packet we find that for non-dispersive waves

$$\Phi(\boldsymbol{x}, t) = \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_0\cdot\boldsymbol{x}-\omega_0\,t)}\, \frac{1}{(2\pi)^3} \int \mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}-\boldsymbol{k}_0)\cdot(\boldsymbol{x}-\boldsymbol{c}_{\mathrm{g}}\,t)}\, \mathrm{d}\boldsymbol{k} \tag{49.85a}$$

$$= \frac{1}{(2\pi)^3} \int \mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{c}_{\mathrm{g}}\,t)}\, \mathrm{d}\boldsymbol{k} \tag{49.85b}$$

$$= \Phi_0(\boldsymbol{x} - \boldsymbol{c}_{\mathrm{g}}\, t), \tag{49.85c}$$

where we introduced the initial condition, Φ_0, from equation (49.56a). Evidently, packets of non-dispersive waves translate their initial condition without any alteration, with translation determined by the group velocity as determined by the carrier wavevector, $\boldsymbol{k}_0$. We make this result compatible with the one dimensional case found in equation (49.69b) by noting that here we only focus on the carrier wavenumber, whereas for the one dimensional packet in equation (49.69b) we considered both the carrier wavenumber, $k_\circ$, and its opposite, $-k_\circ$. However, for a wave packet, we generally focus only on the group velocity determined by the carrier wave since any other wavevectors outside the local neighborhood have an exponentially small amplitude. We consider this result for the specific case of a Gaussian wave packet in Section 49.7.7, with further comment in Section 49.7.9.

49.6.9 Wave function PDE implied by the dispersion relation

Typically when studying waves we start with a partial differential equation in space and time, linearize this equation, and then insert a plane wave ansatz to determine a dispersion relation. Here we follow in a manner analogous to that in Section 49.6.7 and seek the partial differential equation satisfied by the wave function, now assuming knowledge of the dispersion relation as might be provided by measurements of wave properties. The method is best illustrated by an example, here taken as that for a planetary Rossby wave for the horizontally non-divergent barotropic model (Section 54.3.4)

$$\varpi(\boldsymbol{k}) = -\beta\, k_x / |\boldsymbol{k}|^2, \tag{49.86}$$

where $\beta = \partial_y f \geq 0$ is the meridional derivative of the Coriolis parameter, and $\boldsymbol{k} = k_x\,\hat{\boldsymbol{x}} + k_y\,\hat{\boldsymbol{y}}$ is a two-dimensional wavevector. Now build a wave function from such waves, where the wave function is written as in equation (49.47)

$$\Phi(\boldsymbol{x},t) = \frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi\,t)}\,\mathrm{d}\boldsymbol{k} = \frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}+t\,\beta\,k_x/|\boldsymbol{k}|^2)}\,\mathrm{d}\boldsymbol{k}. \tag{49.87}$$

What is the partial differential equation satisfied by this wave function?

To answer this question we proceed as in Section 49.6.7 for the modulation function by taking partial derivatives in space and time, and noting that the integral for the wave function is over $\boldsymbol{k}$-space so that space and time derivatives commute with the integral. Hence, the Laplacian of the wave function is given by

$$\nabla^2\Phi = -\frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,|\boldsymbol{k}|^2\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi\,t)}\,\mathrm{d}\boldsymbol{k}, \tag{49.88}$$

and its time derivative is

$$\partial_t(\nabla^2\Phi) = \frac{\mathrm{i}}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\varpi\,|\boldsymbol{k}|^2\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi\,t)}\,\mathrm{d}\boldsymbol{k} \tag{49.89a}$$

$$= -\frac{\mathrm{i}\,\beta}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,k_x\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi\,t)}\,\mathrm{d}\boldsymbol{k} \tag{49.89b}$$

$$= -\beta\,\partial_x\Phi, \tag{49.89c}$$

which then leads to the linear partial differential equation

$$\partial_t(\nabla^2\Phi) + \beta\,\partial_x\Phi = 0. \tag{49.90}$$

As we see in Chapter 54, equation (49.90) is the linearized version of the vorticity equation (54.29) with zero background flow, and solutions of this equation are planetary Rossby waves. Consequently, equation (49.90) describes the evolution of a packet of planetary Rossby waves in a two-dimensional non-divergent barotropic fluid.

49.6.10 Standing wave packets

The wave packet (49.47) can be written in the form

$$\Phi^{(+)}(\boldsymbol{x},t) = \frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,[\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t]}\,\mathrm{d}\boldsymbol{k} = \frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,|\boldsymbol{k}|[S_{\hat{\boldsymbol{k}}}-C_\mathrm{p}\,t]}\,\mathrm{d}\boldsymbol{k}, \tag{49.91}$$

where

$$S_{\hat{\boldsymbol{k}}} = \hat{\boldsymbol{k}}\cdot\boldsymbol{x} \tag{49.92}$$

is the phase distance from equation (49.32), and $C_\mathrm{p} = \varpi(\boldsymbol{k})/|\boldsymbol{k}| > 0$ is the phase speed. As noted in Section 49.6.1, the phase speed is a constant for non-dispersive waves, whereas for dispersive waves it is a function of the wavevector, $C_\mathrm{p} = C_\mathrm{p}(\boldsymbol{k})$. We introduce the + notation on the packet (49.91) to distinguish from the oppositely traveling packet, $\Phi^{(-)}$, defined according to

$$\Phi^{(-)}(\boldsymbol{x},t) = \frac{1}{(2\pi)^3}\int \mathcal{A}(-\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,[\boldsymbol{k}\cdot\boldsymbol{x}+\varpi(\boldsymbol{k})\,t]}\,\mathrm{d}\boldsymbol{k}. \tag{49.93}$$

If the amplitude function has even parity

$$\mathcal{A}(-\boldsymbol{k}) = \mathcal{A}(\boldsymbol{k}), \tag{49.94}$$

then $\Phi^{(-)}(\boldsymbol{x},t) = \Phi^{(+)}(-\boldsymbol{x},t)$, in which case the sum of these two traveling packets is a standing wave packet

$$\Phi^{(-)}(\boldsymbol{x},t) + \Phi^{(+)}(\boldsymbol{x},t) = \frac{2}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t}\cos(\boldsymbol{k}\cdot\boldsymbol{x})\,\mathrm{d}\boldsymbol{k} \qquad \text{if } \mathcal{A}(-\boldsymbol{k}) = \mathcal{A}(\boldsymbol{k}), \quad (49.95)$$

and the initial condition is the inverse cosine transform of $\mathcal{A}(\boldsymbol{k})$

$$\Phi^{(-)}(\boldsymbol{x},t=0) + \Phi^{(+)}(\boldsymbol{x},t=0) = \frac{2}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\cos(\boldsymbol{k}\cdot\boldsymbol{x})\,\mathrm{d}\boldsymbol{k} \qquad \text{if } \mathcal{A}(-\boldsymbol{k}) = \mathcal{A}(\boldsymbol{k}). \quad (49.96)$$

Recall that to ensure the wave function is real, then the amplitude function must satisfy conjugate symmetry via equation (49.94). Hence, with the further assumption of even parity (49.94), then the amplitude function, $\mathcal{A}(\boldsymbol{k})$, is real, in which case we indeed see that $\Phi^{(-)}(\boldsymbol{x},t=0) + \Phi^{(+)}(\boldsymbol{x},t=0)$ is a real function.

As seen in Section 49.7.5, we generally consider Gaussian packets that include modulated traveling waves, so that such wave packets have amplitude functions that are not even functions of the wavevector, $\mathcal{A}(-\boldsymbol{k}) \neq \mathcal{A}(\boldsymbol{k})$. Even so, the present discussion identifies the general properties satisfied by standing waves, which occur, for example, in bounded regions (e.g., see Section 52.8 for standing gravity waves in a closed basin).

49.7 Wave packets in one-dimension

In this section we study a variety of packets moving in one space dimension.[16] Doing so provides a pedagogical means to explicitly reveal some of the general ideas developed in Section 49.6. We give particular attention to the Gaussian wave packet since it allows for analytic expressions that serve pedagogical needs.[17]

49.7.1 The positive wave packet

For a packet built from plane waves traveling in the $+\hat{\boldsymbol{x}}$ direction, we write the wavevector as $\boldsymbol{k} = k\,\hat{\boldsymbol{x}}$ with wavenumber $k \geq 0$ so that a positive-traveling packet takes the form

$$\Phi^{(+)}(x,t) = \frac{1}{2\pi}\int_0^\infty \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,(k\,x-\varpi\,t)}\,\mathrm{d}k. \quad (49.97)$$

49.7.2 The negative wave packet

A packet moving in the negative $\hat{\boldsymbol{x}}$ direction is built from plane waves with $\boldsymbol{k} = -k\,\hat{\boldsymbol{x}}$, again with wavenumber $k \geq 0$, so that

$$\Phi^{(-)}(x,t) = \frac{1}{2\pi}\int_0^\infty \mathcal{A}(-k)\,\mathrm{e}^{-\mathrm{i}\,[k\,x+\varpi\,t]}\,\mathrm{d}k. \quad (49.98)$$

Observe that $\Phi^{(-)}(x,t)$ can be written in the equivalent form

$$\Phi^{(-)}(x,t) = \frac{1}{2\pi}\int_0^\infty \mathcal{A}(-k)\,\mathrm{e}^{-\mathrm{i}\,[k\,x+\varpi\,t]}\,\mathrm{d}k = \frac{1}{2\pi}\int_{-\infty}^0 \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,[k\,x-\varpi\,t]}\,\mathrm{d}k, \quad (49.99a)$$

[16] Section 7.8 of *Stakgold* (2000b) provides a thorough discussion of one-dimensional waves, such as those propagating on a string.

[17] As a wave packet in one-dimension, the wave function Φ has dimensions of its amplitude function, $\mathcal{A}$, times inverse length. In three dimensions, in contrast, the wave function has dimensions of $\mathcal{A}$ times inverse volume as in equation (49.47).

where we assumed that the dispersion relation has even parity

$$\varpi(k) = \varpi(-k) > 0. \tag{49.100}$$

This assumption for the dispersion relation does not hold for all waves (e.g., Rossby waves). When it does hold, it means that a wave traveling to the right with wavenumber k has the same angular frequency as a wave traveling to the left with the same wavenumber. The equality (49.99a) allows us to interpret integration over negative wavenumbers to represent a wave packet traveling in a direction opposite to the sense suggested by the phase relation. That is, the phase $k\,x - \varpi\,t$ suggests a positive traveling packet, but the packet is actually a negative packet since the integration extends over negative wavenumbers.

49.7.3 The positive-negative wave packet

The sum of the positive packet (49.97) and negative packet (49.99a) leads us to define the positive-negative packet

$$\Phi^{(+-)}(x,t) = \Phi^{(+)}(x,t) + \Phi^{(-)}(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,(k\,x - \varpi\,t)}\,\mathrm{d}k. \tag{49.101}$$

49.7.4 The positive-positive wave packet

This final wave packet is designed to travel in a single direction, which defines the positive-positive packet

$$\Phi^{(++)}(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,k\,(x - C_\mathrm{p}\,t)}\,\mathrm{d}k, \tag{49.102}$$

where $C_\mathrm{p} = \varpi/|k| > 0$ is the phase speed. It is revealing to decompose this packet as[18]

$$\Phi^{(++)}(x,t) = \frac{1}{2\pi}\int_{-\infty}^{0} \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,k\,(x - \varpi\,t/|k|)}\,\mathrm{d}k + \frac{1}{2\pi}\int_{0}^{\infty} \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,k\,(x - \varpi\,t/|k|)}\,\mathrm{d}k \tag{49.103a}$$

$$= \frac{1}{2\pi}\int_{-\infty}^{0} \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,(k\,x + \varpi\,t)}\,\mathrm{d}k + \frac{1}{2\pi}\int_{0}^{\infty} \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,(k\,x - \varpi\,t)}\,\mathrm{d}k. \tag{49.103b}$$

The second integral equals to $\Phi^{(+)}(x,t)$, whereas the first is new. Again, both contributions to $\Phi^{(++)}(x,t)$ move in the $+\hat{\boldsymbol{x}}$ direction.

49.7.5 Initial uncertainty relation for a Gaussian packet

The initial condition for both $\Phi^{(+-)}$ and $\Phi^{(++)}$ are the same, which we write as

$$\Phi_0(x) = \Phi^{(+-)}(x,0) = \Phi^{(++)}(x,0) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k. \tag{49.104}$$

The specific case of a Gaussian wave packet offers insight into the physics while allowing for analytically tractable expressions. Specifically, consider the $\boldsymbol{k}$-space representation of a wave packet with a Gaussian spread around a central wavevector, $\boldsymbol{k}_0 = k_\circ\,\hat{\boldsymbol{x}}$. We choose the wave amplitude as

$$\mathcal{A}(k) = A\,\mathrm{e}^{-\sigma(k-k_\circ)^2}, \tag{49.105}$$

where $A > 0$ is a real constant and $\sigma > 0$ has dimensions of squared length. If we choose the central wavenumber to be positive, $k_\circ > 0$, then the wave packet is dominated by plane

[18] In deriving equation (49.103b), it is important to remember that $\varpi > 0$ for all wavenumbers.

waves moving in the $+\hat{\boldsymbol{x}}$ direction. Referring to the discussion in Section 49.6.10, note that $\mathcal{A}(k) \neq \mathcal{A}(-k)$ when $k_\circ \neq 0$. As we will see, if $k_\circ = 0$ then we have a Gaussian packet without any modulated plane waves.

Width of the initial wave packet in $\boldsymbol{k}$-space

The squared modulus of the $\boldsymbol{k}$-space wave packet (49.105) provides a measure of the packet's intensity

$$|\mathcal{A}(k)|^2 = A^2\, \mathrm{e}^{-2\,\sigma (k-k_\circ)^2}, \tag{49.106}$$

with the intensity peaked at the wavenumber $k = k_\circ$ and declining to e^{-1} times the maximum for

$$k = k_\circ \pm (2\,\sigma)^{-1/2} \Longrightarrow \Delta k^{\text{e-fold}} \equiv 2\,(2\,\sigma)^{-1/2}, \tag{49.107}$$

where $\Delta k^{\text{e-fold}}$ measures the $\boldsymbol{k}$-space width of the wave packet. We say that the $\boldsymbol{k}$-space width of the packet is *narrow band* for σ large, in which the packet is concentrated around $k = k_\circ$ since $\Delta k^{\text{e-fold}} \to 0$.

The initial wave packet in $\boldsymbol{x}$-space

The inverse Fourier transform of the $\boldsymbol{k}$-space wave function (49.105) leads to the initial condition for the $\boldsymbol{x}$-space wave function (49.104)

$$\Phi_0(x) = \frac{A}{2\pi} \int_{-\infty}^{\infty} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\, \mathrm{e}^{\mathrm{i}\,k\,x}\, \mathrm{d}k = \frac{A\, \mathrm{e}^{\mathrm{i}\,k_\circ\,x}}{2\pi} \int_{-\infty}^{\infty} \mathrm{e}^{-\sigma\,q^2}\, \mathrm{e}^{\mathrm{i}\,q\,x}\, \mathrm{d}q, \tag{49.108}$$

with the corresponding initial conditions for the positive and negative wave packets

$$\Phi^{(+)}(x,0) = \frac{A}{2\pi} \int_{0}^{\infty} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\, \mathrm{e}^{\mathrm{i}\,k\,x}\, \mathrm{d}k = \frac{A\, \mathrm{e}^{\mathrm{i}\,k_\circ\,x}}{2\pi} \int_{-k_\circ}^{\infty} \mathrm{e}^{-\sigma\,q^2}\, \mathrm{e}^{\mathrm{i}\,q\,x}\, \mathrm{d}q \tag{49.109a}$$

$$\Phi^{(-)}(x,0) = \frac{A}{2\pi} \int_{-\infty}^{0} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\, \mathrm{e}^{\mathrm{i}\,k\,x}\, \mathrm{d}k = \frac{A\, \mathrm{e}^{\mathrm{i}\,k_\circ\,x}}{2\pi} \int_{-\infty}^{-k_\circ} \mathrm{e}^{-\sigma\,q^2}\, \mathrm{e}^{\mathrm{i}\,q\,x}\, \mathrm{d}q. \tag{49.109b}$$

With the central wavenumber assumed positive, $k_\circ > 0$, observe that the initial negative wave packet, $\Phi^{(-)}(x,0)$, has an exponentially small amplitude since the integral in equation (49.109b) never samples $q = k - k_\circ = 0$. In contrast, $\Phi^{(+)}(x,0)$ samples $q = 0$ so that

$$\Phi_0(x) = \Phi^{(+)}(x,0) + \Phi^{(-)}(x,0) \approx \Phi^{(+)}(x,0). \tag{49.110}$$

Although there is no exact closed form expression for the initial conditions, $\Phi^{(+)}(x,0)$ and $\Phi^{(-)}(x,0)$, we can evaluate the integral for $\Phi_0(x)$ in equation (49.108). First observe that

$$\int_{-\infty}^{\infty} \mathrm{e}^{-\sigma\,q^2}\, \sin(q\,x)\, \mathrm{d}q = 0, \tag{49.111}$$

since the Gaussian is symmetric under $q \to -q$, whereas $\sin(q\,x)$ switches sign. Hence, expanding the imaginary exponential in equation (49.108) according to Euler's identity leaves only the cosine contribution, so that[19]

$$\Phi_0(x) = \frac{A\, \mathrm{e}^{\mathrm{i}\,k_\circ\,x}}{2\pi} \int_{-\infty}^{\infty} \mathrm{e}^{-\sigma\,q^2}\, \cos(q\,x)\, \mathrm{d}q = \frac{A\, \mathrm{e}^{\mathrm{i}\,k_\circ\,x}}{2\pi} \sqrt{\frac{\pi}{\sigma}}\, \mathrm{e}^{-x^2/(4\sigma)}, \tag{49.112}$$

where we made use of an integral table for the final equality (e.g., integral 679 of *Beyer* (1973)).

[19]The integral in equation (49.112) is also encountered in Section 8.5.3 when studying Fourier transforms.

Evidently, the initial wave packet, $\Phi_0(x)$, in equation (49.112) consists of a single plane wave, $e^{i\,k_\circ\,x}$, modulated by the Gaussian, $e^{-x^2/(4\sigma)}$. In this manner the plane wave, which is defined for all space, has been localized in space by the Gaussian modulation function. In Figure 49.6 we illustrate a Gaussian wave packet of the form (49.112).

If we choose the central wavenumber to be zero, $k_\circ = 0$, then the wavenumber amplitude function has even parity, $\mathcal{A}(k) = \mathcal{A}(-k)$. The wave function, $\Phi_0(x)$, in equation (49.112) reduces to just the Gaussian modulation function without a carrier wave, so that Figure 49.6 reduces to just the positive Gaussian modulation function. Hence, the $k_\circ = 0$ limit results in a Gaussian signal, constructed with a continuum of plane waves, yet without any modulated carrier wave.

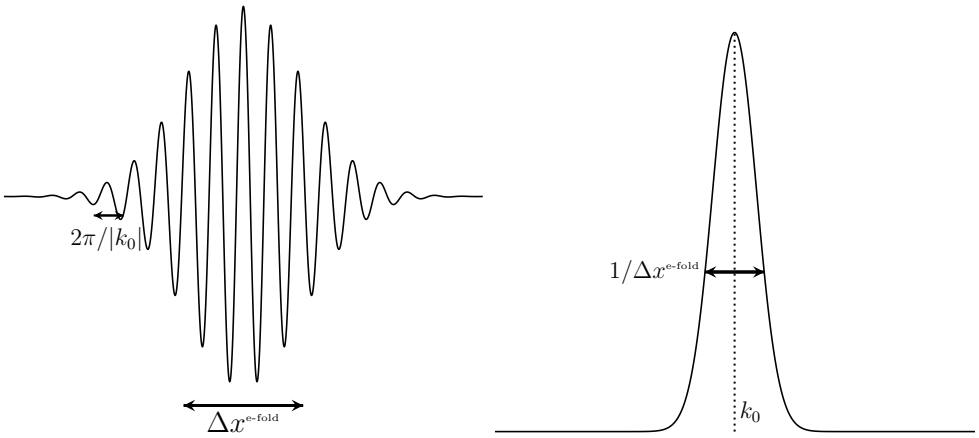

FIGURE 49.6: Left panel: example of a Gaussian wave packet, $\Phi_0(x)$, of the form given by the real part of equation (49.112), with $2\pi/|k_\circ|$ wavelength for the modulated carrier wave. From equation (49.113) we also show $\Delta x^{\text{e-fold}} = 2\,(2\,\sigma)^{1/2} \gg 2\pi/|k_\circ|$, which determines the e-folding width of the squared modulus of the packet. The plane wave, $e^{i\,k_\circ\,x}$, is referred to as the *carrier wave*. Right panel: the $\boldsymbol{k}$-space Gaussian amplitude function (49.105). Units are arbitrary in both panels.

The uncertainty relation

The squared modulus of the $\boldsymbol{x}$-space wave function (49.112) is proportional to $\exp[-x^2/(2\sigma)]$, which has an e-folding width

$$\Delta x^{\text{e-fold}} = 2\,(2\,\sigma)^{1/2}. \tag{49.113}$$

This $\boldsymbol{x}$-space wave function spread exactly complements its $\boldsymbol{k}$-space spread (49.107), so that their product is a constant

$$\Delta x^{\text{e-fold}}\,\Delta k^{\text{e-fold}} = 4. \tag{49.114}$$

The precise value of the constant is not important since it depends on the somewhat arbitrary choices made for defining Δx and Δk. What is important is that if we narrow the wavenumber band by increasing σ and thus making $\mathcal{A}(\boldsymbol{k})$ more sharply peaked, then we broaden the $\boldsymbol{x}$-space width of the wave function. That is, a narrow Gaussian wave packet in $\boldsymbol{k}$-space leads to a broad wave packet in $\boldsymbol{x}$-space. The complement holds, whereby a narrow packet in $\boldsymbol{x}$-space leads to a broad packet in $\boldsymbol{k}$-space. This tradeoff holds for general wave packets, whereby it is not possible to have a narrow packet in both $\boldsymbol{x}$-space and $\boldsymbol{k}$-space. We refer to equation (49.114) as an *uncertainty relation*. It is a fundamental feature of quantum wave mechanics, where it is known as the *Heisenberg uncertainty principle* (e.g., Chapter 3 of *Bohm* (1951) or Chapter 2 of *Gasiorowicz* (1974)). We also encountered this relation when studying the Fourier transform of a Gaussian function in Section 8.5.3.

49.7.6 Extreme examples of the uncertainty relation

The uncertainty relation is a bit odd on first encounter. Why is it impossible to know arbitrarily precise information about both the $\boldsymbol{k}$-space location and $\boldsymbol{x}$-space location of a wave packet? The answer fundamentally boils down to the dual relation between these two spaces. As a means to further exemplify this relation, and thus to build understanding, we consider the most extreme example of the uncertainty relation.[20]

First assume we know that the $\boldsymbol{k}$-space wave function is a single plane wave with just one wavevector, $\boldsymbol{k} = k_\circ \hat{\boldsymbol{x}}$. In this case the $\boldsymbol{k}$-space amplitude function is

$$\mathcal{A}(k) = a_0 \, \delta(k - k_\circ), \tag{49.115}$$

where a_0 is a constant and δ is the Dirac delta discussed in Chapter 7. Note that $\delta(k - k_\circ)$ has physical dimensions of length and is normalized so that

$$\int_{-\infty}^{\infty} \delta(k - k_\circ) \, \mathrm{d}k = 1. \tag{49.116}$$

The sifting property of the Dirac delta (Section 7.2) yields the $\boldsymbol{x}$-space wave function

$$\Phi_0(x) = \frac{a_0}{2\pi} \int_{-\infty}^{\infty} \delta(k - k_\circ) \, \mathrm{e}^{\mathrm{i}\, k\, x} \, \mathrm{d}k = \frac{a_0 \, \mathrm{e}^{\mathrm{i}\, k_\circ\, x}}{2\pi}. \tag{49.117}$$

So although we know the precise $\boldsymbol{k}$-space position, $k = k_\circ$, we have zero information about the wave function's $\boldsymbol{x}$-space position. That is, the wave function is a pure carrier wave without any modulation function so that the wave function is equally present throughout all space.

We turn the table by assuming precise $\boldsymbol{x}$-space information, in which case the modulation function is a Dirac delta

$$\Phi_0(x) = \phi_0 \, \delta(x - x_0), \tag{49.118}$$

where ϕ_0 is a constant and $\delta(x - x_0)$ is normalized so that

$$\int_{-\infty}^{\infty} \delta(x - x_0) \, \mathrm{d}x = 1. \tag{49.119}$$

We say that the modulation function has exactly specified the spatial position of this packet. Yet the price to pay for this precise x-space information is that there is zero information concerning the $\boldsymbol{k}$-space location since

$$\mathcal{A}(k) = \phi_0 \int_{-\infty}^{\infty} \delta(x - x_0) \, \mathrm{e}^{-\mathrm{i}\, k\, x} \, \mathrm{d}x = \phi_0 \, \mathrm{e}^{-\mathrm{i}\, k\, x_0}. \tag{49.120}$$

That is, the carrier wave can be any plane wave with arbitrary wavenumber, k. So although we know the precise $\boldsymbol{x}$-space position, $x = x_0$, we have zero information about the wave function's $\boldsymbol{k}$-space position. That is, the wave function carries precise $\boldsymbol{x}$-space information (delta modulated) yet zero $\boldsymbol{k}$-space information.

[20] For a similar example, see Section 8.5.1 where we discuss the Fourier transform of the Dirac delta.

49.7.7 Evolution of a non-dispersive Gaussian wave packet

We now study the evolution of the $\boldsymbol{x}$-space wave functions, $\Phi^{(+-)}(x,t)$ and $\Phi^{(++)}(x,t)$. Starting with the positive-negative wave function, recall that it evolves according to equation (49.101)

$$\Phi^{(+-)}(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathcal{A}(k)\, \mathrm{e}^{\mathrm{i}\,(k\,x - \varpi\,t)}\,\mathrm{d}k = \frac{A}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\,\mathrm{e}^{\mathrm{i}\,[k\,x - \varpi(k)\,t]}\,\mathrm{d}k. \tag{49.121}$$

This integral offers a complete space and time specification of $\Phi^{(+-)}(x,t)$. Even so, it is useful to massage the integral to garner insight into the physics of this evolving pattern. We do so in this section for the case of non-dispersive waves, where we show that the $\boldsymbol{x}$-space wave packet propagates the initial wave packet without alteration. This result is expected since non-dispersive waves are described by hyperbolic partial differential equations that translate initial patterns without alteration (Section 49.3.1). Furthermore, we already proved this result for a general packet of non-dispersive waves in Section 49.6.8. Even so, it is useful to expose the details in the context of the one dimensional Gaussian packets. Doing so offers insights into certain features of wave packets, and provides practice for the technically more challenging case of dispersive waves in Section 49.7.8.

Evolution of a Gaussian $\Phi^{(+-)}(x,t)$ packet of non-dispersive waves

As already encountered in this chapter, a non-dispersive wave is characterized by a dispersion relation with a constant phase speed

$$\omega = \varpi = C_{\mathsf{p}}\,|k|. \tag{49.122}$$

Such waves are said to be non-dispersive since waves with arbitrary wavenumber travel at the same phase speed. The absolute value sign in the dispersion relation (49.122) means that the relation has a continuous derivative only when $k \neq 0$. In that manner, it is a linear dispersion relation only when $k \neq 0$. Care must be exercised to account for the sign swap when moving across $k = 0$, with this movement corresponding to waves moving in opposite directions as seen earlier in Section 49.6.5.

The $\boldsymbol{x}$-space wave packet (49.121) propagates according to

$$\begin{aligned}
\Phi^{(+-)}(x,t) &= \frac{A}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\,\mathrm{e}^{\mathrm{i}\,(k\,x - |k|\,C_{\mathsf{p}}\,t)}\,\mathrm{d}k && \text{(49.123a)}\\
&= \frac{A}{2\pi}\int_{0}^{\infty} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\,\mathrm{e}^{\mathrm{i}\,k\,(x - C_{\mathsf{p}}\,t)}\,\mathrm{d}k + \frac{A}{2\pi}\int_{-\infty}^{0} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\,\mathrm{e}^{\mathrm{i}\,k\,(x + C_{\mathsf{p}}\,t)}\,\mathrm{d}k && \text{(49.123b)}\\
&= \frac{A}{2\pi}\int_{0}^{\infty} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\,\mathrm{e}^{\mathrm{i}\,k\,(x - C_{\mathsf{p}}\,t)}\,\mathrm{d}k + \frac{A}{2\pi}\int_{0}^{\infty} \mathrm{e}^{-\sigma\,(k+k_\circ)^2}\,\mathrm{e}^{-\mathrm{i}\,k\,(x + C_{\mathsf{p}}\,t)}\,\mathrm{d}k && \text{(49.123c)}\\
&= \Phi^{(+)}(x - C_{\mathsf{p}}\,t, 0) + \Phi^{(-)}(x + C_{\mathsf{p}}\,t, 0), && \text{(49.123d)}
\end{aligned}$$

where we made use of equations (49.109a) and (49.109b) for the $\Phi^{(+)}$ and $\Phi^{(-)}$ initial conditions. Evidently, the x-space wave packet splits from its initial condition into positive and negative propagating wave packets, and the packets move without altering their respective initial conditions. However, as already discussed for the initial conditions leading up to equation (49.110), the wave packets are *not* symmetric reflections of each other if $k_\circ \neq 0$. In fact, $\Phi^{(-)}$ is exponentially smaller than $\Phi^{(+)}$ if $k_\circ > 0$.

Evolution of a Gaussian $\Phi^{(++)}(x,t)$ packet of non-dispersive waves

Now consider evolution of the $\Phi^{(++)}$ packet (49.102) built from non-dispersive waves. In this case we can perform the integral to produce

$$\Phi^{(++)}(x,t) = \frac{A}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{-\sigma\,(k-k_\circ)^2}\,\mathrm{e}^{\mathrm{i}\,k\,(x-C_\mathsf{p}\,t)}\,\mathrm{d}k \tag{49.124a}$$

$$= \frac{A}{2\,\pi}\,\mathrm{e}^{\mathrm{i}\,k_\circ\,(x-C_\mathsf{p}\,t)}\,\mathrm{e}^{-(x-C_\mathsf{p}\,t)^2/(4\,\sigma)}\int_{-\infty}^{\infty}\mathrm{e}^{-\sigma\,[q-\mathrm{i}\,(x-C_\mathsf{p}\,t)/(2\,\sigma)]^2}\,\mathrm{d}q \tag{49.124b}$$

$$= \frac{A\,\mathrm{e}^{\mathrm{i}\,k_\circ\,(x-C_\mathsf{p}\,t)}}{2\,\pi}\sqrt{\frac{\pi}{\sigma}}\,\mathrm{e}^{-(x-C_\mathsf{p}\,t)^2/(4\,\sigma)}. \tag{49.124c}$$

The second equality resulted from completing the square in the exponential, and the final equality evaluated the integral using methods from complex analysis.[21] Comparing the expression in equation (49.124c) to the initial wave packet in equation (49.112) reveals that

$$\Phi^{(++)}(x,t) = \Phi^{(++)}(x-C_\mathsf{p}\,t,0) = \Phi_0(x-C_\mathsf{p}\,t). \tag{49.125}$$

As noted in Section 49.7.4, the initial condition for $\Phi^{(++)}(x,t)$ is propagated in the positive direction as a single coherent packet, which contrasts to the splitting found for the packet $\Phi^{(+-)}(x,t)$ in equation (49.123d).

49.7.8 Evolution of a dispersive Gaussian wave packet

Most geophysical waves are *dispersive*. As we see in the following, dispersive waves render a spreading of the $\boldsymbol{x}$-space wave packet as it evolves, along with a decay in its amplitude. Furthermore, the packet moves at the *group velocity*, which, for dispersive waves, is distinct from the phase velocity. To reveal these properties analytically, we here characterize evolution of the $\Phi^{(+-)}$ wave packet when constructed with dispersive waves, following steps taken for the general case in Section 49.6.6. Though straightforward, the maths is more tedious than for the non-dispersive packets from Section 49.7.7.

Taylor expanding the phase function

To examine the propagation of a dispersive wave packet, we Taylor expand the dispersion relation around the central wavenumber, $k = k_\circ$, and assume the packet is relatively narrow band in wavevector space. With these assumptions we truncate the Taylor series at second order

$$\varpi(k) \approx \varpi(k_\circ) + (k-k_\circ)\left[\frac{\mathrm{d}\varpi}{\mathrm{d}k}\right]_{k=k_\circ} + \frac{(k-k_\circ)^2}{2}\left[\frac{\mathrm{d}^2\varpi}{\mathrm{d}k^2}\right]_{k=k_\circ} \tag{49.126a}$$

$$\equiv \omega_0 + (k-k_\circ)\,c_\mathsf{g} + (k-k_\circ)^2\,\mu. \tag{49.126b}$$

We here introduced the one-dimensional group velocity evaluated at $k = k_\circ$

$$\boldsymbol{c}_\mathsf{g} = \hat{\boldsymbol{x}}\,c_\mathsf{g} = \hat{\boldsymbol{x}}\left[\frac{\mathrm{d}\varpi}{\mathrm{d}k}\right]_{k=k_\circ}. \tag{49.127}$$

Recall from its definition in equation (49.26) that the phase speed is positive by definition, $C_\mathsf{p} > 0$. In contrast, c_g can be positive or negative, or even zero, depending on the slope of the dispersion relation at $k = k_\circ$. In equation (49.126b) we also introduced one-half the second

[21] More precisely, it makes use of the calculus of residues, with Section G_I in *Cohen-Tannoudji et al.* (1977) providing a discussion and Appendix A9 of *Fetter and Walecka* (2003) providing a tutorial for physicists.

derivative of the dispersion relation (dimensions of L^2/T)

$$\mu = \frac{1}{2}\left[\frac{\mathrm{d}^2\varpi}{\mathrm{d}k^2}\right]_{k=k_\circ}. \tag{49.128}$$

As shown below, a nonzero μ leads to an $\boldsymbol{x}$-space modification of the wave packet shape, and generally leading to a reduction in the packet's amplitude (regardless the sign of μ).

Performing the integral

Making use of the Taylor expansion (49.126b) yields the approximate form of the phase function appearing in the $\boldsymbol{x}$-space wave packet (49.121)

$$k\,x - \varpi(k)\,t = (k-k_\circ)\,x + k_\circ\,x - t\,[\omega_0 + c_\mathrm{g}\,(k-k_\circ) + \mu\,(k-k_\circ)^2] \tag{49.129a}$$

$$= (k_\circ\,x - \omega_0\,t) + (x - c_\mathrm{g}\,t)\,(k-k_\circ) - t\,\mu\,(k-k_\circ)^2. \tag{49.129b}$$

As a result, the $\boldsymbol{x}$-space wave packet takes on the approximate form

$$\Phi^{(+-)}(x,t) \approx \frac{A\,\mathrm{e}^{\mathrm{i}\,(k_\circ\,x-\omega_0\,t)}}{2\pi}\int_{-\infty}^{\infty}\mathrm{e}^{-(\sigma+\mathrm{i}\,\mu\,t)\,(k-k_\circ)^2+\mathrm{i}\,(k-k_\circ)\,(x-c_\mathrm{g}\,t)}\,\mathrm{d}k \tag{49.130a}$$

$$= \frac{A\,\mathrm{e}^{\mathrm{i}\,(k_\circ\,x-\omega_0\,t)}}{2\pi}\int_{-\infty}^{\infty}\mathrm{e}^{-(\sigma+\mathrm{i}\,\mu\,t)\,q^2+\mathrm{i}\,q\,(x-c_\mathrm{g}\,t)}\,\mathrm{d}q, \tag{49.130b}$$

where the second equality made use of the same substitution, $q = k - k_\circ$, used when evaluating the integral for the initial value wave packet in Section 49.7.5. Introducing the shorthand

$$\alpha = x - c_\mathrm{g}\,t \quad \text{and} \quad \beta = \sigma + \mathrm{i}\,\mu\,t, \tag{49.131}$$

proves useful for completing the square in the integral exponential

$$-(\sigma+\mathrm{i}\,\mu\,t)\,q^2 + \mathrm{i}\,q\,(x-c_\mathrm{g}\,t) = -\beta\,[q - \mathrm{i}\,\alpha/(2\,\beta)]^2 - \alpha^2/(4\,\beta), \tag{49.132}$$

which brings the $\boldsymbol{x}$-space wave packet (49.130b) to the form[22]

$$\Phi^{(+-)}(x,t) = \frac{A\,\mathrm{e}^{\mathrm{i}\,(k_\circ\,x-\omega_0\,t)}\,\mathrm{e}^{-\alpha^2/(4\,\beta)}}{2\pi}\int_{-\infty}^{\infty}\mathrm{e}^{-\beta\,[q-\mathrm{i}\,\alpha/(2\,\beta)]^2}\,\mathrm{d}q \tag{49.133a}$$

$$= \frac{A\,\mathrm{e}^{\mathrm{i}\,(k_\circ\,x-\omega_0\,t)}}{2\pi}\sqrt{\frac{\pi}{\beta}}\,\mathrm{e}^{-\alpha^2/(4\,\beta)}. \tag{49.133b}$$

We next expose a complex exponential multiplied by a real exponential

$$\Phi^{(+-)}(x,t) = \frac{A\,\mathrm{e}^{\mathrm{i}\,(k_\circ\,x-\omega_0\,t)}}{2\sqrt{\pi}}\frac{\mathrm{e}^{-[(x-c_\mathrm{g}\,t)^2/(4\,(\sigma+\mathrm{i}\,\mu\,t))]}}{\sqrt{\sigma+\mathrm{i}\,\mu\,t}} \tag{49.134a}$$

$$= \frac{A\,\mathrm{e}^{\mathrm{i}\,(k_\circ\,x-\omega_0\,t)}}{2\sqrt{\pi}}\frac{\mathrm{e}^{\mathrm{i}\left[\frac{(x-c_\mathrm{g}\,t)^2\,\mu\,t}{4\,(\sigma^2+(\mu\,t)^2)}\right]}\,\mathrm{e}^{-\frac{(x-c_\mathrm{g}\,t)^2\,\sigma}{4\,(\sigma^2+(\mu\,t)^2)}}}{\sqrt{\sigma+\mathrm{i}\,\mu\,t}} \tag{49.134b}$$

$$= \frac{A\,\mathrm{e}^{\mathrm{i}\,(k_\circ\,x-\omega_0\,t)}}{2\sqrt{\pi}}\frac{\mathrm{e}^{\mathrm{i}\left[\frac{(x-c_\mathrm{g}\,t)^2\,\mu\,t}{4\,(\sigma^2+(\mu\,t)^2)}+\varphi/2\right]}\,\mathrm{e}^{-\frac{(x-c_\mathrm{g}\,t)^2\,\sigma}{4\,(\sigma^2+(\mu\,t)^2)}}}{[\sigma^2+(\mu\,t)^2]^{1/4}}, \tag{49.134c}$$

where $\tan\varphi = -\mu\,t/\sigma$.

[22] The integral in equation (49.133b) is evaluated using complex analysis as discussed in Section G_I of *Cohen-Tannoudji et al.* (1977) as well as Section 54 and Appendix A9 of *Fetter and Walecka* (2003).

Interpreting the wave packet

The phase factor in the $\boldsymbol{x}$-space wave packet (49.134c)

$$\mathcal{P} = (k_\circ\, x - \omega_0\, t) + \frac{(x - c_g\, t)^2\, \mu\, t}{4\,(\sigma^2 + (\mu\, t)^2)} + \varphi/2, \tag{49.135}$$

equals to that for a non-dispersive wave, $k_\circ\, x - \omega_0\, t$, plus a space and time dependent phase shift that is nonzero for dispersive waves ($\mu \neq 0$). The phase shift simplifies for points following the group velocity, $x = c_g\, t$, and it is here that the Gaussian exponential is maximized

$$\Phi^{(+-)}(x = c_g\, t, t) = \frac{A\, \mathrm{e}^{\mathrm{i}\,(k_\circ\, x - \omega_0\, t + \varphi/2)}}{2\sqrt{\pi}\,[\sigma^2 + (\mu\, t)^2]^{1/4}}. \tag{49.136}$$

Evidently, as the $\boldsymbol{x}$-space wave packet moves with the group velocity (which can be either signed), its amplitude declines according to $|\mu\, t|^{-1/2}$. The $t^{-1/2}$ decay of the packet amplitude is also found from the method of stationary phase for dispersive packets considered in Section 49.8.3.

Time dependent uncertainty relation

As for the $\boldsymbol{k}$-space packet in Section (49.7.5), we consider the squared modulus of the $\boldsymbol{x}$-space packet (49.134c) as a measure of its intensity

$$|\Phi^{(+-)}(x, t)|^2 = \frac{A^2\, \mathrm{e}^{-\frac{(x - c_g\, t)^2\, \sigma}{2\,(\sigma^2 + (\mu\, t)^2)}}}{4\pi\,[\sigma^2 + (\mu\, t)^2]^{1/2}}. \tag{49.137}$$

The e-folding width of $|\Phi(x, t)|^2$ is revealed by setting the decaying exponential to unity, which leads to

$$x = c_g\, t \pm (2\,\sigma)^{1/2}\left[1 + (\mu\, t/\sigma)^2\right]^{1/2} \Longrightarrow \Delta x^{\text{e-fold}} = 2\,(2\,\sigma)^{1/2}\left[1 + (\mu\, t/\sigma)^2\right]^{1/2}. \tag{49.138}$$

Multiplying by the time-independent $\boldsymbol{k}$-space packet width (49.107) leads to the time dependent uncertainty relation

$$\Delta x^{\text{e-fold}}\, \Delta k^{\text{e-fold}} = 2\,(2\,\sigma)^{1/2}\left[1 + (\mu\, t/\sigma)^2\right]^{1/2} 2\,(2\,\sigma)^{-1/2} = 4\left[1 + (\mu\, t/\sigma)^2\right]^{1/2}. \tag{49.139}$$

The time dependent uncertainty relation starts from its initial condition (49.114) at $t = 0$, and then grows as $t^{1/2}$. For non-dispersive waves ($\mu = 0$), the uncertainty relation is time-independent, which is expected since non-dispersive waves translate the initial packet without changing the properties of the packet.

49.7.9 The non-dispersive limit of a dispersive packet

We set the spreading parameter, μ, to zero for for non-dispersive waves, in which case $\mu = 0 \Longrightarrow \varphi = 0$. In this limit the wave packet (49.134c) takes on the form

$$\mu = 0 \Longrightarrow \Phi^{(+-)}(x, t) = \frac{A\, \mathrm{e}^{\mathrm{i}\, k_\circ\,(x - c_g\, t)}}{2\,\pi}\sqrt{\frac{\pi}{\sigma}}\, \mathrm{e}^{-(x - c_g\, t)^2/(4\,\sigma)}. \tag{49.140}$$

If we set $c_g = C_p$ then this result corresponds to equation (49.124c), which is the non-dispersive form of the packet $\Phi^{(++)}(x, t)$.

So why did the non-dispersive limit not reduce to equation (49.123d), which is the non-dispersive form of $\Phi^{(+-)}(x, t)$? The reason is that when performing the Taylor series expansion

for the dispersive packet, we only picked out the group velocity at the single wavenumber, $k = k_\circ$. Hence, we can only get one of the two packets comprising $\Phi^{(+-)}(x,t)$ in equation (49.123d). Namely, we ignore the exponentially small packet using the Taylor series approach. Furthermore, note that c_g can be positive or negative for dispersive waves (indeed, it can even be zero). In contrast, C_p is the phase speed and that is always positive. So in the case of $c_\mathrm{g} = -C_\mathrm{p} < 0$ then equation (49.140) is a negative moving wave packet.

So in summary, the non-dispersive limit of a dispersive packet does not exactly correspond to the purely non-dispersive packet due to a few subtleties. In particular, if one cares about the exponentially small packet exposed with the non-dispersive analysis in Section 49.7.7, then it is necessary to follow the approach taken in that section rather than taking the non-dispersive limit of dispersive waves as considered here.

49.7.10 Comments and further study

The study of wave packets in this section revealed properties that appear throughout the study of waves. First, there is the uncertainty relation, whereby a packet that is narrow banded in wavevector space is broad banded in position space, and conversely. Second, dispersive wave packets have a modulation function that is modified with time, thus producing a time dependent uncertainty relation. Regardless the sign of the dispersion coefficient, μ (equation (49.128)), the packet amplitude decays in time and the uncertainty grows. We see this behavior for generic wave packets when studying the stationary phase method in Section 49.8. Third, the center of the packet moves with the group velocity rather than phase velocity, with the two velocities distinct for dispersive waves. We also encountered this property in Section 49.6.7 when studying how the wave packet modulation function evolves. It will appear again in Chapter 50 when studying how energy (or more generally the wave action) propagates with the wave field.

The study of wave packets and their evolution is a central concern of quantum mechanics. Most books on the subject have a discussion of quantum wave packets at the level discussed here. In particular, we made use in this section of Chapter 3 of *Bohm* (1951), Chapter 2 of *Gasiorowicz* (1974), and Section G_I of *Cohen-Tannoudji et al.* (1977). We also followed Section 54 of *Fetter and Walecka* (2003), who consider wave packets built from surface gravity waves. However, it is notable that the distinctions we made here between positive and negative moving packets in Section 49.7.7 are not considered by this literature.

49.8 Method of stationary phase

As shown in Section 49.6.8, a packet of non-dispersive waves holds its initial condition unchanged as it propagates at the phase speed. This evolution is exact. Hence, we know everything about a packet of non-dispersive waves for all time, given the phase velocity and the initial conditions.

The situation is more complicated for packets of dispersive waves, whose modulation function changes its shape due to wave dispersion. We encountered such behavior when introducing wave trains and wave packets in Section 49.6.6, as well as when studying Gaussian wave packets of dispersive waves in Section 49.7. In the present section we study the long-time behavior for a packet of dispersive waves using the *method of stationary phase*. From the Gaussian wave packet study in Section 49.7.8, we expect the packet to decay according to $t^{-1/2}$, as revealed by the exact Gaussian packet results in Section 49.7. Here we show that this $t^{-1/2}$ behavior is generic for packets of dispersive waves.

For analytical simplicity we focus on a wave function in one space dimension, written as

$$\Phi(x,t) = \frac{1}{2\pi} \int_{k_\mathrm{a}}^{k_\mathrm{b}} \mathcal{A}(k)\, \mathrm{e}^{\mathrm{i}\, h(k)\, t}\, \mathrm{d}k, \tag{49.141}$$

where $\mathcal{A}(k)$ is the amplitude function, $h(k)$ is a real phase function, and we focus on a wavenumber interval $k \in [k_a, k_b]$. For example, with a plane wave we have

$$h(k) = k\,x/t - \varpi(k), \tag{49.142}$$

where $\varpi(k)$ is the dispersion relation. Note that for the integral in equation (49.141), x and t are considered parameters, so we only expose the k dependence to the phase function, $h(k)$. Finally, with a focus on dispersive waves we assume

$$\varpi''(k) \neq 0. \tag{49.143}$$

49.8.1 Riemann-Legesque lemma and center of the packet

As $t \to \infty$, the wave packet's integrand, $\mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,h(k)\,t}$, oscillates faster. Consequently, terms in the integral cancel since the oscillations dominate any behavior of the amplitude (which is assumed smooth). Indeed, the *Riemann-Legesque lemma* states that the integral has a zero limit as $t \to \infty$, so long as the amplitude function is integrable and finite.

Contributions to the wave packet are maximized when two elements of the integrand align. First we want to maximize the amplitude, which for a wave packet is assumed to be maximized in a small interval surrounding a wavenumber, k_o or k_o. Next we want the phase function to be in a small neighborhood of an extrema, which is where $h'(k) = 0$. Aligning this phase extrema with the amplitude maximum means we want space-time locations where $h'(k_o) = 0$. For a packet built from plane waves, $h'(k_o) = 0$ occurs at a specific space-time point determined by the group velocity

$$h'(k_o) = x/t - c_g = 0 \Longrightarrow x/t = c_g, \tag{49.144}$$

where

$$c_g = c_g(k_o) = \varpi'(k_o) \tag{49.145}$$

is the group velocity for the packet as determined at the wavenumber, k_o, where the amplitude has its maximum. Evidently, the center of the wave packet (i.e., where the packet has its maximum amplitude) is located at

$$x_{\text{center}} = t\,c_g, \tag{49.146}$$

so that the center moves at the group velocity. This result for the packet center was previously found using different approaches in Sections 49.6.6, 49.7.7, and 49.7.8.

In addition to wanting information about the packet center, it is useful to know about its amplitude which, according to Riemann-Legesque, decays to zero as time increases. To get an expression for the amplitude modulation requires some work, which is the topic of the remainder of this section.

49.8.2 Wavenumber intervals with no phase extrema

Consider the case whereby the phase has no extrema within the chosen wavenumber interval, $k \in [k_a, k_b]$, so that $h'(k) \neq 0$. This assumption allows us to use integration by parts in the form

$$\int_{k_a}^{k_b} v\,\mathrm{d}u = [u\,v]\Big|_{k_a}^{k_b} - \int_{k_a}^{k_b} u\,\mathrm{d}v, \tag{49.147}$$

where

$$v = \mathcal{A}/h' \quad \text{and} \quad u = \mathrm{e}^{\mathrm{i}\,h\,t}/(\mathrm{i}\,t), \tag{49.148}$$

so that

$$v\,\mathrm{d}u = (\mathcal{A}/h')\,\mathrm{d}[\mathrm{e}^{\mathrm{i}\,h\,t}/(\mathrm{i}\,t)] = \mathcal{A}\,\mathrm{e}^{\mathrm{i}\,h\,t}\,\mathrm{d}k, \tag{49.149}$$

and

$$u\,\mathrm{d}v = [\mathrm{e}^{\mathrm{i}\,h\,t}/(\mathrm{i}\,t)]\,\mathrm{d}(\mathcal{A}/h'). \tag{49.150}$$

We can thus write the integral as

$$2\,\pi\,\Phi = \frac{1}{\mathrm{i}\,t}\left[(\mathcal{A}/h')\,\mathrm{e}^{\mathrm{i}\,h\,t}\Big|_{k_\mathrm{a}}^{k_\mathrm{b}} - \int_{k_\mathrm{a}}^{k_\mathrm{b}} \mathrm{e}^{\mathrm{i}\,h\,t}\,\mathrm{d}(g/h')\right] \sim \mathcal{O}(t^{-1}). \tag{49.151}$$

The key point is that the integral decays as t^{-1} for wavenumber intervals, $k \in [k_\mathrm{a}, k_\mathrm{b}]$, where the phase, $h(k)$, has no extrema.

49.8.3 Wavenumber interval including a phase extrema

We expect that contributions from regions near an extrema decay slower in time, since near those regions the phase does not oscillate so rapidly.[23] In particular, as noted in Section 49.8.1, we expect that the packet center follows a point in space determined by the group velocity. We thus consider the case where the phase has an extrema at the wavenumber $k_\circ$, which is now included in the interval: $k_\circ \in [k_\mathrm{a}, k_\mathrm{b}]$, in which case we Taylor expand the phase

$$h(k) = h(k_\circ) + h'(k_\circ)\,(k-k_\circ) + (k-k_\circ)^2\,h''(k_\circ)/2 + ... = h(k_\circ) + (k-k_\circ)^2\,h''(k_\circ)/2 + ..., \tag{49.152}$$

where we set

$$h'(k_\circ) = 0 \tag{49.153}$$

since it is an extrema. We showed in Section 49.8.2 that wavenumber regions where there is no extrema contribute terms of order $\mathcal{O}(t^{-1})$ to the integral. We now show that regions including an extrema decay like $\mathcal{O}(t^{-1/2})$, thus allowing us to focus on the region surrounding the packet center,

$$k_\circ - 1/\sqrt{2\sigma} \leq k \leq k_\circ + 1/\sqrt{2\sigma}. \tag{49.154}$$

We introduced $1/\sqrt{2\sigma}$ as a measure of the packet width, such as used for the Gaussian packet in equation (49.107). We thus have the integral

$$2\,\pi\,\Phi = \mathrm{e}^{\mathrm{i}\,t\,h(k_\circ)} \int_{k_\circ - 1/\sqrt{2\sigma}}^{k_\circ + 1/\sqrt{2\sigma}} \mathcal{A}(k)\,\mathrm{e}^{\mathrm{i}\,t\,(k-k_\circ)^2\,h''(k_\circ)/2}\,\mathrm{d}k + \mathcal{O}(t^{-1}). \tag{49.155}$$

Changing variables to a shifted wavenumber $\ell = k - k_\circ$ gives the expression

$$2\,\pi\,\Phi = \mathrm{e}^{\mathrm{i}\,t\,h(k_\circ)} \int_{-1/\sqrt{2\sigma}}^{1/\sqrt{2\sigma}} \mathcal{A}(\ell + k_\circ)\,\mathrm{e}^{\mathrm{i}\,t\,\ell^2\,h''(k_\circ)/2}\,\mathrm{d}\ell + \mathcal{O}(t^{-1}). \tag{49.156}$$

One more change in variables to $p = \ell\,\sqrt{t}$ renders the integral

$$2\,\pi\,\Phi = t^{-1/2}\,\mathrm{e}^{\mathrm{i}\,t\,h(k_\circ)} \int_{-1/\sqrt{2\sigma}}^{1/\sqrt{2\sigma}} \mathcal{A}(p\,t^{-1/2} + k_\circ)\,\mathrm{e}^{\mathrm{i}\,p^2\,h''(k_\circ)/2}\,\mathrm{d}p + \mathcal{O}(t^{-1}). \tag{49.157}$$

We simplify the integrand by performing a Taylor expansion

$$\mathcal{A}(p\,t^{-1/2} + k_\circ) = \mathcal{A}(p_0) + \mathcal{O}(t^{-1/2}), \tag{49.158}$$

[23] According to Section 11.3 of *Whitham* (1974), this insight is originally due to Lord Kelvin.

so that, keeping only terms of order $t^{-1/2}$, brings about the integral

$$2\,\pi\,\Phi = t^{-1/2}\,\mathcal{A}(k_\circ)\,\mathrm{e}^{\mathrm{i}\,t\,h(k_\circ)}\int_{-\sqrt{t/2\sigma}}^{\sqrt{t/2\sigma}}\mathrm{e}^{\mathrm{i}\,p^2\,h''(k_\circ)/2}\,\mathrm{d}p + \mathcal{O}(t^{-1}). \tag{49.159}$$

For a dispersive packet with non-zero $h''(k_\circ)$, the $t\to\infty$ limit allows us to extend the limit on the integral (49.159) to infinity so that

$$2\,\pi\,\Phi = t^{-1/2}\,\mathcal{A}(k_\circ)\,\mathrm{e}^{\mathrm{i}\,t\,h(k_\circ)}\int_{-\infty}^{\infty}\mathrm{e}^{\mathrm{i}\,p^2\,h''(k_\circ)/2}\,\mathrm{d}p + \mathcal{O}(t^{-1}). \tag{49.160}$$

The integral is in the form of a *Fresnal integral* and it can be done using methods from complex analysis to find

$$\int_{-\infty}^{\infty}\mathrm{e}^{\mathrm{i}\,p^2\,h''(k_\circ)/2}\,\mathrm{d}p = \sqrt{\frac{2\,\pi}{|h''(k_\circ)|}}\,\mathrm{e}^{\pm\,\mathrm{i}\pi/4}, \tag{49.161}$$

where the $\pm$ sign corresponds to the sign of $h''(k_\circ)$. We thus have the stationary phase expression for the wave function

$$\Phi(x,t) = \frac{\mathcal{A}(k_\circ)\,\mathrm{e}^{\mathrm{i}\,t\,h(k_\circ)\pm\mathrm{i}\,\pi/4}}{[2\,\pi\,t\,|h''(k_\circ)|]^{1/2}} + \mathcal{O}(t^{-1}). \tag{49.162}$$

As noted at the start of this section, a packet built from plane waves has

$$h(k_\circ)\,t = k_\circ\,x - \varpi(k_\circ)\,t, \tag{49.163}$$

so that the long-time behavior of the wave packet is given by

$$\Phi(x,t) = \mathcal{A}(k_\circ)\,\mathrm{e}^{\mathrm{i}\,(k_\circ\,x-\varpi(k_\circ)\,t)}\,\frac{\mathrm{e}^{\pm\mathrm{i}\,\pi/4}}{[2\,\pi\,t\,|\varpi''(k_\circ)|]^{1/2}} + \mathcal{O}(t^{-1}). \tag{49.164}$$

This wave function is built from a plane wave with wavenumber $k_\circ$ that is modulated by a function whose amplitude is decaying according to $t^{-1/2}$. The $t^{-1/2}$ decay accords with the exact solution of the dispersive Gaussian packet in Section 49.7.8. Furthermore, note how the strength of the $t^{-1/2}$ decay is affected by the size of $|\varpi''(k_\circ)|$.

As noted in Section 49.8.1, the packet is a maximum when sampled at the center, which is given by (equation (49.146)) $x_{\text{center}} = c_{\mathsf{g}}\,t$. At this point, the phase of the wave function (49.164) takes the form

$$k_\circ\,x_{\text{center}} - \varpi(k_\circ)\,t = k_\circ\,c_{\mathsf{g}}\,t - \varpi(k_\circ)\,t = k_\circ\,(c_{\mathsf{g}} - c_{\mathsf{p}})\,t, \tag{49.165}$$

where we introduced the phase velocity for the carrier wave

$$c_{\mathsf{p}} = \varpi(k_\circ)/k_\circ. \tag{49.166}$$

As a result, the wave function as evaluated at the packet center is given by

$$\Phi(x_{\text{center}},t) = \mathcal{A}(k_\circ)\,\mathrm{e}^{\mathrm{i}\,k_\circ\,(c_{\mathsf{g}}-c_{\mathsf{p}})\,t}\,\frac{\mathrm{e}^{\pm\mathrm{i}\,\pi/4}}{[2\,\pi\,t\,|\varpi''(k_\circ)|]^{1/2}} + \mathcal{O}(t^{-1}). \tag{49.167}$$

49.8.4 Comments and further study

If both the first and second derivatives vanish, $h'(k_\circ) = 0$ and $h''(k_\circ) = 0$, then the same procedure as used above must be pursued but to the next higher order in the Taylor series expansion. Also if there are multiple extrema, then each will add a contribution of the form given by equation (49.162).

Variations on the derivation given in this section can be found in section 11.3 of *Whitham* (1974), section 3.7 of *Lighthill* (1978), section 55 of *Fetter and Walecka* (2003) and section 1.C.2 of *Cohen-Tannoudji et al.* (1977).

49.9 Exercises

EXERCISE 49.1: PARSEVAL'S IDENTITY FOR WAVE PACKETS
Consider the expression (49.47) for a wave function

$$\Phi(\boldsymbol{x},t) = \frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi\,t)}\,\mathrm{d}\boldsymbol{k}. \tag{49.168}$$

Prove the following expression of Parseval's identity (Section 8.3.6)

$$\int |\nabla\Phi|^2\,\mathrm{d}\boldsymbol{x} = \frac{1}{(2\pi)^3}\int |\boldsymbol{k}|^2\,|\mathcal{A}(\boldsymbol{k})|^2\,\mathrm{d}\boldsymbol{k}. \tag{49.169}$$

Notice that the right hand side is time-independent, so that the left hand side must be likewise. Hint: make use of the following representation of the Dirac delta from Section 8.5.1

$$\delta(\boldsymbol{k}-\boldsymbol{q}) = \frac{1}{(2\pi)^3}\int \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}-\boldsymbol{q})\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{x}. \tag{49.170}$$

EXERCISE 49.2: SQUARE WAVE PACKET (EXERCISE 2.1 OF *Gasiorowicz* (1974))
Consider a wave packet in one space dimension with real k-space amplitude function

$$A(k) = \begin{cases} 0 & k < -K \\ N & -K < k < K \\ 0 & k > K, \end{cases} \tag{49.171}$$

where $K > 0$.

(a) Find the $\boldsymbol{x}$-space wave function, which in one space dimension takes the form

$$\Phi_0(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} A(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k. \tag{49.172}$$

Hint: $\Phi_0(x)$ is the inverse Fourier transform of $A(k)$. The integral is simple to do.

(b) Find the value of N for which

$$\int_{-\infty}^{\infty} |\Phi_0(x)|^2\,\mathrm{d}x = 1. \tag{49.173}$$

Hint: massage the integral until it looks like one found in a standard integral table.

(c) Relate the above choice for N to one that makes

$$\int_{-\infty}^{\infty} |A(k)|^2\,\mathrm{d}k = 1. \tag{49.174}$$

(d) Show that a reasonable definition for Δx in part (a) yields the uncertainty relation

$$\Delta x \, \Delta k > 1. \tag{49.175}$$

Hint: this uncertainty relation holds independently of K.

EXERCISE 49.3: INVERSE SQUARED WAVE PACKET (EXERCISE 2.2 OF *Gasiorowicz* (1974))
Consider a wave packet in one space dimension with real k-space amplitude function

$$A(k) = \frac{N}{k^2 + \alpha^2} \tag{49.176}$$

with $\alpha > 0$.

(a) Find the $\boldsymbol{x}$-space wave function, which in one space dimension takes the form

$$\Phi_0(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} A(k) \, \mathrm{e}^{\mathrm{i}\, k\, x} \, \mathrm{d}k \tag{49.177}$$

Hint: $\Phi_0(x)$ is the inverse Fourier transform of $A(k)$. Massage the integral until it looks like one found in a standard integral table.

(b) Show that a reasonable definition for Δx in part (a) yields the uncertainty relation

$$\Delta x \, \Delta k > 1. \tag{49.178}$$

Hint: this relation holds independently of α.

EXERCISE 49.4: WAVE FUNCTION PDE DERIVED FROM THE DISPERSION RELATION
Follow the method from Section 49.6.9 to derive the partial differential equation satisfied by a wave function, $\Phi(\boldsymbol{x}, t)$, whose constituent waves satisfy the following dispersion relations, where for each case $\boldsymbol{k} = k_x \, \hat{\boldsymbol{x}} + k_y \, \hat{\boldsymbol{y}} + k_z \, \hat{\boldsymbol{z}}$ a three-dimensional wavevector.

(a) $\varpi^2 = c^2 \, |\boldsymbol{k}|^2$, with c a constant with dimensions L T^{-1}.

(b) $\varpi^2 = B^2 \, k_z^2 / |\boldsymbol{k}|^2$, with B a constant with dimensions T^{-1}.

Chapter 50

Waves in a gently varying background

We here study linear waves propagating through a prescribed gently varying (in space and time) background environment, such as for waves moving through a stratified ocean or atmosphere, or waves moving through a mean flow. We assume the relevance of space and time coherent wave patterns so that we can consider a wave phase function. However, the wavevector and angular frequency, as well as the wave amplitude, are here functions of space and time and as such we cannot use traditional Fourier analysis. Instead, asymptotic methods are needed, and we develop the leading order theory referred to in various contexts as *ray theory*, *geometric optics*, *eikonal approximation* or the *WKBJ approximation*.[1] Notably, we do *not* consider the back-reaction effects of waves on the background state, which is the subject matter of *waves and mean flow interaction* theory.

Given the more general background state, we must consider a wave ansatz that is more general than the plane wave Fourier ansatz from Chapter 49. We refer to the new ansatz as the *WKBJ wave ansatz* or equivalently the *eikonal wave ansatz* (the specific form is given by equation (50.54)). Plugging in this wave ansatz to the wave equation then leads to a suite of asymptotic equations that are used to build the wave function, ray equations, energy equation, etc. In principle this approach is straightforward, yet in practice it is tedious and uninspired. *Whitham's variational principle* provides an alterative that is both elegant and powerful. In brief, Whitham's principle is based on Hamilton's principle from classical continuum mechanics (Part IX of this book), only now applied to the leading order (in WKBJ expansion) phase averaged action. The resulting Euler-Lagrange equations render the dispersion relation and conservation equations for an energy-momentum-stress tensor. As part of these conservation equations, we encounter the *wave action*, which offers a generalization of wave energy, and the flux of wave action is determined by the group velocity.

READER'S GUIDE TO THIS CHAPTER

We assume familiarity with the material from Chapter 49, which considered wave kinematics for traveling plane waves on a static and homogeneous background state. We here make use of Cartesian coordinates and Cartesian tensors (Chapters 1 and 2). The wave energetics/action discussion makes use of Hamilton's principle for a continuum from Part IX of this book, in particular the material in Chapter 46. Much of the material here is inspired by the review chapter from *Bretherton* (1971), as well as *Bretherton and Garrett* (1969), chapter 11 of *Whitham* (1974), Part 2 in the Epilogue of *Lighthill* (1978), *Andrews and McIntyre* (1978b), chapter 9 of *Olbers et al.* (2012), and *Tracy et al.* (2014).

[1] WKBJ stands for Wentzel, Kramers, Brillouin, and Jeffreys, scientists who promoted the method in the 20th century for use in quantum mechanics. Often this method is referred to as WKB. In fact, the method was developed in the 19th century by Liouville and Green.

50.1 Loose threads

- Figures
- Adiabatic invariants as per Section 9.2 of *Olbers et al.* (2012) and Section 49 of *Landau and Lifshitz* (1976). See also *José and Saletan* (1998).

50.2 General phase functions

Throughout Chapter 49 , the phase of the wave function takes the linear plane wave form given by equation (49.20) (here written with zero phase shift)

$$\mathcal{P}(\boldsymbol{x}, t) = \boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t = k_a\, x^a - \omega\, t, \tag{50.1}$$

where the wavevector, $\boldsymbol{k}$, and angular frequency, ω, are parameters of the wave that are independent of space and time. The second equality made use of the summation convention, with the wavevector components written with lower indices to accord with the upstairs spatial indices. The relatively simple form (50.1) of the phase function is suited only for background states that are homogeneous and static. In this chapter we consider a more general phase function that allows us to study waves moving through a background state that is inhomogeneous and/or time

dependent. The key restriction to our approach is that we retain the notion of a locally defined wavevector and angular frequency, which are now considered to be functions of space and time

$$\nabla\mathcal{P} \equiv \boldsymbol{k}(\boldsymbol{x},t) \quad \text{and} \quad -\partial_t\mathcal{P} \equiv \omega(\boldsymbol{x},t). \tag{50.2}$$

These expressions tacitly assume that the base state fluid properties are changing slowly in space and time relative to the wave phase, thus allowing us to generalize much of the wave kinematics holding for homogeneous/static media while locally considering the waves to be planar. For this assumption to hold, it is sufficient to make the following space and time scale separation, as assumed throughout this chapter

$$|\boldsymbol{k}| = |\nabla\mathcal{P}| \gg L^{-1} \quad \text{and} \quad \omega = -\partial_t\mathcal{P} \gg T^{-1}, \tag{50.3}$$

where L is a characteristic length scale defined by spatial variations in the background state, and T is the corresponding time scale for changes in the background state. In terms of the local measure of the wavelength, $\Lambda = 2\pi/|\boldsymbol{k}|$, and period, $2\pi/\omega$, we have

$$\Lambda \ll 2\pi\, L \quad \text{and} \quad 2\pi/\omega \ll T. \tag{50.4}$$

Values for L and T depend on details of the physical system defining the background state. For example, in Section 50.5.2 we consider L and T for a stretched string with time dependent tension and space dependent mass density, and in Section 51.9.5 we consider L for the case of acoustic waves moving through a spatially inhomogenous yet static background.

50.2.1 Path independence of phase difference

Given that the wavevector is defined as the gradient of the phase as per equation (50.2), it must satisfy the consistency condition

$$\nabla \times \boldsymbol{k} = \nabla \times \nabla\mathcal{P} = 0. \tag{50.5}$$

This property of the wavevector means that there are the same number of wave crests between any two points in the fluid at any particular time instance, no matter what path is taken to connect the two points. This property is trivially maintained by plane waves in a homogeneous media since $\boldsymbol{k}$ is a space-time constant vector. To prove it holds for the more general phase function, consider the difference in phase (at a fixed time) between points A and B within the fluid (see Figure 50.1). Compute this phase difference via a path, $\mathcal{C}_1$, that goes from point A to point B, and then via an alternative path, $\mathcal{C}_2$, that also goes from point A to point B

$$\Delta\mathcal{P}_{\mathcal{C}_1} = \int_{\mathcal{C}_1} \boldsymbol{k}\cdot \mathrm{d}\boldsymbol{x} \quad \text{and} \quad \Delta\mathcal{P}_{\mathcal{C}_2} = \int_{\mathcal{C}_2} \boldsymbol{k}\cdot \mathrm{d}\boldsymbol{x}. \tag{50.6}$$

The path $\mathcal{C}_1 - \mathcal{C}_2$ is a closed loop that is oriented in the counterclockwise direction. We can thus make use of Stokes' theorem to find

$$\Delta\mathcal{P}_{\mathcal{C}_1} - \Delta\mathcal{P}_{\mathcal{C}_2} = \oint_{\mathcal{C}_1-\mathcal{C}_2} \boldsymbol{k}\cdot \mathrm{d}\boldsymbol{x} = \oint (\nabla\times\boldsymbol{k})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0, \tag{50.7}$$

which proves the path independence of the phase difference.

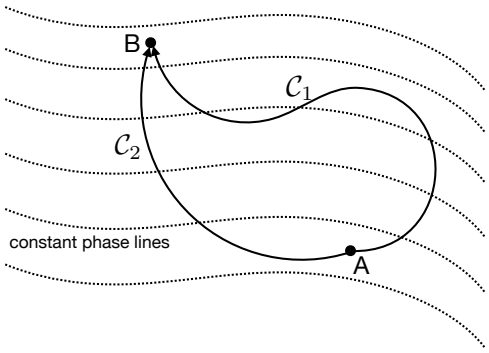

FIGURE 50.1: This figure illustrates the conservation of wave crests embodied by equation (50.9). Here we consider two paths in space, $\mathcal{C}_1$ and $\mathcal{C}_2$, that go from point A to point B. Both paths move across surfaces of constant phase, illustrated by the dotted lines and shown for a particular time instance. As shown by equation (50.7), the difference in phase computed along the two different paths is the same, and this property follows from $\nabla \times \boldsymbol{k} = 0$ and Stokes' theorem.

50.2.2 Conservation of wave crests

Because the mixed partial derivatives of the phase function commute, we have

$$\frac{\partial \omega}{\partial x^a} = -\frac{\partial^2 \mathcal{P}}{\partial t \, \partial x^a} \quad \text{and} \quad \frac{\partial k_a}{\partial t} = \frac{\partial^2 \mathcal{P}}{\partial x^a \, \partial t}, \tag{50.8}$$

which leads to the vector equation

$$\frac{\partial \boldsymbol{k}}{\partial t} + \nabla \omega = 0. \tag{50.9}$$

This equation says that the time change in wavevector, $\partial_t \boldsymbol{k}$, is exactly compensated by the spatial change in angular frequency, $\nabla\omega$. This self-consistency condition is referred to as the *conservation of wave crests*. Motivation for this name follows since the wavenumber, $|\boldsymbol{k}|$, is the number of wave crests per unit length at a fixed time. Likewise, the angular frequency, ω, is the number of wave crests passing a fixed location per unit time. Having their respective space and time derivatives match is a self-consistency condition for a coherent wave pattern to exist.

As a further means to understand the balance equation (50.9), and the name "conservation of wave crests", consider an integral between two points fixed in space taken along a fixed path in space, such as the path C_1 in Figure 50.1. The time tendency of the phase difference is given by

$$\partial_t(\Delta \mathcal{P}_{\mathcal{C}_1}) = \frac{\partial}{\partial t} \int_{\mathcal{C}_1} \boldsymbol{k} \cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{C}_1} \partial_t \boldsymbol{k} \cdot \mathrm{d}\boldsymbol{x} = -\int_{\mathcal{C}_1} \nabla\omega \cdot \mathrm{d}\boldsymbol{x} = \omega(A) - \omega(B). \tag{50.10}$$

If the angular frequency is greater at point A than at point B, then that means that there is an accumulation of wave crests entering the region at point A relative to those leaving at point B; i.e., there is a convergence of wave crests between the two points. This convergence is associated with an increase in the wavenumber between the two points.

50.2.3 Phase velocity and phase speed

Consider an observer moving on a smooth trajectory through space and time defined by a fixed point on a constant phase surface, such as when the observer remains fixed on the crest of a traveling wave.[2] As such, we assume that the trajectory is aligned in the direction of $\nabla\mathcal{P}$, which

[2]Our formulation in this section emulates that used in Section 17.4 for the Lagrangian time derivative, which is concerned with measuring fluid properties following a fluid particle. Here, we are following a wave as defined by a surface of constant phase.

is the local direction of the wave

$$\hat{\boldsymbol{k}} \equiv \nabla\mathcal{P}/|\nabla\mathcal{P}| \equiv \boldsymbol{k}/|\boldsymbol{k}|, \tag{50.11}$$

with the local wavevector defined by equation (50.2).

To determine the velocity of the fixed-phase observer, consider an infinitesimal spatial increment, $\delta\boldsymbol{x}^{\text{phase}}$, that occurs over a small time increment, δt. Assuming this space increment follows the fixed-phase observer leads to the identity

$$\mathcal{P}(\boldsymbol{x} + \delta\boldsymbol{x}^{\text{phase}}, t + \delta t) = \mathcal{P}(\boldsymbol{x}, t). \tag{50.12}$$

Truncating a Taylor series expansion of this identity leads to the differential equation satisfied by the phase

$$(\partial_t + \boldsymbol{c}_{\text{p}} \cdot \nabla)\mathcal{P} = 0, \tag{50.13}$$

where we defined the *phase velocity*

$$\boldsymbol{c}_{\text{p}} = \delta\boldsymbol{x}^{\text{phase}}/\delta t. \tag{50.14}$$

The partial differential equation (50.13) specifies $\boldsymbol{c}_{\text{p}} \cdot \nabla\mathcal{P} = \boldsymbol{c}_{\text{p}} \cdot \boldsymbol{k}$ in terms of the time derivative of the phase

$$\boldsymbol{c}_{\text{p}} \cdot \boldsymbol{k} = \boldsymbol{c}_{\text{p}} \cdot \nabla\mathcal{P} = -\partial_t\mathcal{P}. \tag{50.15}$$

Indeed, since the observer is assumed to move along the direction of the wavevector, $\hat{\boldsymbol{k}}$, then $\boldsymbol{c}_{\text{p}} \cdot \hat{\boldsymbol{k}}$ is the only component of the phase velocity. We thus write the phase velocity as in our discussion of plane waves in Section 49.5.2

$$\boldsymbol{c}_{\text{p}} = (\boldsymbol{c}_{\text{p}} \cdot \hat{\boldsymbol{k}})\,\hat{\boldsymbol{k}} \equiv C_{\text{p}}\,\hat{\boldsymbol{k}}, \tag{50.16}$$

where $C_{\text{p}} > 0$ is the *phase speed*, which is the magnitude of the phase velocity. Figure 49.2 provides an illustration.

50.2.4 Angular frequency and wavelength

The time derivative, $\partial_t\mathcal{P}$, measures the time change of the phase at a fixed point in space, which we use to define the local angular frequency of the wave as per equation (50.2)

$$\omega = -\partial_t\mathcal{P}. \tag{50.17}$$

The differential equation (50.13) for the phase can thus be written in the equivalent manners

$$(\partial_t + \boldsymbol{c}_{\text{p}} \cdot \nabla)\mathcal{P} = 0 \iff \omega = \boldsymbol{c}_{\text{p}} \cdot \boldsymbol{k}, \tag{50.18}$$

which also leads to the relations

$$\boldsymbol{c}_{\text{p}} = C_{\text{p}}\,\hat{\boldsymbol{k}} = \frac{-\partial_t\mathcal{P}}{|\nabla\mathcal{P}|}\frac{\nabla\mathcal{P}}{|\nabla\mathcal{P}|}, \tag{50.19}$$

where $C_{\text{p}} \geq 0$ is the phase speed. We likewise identify the wavelength

$$\Lambda = 2\pi/|\boldsymbol{k}| \implies C_{\text{p}} = \omega\,\Lambda/2\pi. \tag{50.20}$$

Note that the relations (50.19) and (50.20) also hold for free plane waves moving through a homogeneous media, as discussed in Section 49.5.

50.3 Kinematics of rays

Recall that when studying wave packets in Section 49.6, we found the group velocity to be fundamental to the wave packet evolution. We show later in this chapter that the group velocity defines the paths along which wave action (wave energy divided by wave angular frequency) propagates. Such paths are referred to as *rays*. Given the prominence of rays, we find it useful to develop evolution equations for wave properties along rays. We here start that process, focusing on the wave phase, wavevector, and angular frequency. This material forms elements to *geometric optics*, which is a subject commonly taught in introductory physics courses by presenting a series of rules for how light reflects and refracts. In this section we derive those rules in the form of partial differential equations following from basic principles.

50.3.1 Eikonal equation

The dispersion relation provides the local value of the angular frequency as a function of space, time, and wavevector, where the wavevector itself is a function of space and time

$$\omega = \varpi(\boldsymbol{x}, t, \boldsymbol{k}(\boldsymbol{x}, t)) = \varpi(\boldsymbol{x}, t, \nabla\mathcal{P}). \tag{50.21}$$

As such, the dispersion relation is an explicit function of $(\boldsymbol{x}, t)$, as well as a function of a function, $\boldsymbol{k} = \boldsymbol{k}(\boldsymbol{x}, t)$, which makes ϖ also an implicit function of $(\boldsymbol{x}, t)$. This dependence is reminiscent of the Lagrangian and Hamiltonian densities encountered in Chapter 46. Just like for the Lagrangian density, it is crucial to account for this functional dependency when computing space and time derivatives.[3] A useful rule to remember is that the angular frequency, ω, is a function of space and time, $\omega = \omega(\boldsymbol{x}, t) = -\partial_t\mathcal{P}(\boldsymbol{x}, t)$. Yet when connected to a dispersion relation, $\varpi(\boldsymbol{x}, t, \boldsymbol{k}(\boldsymbol{x}, t))$, which links a wavevector to an angular frequency, then we must treat the dispersion relation as an explicit function of $\boldsymbol{x}, t$, *as well as* an implicit function through the wavevector dependence, $\boldsymbol{k} = \boldsymbol{k}(\boldsymbol{x}, t)$.

Recall from Section 50.2 that there is a relation between the wave phase, $\mathcal{P}$, the local angular frequency, $\omega = -\partial_t\mathcal{P}$, and the local wavevector, $\boldsymbol{k} = \nabla\mathcal{P}$. Inserting these identities into the local dispersion relation (50.21) leads to the *eikonal equation*, which is a nonlinear partial differential equation for the phase[4]

$$\partial_t\mathcal{P} + \varpi(\boldsymbol{x}, t, \nabla\mathcal{P}) = 0. \tag{50.22}$$

This equation is formally the same as the *Hamilton-Jacobi* equation of classical mechanics, yet with ϖ playing the role of the Hamiltonian (e.g., *Marion and Thornton* (1988) or *Goldstein* (1980)). That analogy offers suggestions for how to make use of this equation. Note that on *Olbers et al.* (2012) (see their page 168) write the eikonal equation in the alternative form

$$(\partial_t\mathcal{P})^2 = C_{\mathsf{p}}^2\,(\nabla\mathcal{P})^2, \tag{50.23}$$

which follows from the definition of the local phase speed in equation (50.19).

50.3.2 Rays are integral curves of the group velocity

A *ray* is an integral curve of the group velocity. Hence, the ray trajectory, $\boldsymbol{X}(t)$, follows a ray and is determined by solving the ordinary differential equation

$$\frac{\mathrm{D}_t\boldsymbol{X}}{\mathrm{D}t} = \boldsymbol{c}_{\mathsf{g}}. \tag{50.24}$$

[3] In Section 46.3.1 we provide a detailed discussion of these derivatives, with that discussion suited to the present discussion of geometric optics.

[4] As per page 362 of *Thorne and Blandford* (2017).

The time derivative, $\mathrm{D}_r/\mathrm{D}t$, determines time changes when following a ray, and so it is defined by this equation. Indeed, our specification of $\mathrm{D}_r/\mathrm{D}t$ and $\boldsymbol{c}_g$ correspond precisely to how we defined the trajectory of a fluid particle as the integral curve of the fluid velocity as per equation (17.66a). Introducing the dispersion relation leads to

$$\frac{\mathrm{D}_r \boldsymbol{X}}{\mathrm{D}t} = \boldsymbol{c}_g = \nabla_{\boldsymbol{k}} \varpi(\boldsymbol{x}, t, \boldsymbol{k}). \tag{50.25}$$

Writing this equation in component form

$$\frac{\mathrm{D}_r X^a}{\mathrm{D}t} = c_g^a = \left[\frac{\partial \varpi(\boldsymbol{x}, t, \boldsymbol{k})}{\partial k_a}\right]_{\boldsymbol{x},t} \tag{50.26}$$

emphasizes that the derivative is computed while holding the space and time point fixed while varying the wavevector.

50.3.3 Evolution of $\boldsymbol{k}$ along a ray

To determine the evolution of the wavevector and angular frequency along a ray, we start with the following identity that holds for the phase function, $\mathcal{P} = \mathcal{P}(\boldsymbol{x}, t)$, merely since the partial derivatives commute

$$\nabla(\partial_t \mathcal{P}) = \partial_t(\nabla \mathcal{P}). \tag{50.27}$$

The derivatives in this equation are taken with their complementary variables fixed, and this point is important when inserting the dispersion relation. Indeed, before working through the following manipulations it can be useful to reread Section 50.3.1 to be reminded of the various functional relationships.

Exposing subscripts for clarity, we start from equation (50.27) to write

$$\begin{aligned}
\frac{\partial}{\partial t}\Big]_{\boldsymbol{x}} \left[\frac{\partial \mathcal{P}}{\partial x^a}\right]_t &= \left[\frac{\partial k_a}{\partial t}\right]_{\boldsymbol{x}} && \text{equation (50.2)} && \text{(50.28a)}\\
&= -\left[\frac{\partial \omega(\boldsymbol{x}, t)}{\partial x^a}\right]_t && \text{equation (50.27)} && \text{(50.28b)}\\
&= -\left[\frac{\partial \varpi(\boldsymbol{x}, t, \boldsymbol{k})}{\partial x^a}\right]_t && \text{equation (50.21)} && \text{(50.28c)}\\
&= -\left[\frac{\partial \varpi(\boldsymbol{x}, t, \boldsymbol{k})}{\partial k_b}\right]_{\boldsymbol{x},t} \left[\frac{\partial k_b}{\partial x^a}\right]_t - \left[\frac{\partial \varpi(\boldsymbol{x}, t, \boldsymbol{k})}{\partial x^a}\right]_{\boldsymbol{k},t} && \text{chain rule} && \text{(50.28d)}\\
&= -c_g^b \left[\frac{\partial k_b}{\partial x^a}\right]_t - \left[\frac{\partial \varpi(\boldsymbol{x}, t, \boldsymbol{k})}{\partial x^a}\right]_{\boldsymbol{k},t} && \text{equation (50.25).} && \text{(50.28e)}
\end{aligned}$$

We can massage the first right hand side term in equation (50.28e) by commuting partial derivatives

$$\frac{\partial k_b}{\partial x^a} = \frac{\partial^2 \mathcal{P}}{\partial x^b \, \partial x^a} = \frac{\partial k_a}{\partial x^b}, \tag{50.29}$$

so that

$$\left[\frac{\partial k_a}{\partial t}\right]_{\boldsymbol{x}} = -(\boldsymbol{c}_g \cdot \nabla) k_a - \left[\frac{\partial \varpi(\boldsymbol{x}, t, \boldsymbol{k})}{\partial x^a}\right]_{\boldsymbol{k},t}. \tag{50.30}$$

Introducing the time derivative following a ray renders the wavevector evolution equation

$$\frac{\mathrm{D}_r k_a}{\mathrm{D}t} = -\left[\frac{\partial \varpi(\boldsymbol{x}, t, \boldsymbol{k})}{\partial x^a}\right]_{\boldsymbol{k},t}. \tag{50.31}$$

Evidently, if the dispersion relation has no explicit dependence on x^a, then the corresponding component of the wavevector remains constant when following a ray. However, if there is a dependence, then the wavevector evolves along the ray, with this evolution known as *refraction*.

50.3.4 Evolution of ω along a ray

Being a bit more streamlined than in Section 50.3.3, we compute the time derivative of the angular frequency

$$-\frac{\partial^2 \mathcal{P}}{\partial t^2} = \left[\frac{\partial \omega}{\partial t}\right]_{\boldsymbol{x}} \tag{50.32a}$$

$$= \left[\frac{\partial \varpi}{\partial t}\right]_{\boldsymbol{x}} \tag{50.32b}$$

$$= \left[\frac{\partial \varpi}{\partial k_b}\right]_{\boldsymbol{x},t} \left[\frac{\partial k_b}{\partial t}\right]_{\boldsymbol{x}} + \left[\frac{\partial \varpi}{\partial t}\right]_{\boldsymbol{x},\boldsymbol{k}} \tag{50.32c}$$

$$= -c_{\mathrm{g}}^b \left[\frac{\partial \omega}{\partial x^b}\right]_t + \left[\frac{\partial \varpi}{\partial t}\right]_{\boldsymbol{x},\boldsymbol{k}}, \tag{50.32d}$$

where the final step used

$$\left[\frac{\partial k_b}{\partial t}\right]_{\boldsymbol{x}} = \frac{\partial^2 \mathcal{P}}{\partial t\, \partial x^b} = \frac{\partial}{\partial x^b}\frac{\partial \mathcal{P}}{\partial t} = -\left[\frac{\partial \omega}{\partial x^b}\right]_t. \tag{50.33}$$

We are thus lead to the evolution equation for the angular frequency along a ray

$$\frac{\mathrm{D}_t \omega}{\mathrm{D}t} = \left[\frac{\partial \varpi}{\partial t}\right]_{\boldsymbol{x},\boldsymbol{k}}. \tag{50.34}$$

Evidently, if the dispersion relation has no explicit dependence on time, then the angular frequency is a constant following a ray. For example, this is the situation when gravity waves approach a beach, assuming the slope of the beach is static (considered in Section 52.7.1). For this example, the angular frequency of gravity waves remains constant following a ray, whereas the wavevector changes according to equation (50.31).

50.3.5 Changes in the phase following a ray

Considering the phase function to be a function of space and time, $\mathcal{P}(\boldsymbol{x}, t)$, we compute its time derivative along a ray according to

$$\mathrm{D}_r\mathcal{P}/\mathrm{D}t = (\partial_t + \boldsymbol{c}_{\mathrm{g}} \cdot \nabla)\,\mathcal{P} = -\omega + \boldsymbol{c}_{\mathrm{g}} \cdot \boldsymbol{k} = \boldsymbol{k} \cdot (-\boldsymbol{c}_{\mathrm{p}} + \boldsymbol{c}_{\mathrm{g}}), \tag{50.35}$$

where $\omega = -\partial_t \mathcal{P} = \boldsymbol{c}_{\mathrm{p}} \cdot \boldsymbol{k}$, as per equations (50.17) and (50.18), and $\boldsymbol{k} = \nabla_{\boldsymbol{x}} \mathcal{P}$ as per equation (50.2). Non-dispersive have a phase that remains unchanged when following a ray, which holds so long as

$$\boldsymbol{k} \cdot \boldsymbol{c}_{\mathrm{p}} = \boldsymbol{k} \cdot \boldsymbol{c}_{\mathrm{g}} \quad \text{non-dispersive waves.} \tag{50.36}$$

Otherwise, for dispersive waves the phase changes according to the source term, $\boldsymbol{k} \cdot (-\boldsymbol{c}_{\mathrm{p}} + \boldsymbol{c}_{\mathrm{g}})$.

50.3.6 Summary of the ray equations

We here summarize the evolution equations for wave properties derived thus far in this chapter, with these equations constituting *Hamilton's equations for rays*

$$\frac{\mathrm{D}_r \boldsymbol{X}}{\mathrm{D}t} = \boldsymbol{c}_\mathrm{g} \qquad \text{trajectory on a ray} \quad (50.37a)$$

$$\frac{\mathrm{D}_r \mathcal{P}}{\mathrm{D}t} = \boldsymbol{k}\cdot(-\boldsymbol{c}_\mathrm{p}+\boldsymbol{c}_\mathrm{g}) \iff \partial_t \mathcal{P} + \varpi(\boldsymbol{x},t,\nabla\mathcal{P}) = 0 \qquad \text{eikonal equation for phase} \quad (50.37b)$$

$$\frac{\mathrm{D}_r \boldsymbol{k}}{\mathrm{D}t} = -\left[\frac{\partial \varpi}{\partial \boldsymbol{x}}\right]_{t,\boldsymbol{k}} \qquad \boldsymbol{k} \text{ evolution on a ray} \quad (50.37c)$$

$$\frac{\mathrm{D}_r \omega}{\mathrm{D}t} = \left[\frac{\partial \varpi}{\partial t}\right]_{\boldsymbol{x},\boldsymbol{k}} \qquad \omega \text{ evolution on a ray} \quad (50.37d)$$

$$\frac{\mathrm{D}_r}{\mathrm{D}t} = \partial_t + \boldsymbol{c}_\mathrm{g}\cdot\nabla \qquad \text{time derivative on a ray} \quad (50.37e)$$

$$\omega = -\partial_t \mathcal{P} \qquad \omega \text{ defined} \quad (50.37f)$$

$$\boldsymbol{k} = \nabla\mathcal{P} \qquad \boldsymbol{k} \text{ defined} \quad (50.37g)$$

$$\nabla\times\boldsymbol{k} = 0 \qquad \boldsymbol{k} \text{ consistency condition} \quad (50.37h)$$

$$\partial_t \boldsymbol{k} + \nabla\omega = 0 \qquad \text{conservation of wave crests.} \quad (50.37i)$$

Equation (50.37a) defines the rays as integral lines of the group velocity, $\boldsymbol{c}_\mathrm{g}$. Equation (50.37b) is the eikonal equation that connects the local angular frequency to the dispersion relation

$$\omega = -\partial_t \mathcal{P} = \varpi(\boldsymbol{x},t,\nabla\mathcal{P}). \quad (50.38)$$

Each of the evolution equations (50.37b)–(50.37d) is hyperbolic, which is notable since this property holds even though the wave equation describing the evolution of the wave function is not generally hyperbolic (particularly for dispersive waves).

By definition, the phase remains constant when following along a constant wave phase so that

$$(\partial_t + \boldsymbol{c}_\mathrm{p}\cdot\nabla)\,\mathcal{P} = 0. \quad (50.39)$$

However, for dispersive waves, equation (50.37b) indicates that the phase does not stay fixed when following rays as defined by the group velocity. Hence, wave crests pass through a point following the group velocity, such as a point fixed within a wave packet. Conversely, equations (50.37c) and (50.37d) show that for dispersive waves, the wavevector and angular frequency are not constant when following a constant wave phase. Instead, they remain fixed when following the group velocity in media where the dispersion relation is independent of space and time. For more general media, both the wavevector and angular frequency evolve even when following the group velocity.

50.3.7 Comments and further study

Knowledge of the dispersion relation is sufficient to solve the ray equations (typically using numerical methods), thus mapping the rays and paths of wave packets, and determining the wavevector, angular frequency, and phase following a ray. This procedure works quite well to describe waves moving through smoothly varying media, and is familiar from the rays of light bending through water or glass. Failure of the method occurs when the background media no longer satisfies the "gently varying" assumptions that are formalized in Section 50.5.3 for the case of a stretched string. Breaking these assumptions often results in the intersection of rays which, in many fluid applications, signals a nonlinear process such as a fluid instability and

corresponding turbulent mixing. Chapter 11 of *Whitham* (1974), Chapters 3 and 4 of *Bühler* (2014a), and the bulk of *Tracy et al.* (2014) provide more details and insights.

50.4 Hamilton's principle and the Euler-Lagrange equation

The geometric optics discussion in Section 50.3 is largely kinematic, with the only piece of dynamical information arising from the dispersion relation. To develop a theory for the energetics of waves and wave packets moving through gently varying background states, we make use of Hamilton's principle, or more specifically Whitham's variational principle applying to the phase averaged equations. We pursue that study in Section 50.5, yet here first summarize salient points from Lagrangian field theory from Chapter 46.

50.4.1 Stationary action $\Longleftrightarrow$ Euler-Lagrange equation

The *action*, $\mathcal{S}$, for a continuous scalar field, $\psi(\boldsymbol{x},t)$, is given by equation (46.13)

$$\mathcal{S} = \int_R \mathscr{L}(\psi, \partial_t\psi, \nabla\psi, \boldsymbol{x}, t)\, g\, \mathrm{d}^3x\, \mathrm{d}t, \tag{50.40}$$

where R is a space-time domain, g is the square root of the metric tensor determinant, and $\mathscr{L}$ is the *Lagrangian density*. The Lagrangian density is a functional of the field and its space-time derivatives (i.e., $\mathscr{L}$ is a function of a function). There can also be additional explicit dependencies on the space and time position, which occurs, in particular, for waves moving through a media that is inhomogeneous in space and/or non-stationary in time, in which case $\mathscr{L}$ is an explicit function of $(\boldsymbol{x},t)$. *Hamilton's principle* as stated by equation (46.18) says that variation of the action is stationary (i.e., variation of the action vanishes) for the physically realized field. Hamilton's principle then leads to the *Euler-Lagrange field equation* (46.24)

$$\frac{\partial\mathscr{L}}{\partial\psi} - \frac{1}{g}\frac{\partial}{\partial x^\alpha}\left[g\,\frac{\partial\mathscr{L}}{\partial(\partial_\alpha\psi)}\right] = 0, \tag{50.41}$$

where $\alpha = 0,1,2,3$ is the space-time label. In performing the partial derivative with respect to ψ and its derivatives, $\partial_\alpha\psi$, each of the other variables in the Lagrangian density are held fixed. However, when performing the space and time partial derivatives, ∂_α, we only maintain the complement space and time variable fixed. This technical point is very important when taking derivatives of the Lagrangian density (see Section Section 46.3.1), and it is directly analogous to how we take derivatives of the dispersion relation in Section 50.3.

50.4.2 Hamiltonian density and energy of the continuum

In Section 46.4.1 we introduced the *generalized momentum density*, $\mathscr{P}$, and the *Hamiltonian density*,

$$\mathscr{P} = \frac{\partial\mathscr{L}}{\partial(\partial_t\psi)} \quad \text{and} \quad \mathscr{H} = \mathscr{P}\,\partial_t\psi - \mathscr{L}. \tag{50.42}$$

We then showed that the Hamiltonian density satisfies the budget equation

$$\partial_t\mathscr{H} + \nabla\cdot\boldsymbol{\mathscr{F}} = -(\partial\mathscr{L}/\partial t)_{\psi,\partial_\alpha\psi,\boldsymbol{x}}, \tag{50.43}$$

where the time derivative on the right hand side is computed while fixing ψ, its space and time derivatives, and the space position, $\boldsymbol{x}$. Equation (50.43) also introduced the flux vector, $\boldsymbol{\mathscr{F}}$, with components

$$\mathscr{F}^a = \frac{\partial\mathscr{L}}{\partial(\partial_a\psi)}\frac{\partial\psi}{\partial t}. \tag{50.44}$$

In those cases where the Lagrangian has no explicit time dependence, so that it has the functional dependence

$$\mathscr{L} = \mathscr{L}(\psi, \partial_t \psi, \nabla \psi, \boldsymbol{x}), \tag{50.45}$$

then the Hamiltonian equation (50.43) becomes a conservation equation for energy that follows from time symmetry and Noether's theorem

$$\partial_t \mathscr{H} + \nabla \cdot \mathscr{F} = 0. \tag{50.46}$$

50.4.3 Stress-energy-momentum tensor

As detailed in Section 46.4, the energy equation (50.43) is but one piece of the equation satisfied by the stress-energy-momentum tensor, $T^{\alpha}{}_{\beta}$. This equation is given by equation (46.74)

$$\partial_\alpha T^{\alpha}{}_{\beta} = -\left[\frac{\partial \mathscr{L}}{\partial x^\beta}\right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}}. \tag{50.47}$$

where the *stress-energy-momentum tensor* is

$$T^{\alpha}{}_{\beta} = -\delta^{\alpha}{}_{\beta}\, \mathscr{L} + \frac{\partial \mathscr{L}}{\partial_\alpha \psi} \frac{\partial \psi}{\partial x^\beta}. \tag{50.48}$$

50.5 Whitham's variational principle

The Euler-Lagrange field equation (50.41) and associated energy equation (50.43) provide the foundation for the field theory of continuous classical matter. In this section we specialize the field theory formalism for the purpose of describing waves and the movement of wave energy through a prescribed background environment. Much of this formalism was proposed by Whitham (e.g., see Chapter 11 of *Whitham* (1974)), so that we refer to the method as *Whitham's variational principle*. In other treatments, such as Section 2.2 of *Tracy et al.* (2014), it is referred to as the *reduced variational principle*.

We anticipated much of the material in this section when studying a pendulum with variable length in Section 15.2. In that section we showed that the pendulum energy divided by its frequency is an *adiabatic invariant*; i.e., it is nearly constant. In the present section we show that the *wave action* is the corresponding adiabatic invariant for waves moving on a gently varying background, with the wave action also equal to the energy (or Hamiltonian) divided by the angular frequency.

50.5.1 Some motivation

One practical motivation for developing Whitham's variational principle is to describe the energetics of waves propagating on a non-homogeneous and non-stationary background, though the formalism is also quite useful for homogeneous and stationary backgrounds, particularly for dispersive waves. In the presence of a space dependent background properties, there are no simple sinusoidal (plane) wave solutions. That is, Fourier methods are insufficient. Even so, there are waves that are quite close to plane waves *if* the space and time scales for changes in the background state are well separated from those describing the wave properties (frequency and wavelength). This space-time scale separation constitutes a "gently varying" background state, which in turn enables analytical progress. We introduced the scaling for this gentle background at the start of Section 50.2, and follow up in Section 50.5.3 with more details.

Whitham's method starts by inserting a wave ansatz into the Lagrangian density. Phase averaging then produces the *phase averaged Lagrangian* and corresponding *phase averaged action*.

We maintain only the leading order term in this phase average Lagrangian, and Whitham's variational principle then states that the physically realized wave produces a stationary wave averaged action. There are two associated Euler-Lagrange fields, one arising from varying the wave amplitude and the other from varying the wave phase.

50.5.2 The stretched string

Following *Bretherton and Garrett* (1969) and *Bretherton* (1971), we use a stretched string as a case study for exploring Whitham variational method. In particular, recall from Section 46.2.5 the Lagrangian density for the stretched string whose tension[5] is a function of time, $\tau = \tau(t)$, and whose mass density (mass per length) is a function of space, $\sigma = \sigma(x)$, is given by

$$\mathscr{L} = (1/2)[\sigma\,(\partial_t\psi)^2 - \tau\,(\partial_x\psi)^2], \tag{50.49}$$

and whose Hamiltonian density (50.42) is

$$\mathscr{H} = (1/2)[\sigma\,(\partial_t\psi)^2 + \tau\,(\partial_x\psi)^2]. \tag{50.50}$$

Note that $\psi(x,t)$ measures transverse displacements of the string from its equilibrium position at $\psi = 0$. We furthermore assume that there are no longitudinal waves along the string, thus focusing exclusively on transverse motion.

The action for the stretched string is

$$\mathcal{S} = \int \mathscr{L}\,\mathrm{d}x\,\mathrm{d}t = \int (1/2)\,[\sigma\,(\partial_t\psi)^2 - \tau\,(\partial_x\psi)^2]\,\mathrm{d}x\,\mathrm{d}t, \tag{50.51}$$

and the Euler-Lagrange equation resulting from Hamilton's principle is the wave equation

$$\delta\mathcal{S} = \int (\delta\mathscr{L})\,\mathrm{d}x\,\mathrm{d}t = 0 \Longleftrightarrow (\partial_{tt} - c^2\,\partial_{xx})\psi = 0, \tag{50.52}$$

with the squared wave speed

$$c^2(x,t) = \tau(t)/\sigma(x). \tag{50.53}$$

Because the wave speed is a function of space and time, we cannot use traditional Fourier methods to find a wave solution. Hence, the mathematical goal of this section is to develop methods for use when there are space and time variations of the background state, in particular when such variations are "gentle". In this case we are afforded the *eikonal wave ansatz*[6]

$$\psi(x,t) = A(x,t)\cos[\mathcal{P}(x,t)], \tag{50.54}$$

where $A > 0$ is a space-time dependent real amplitude function, and $\mathcal{P}$ is the phase function introduced in equation (50.2). We have more comments on this form for the wave ansatz in Section 50.5.4. s

50.5.3 Space and time scale separation

To make analytical progress requires us to detail the space and time scale separation between the linear waves and the background state, following from our introduction to this scaling at the start of Section 50.2. Although we here focus on the string, the same sorts of assumptions must

[5]The dimensions of τ are force, M L T^{-2}, but we refer to it as a tension since it is an internal force within the string.

[6]The ansatz (50.54) is commonly used with the WKBJ asymptotic method, and so is sometimes referred to as the WKBJ wave ansatz.

be realized for other waves systems in order to make use of the methods of this section. For the time scale, we assume that changes in the string tension occur over time sales that are much longer than the period of the linear waves supported by the string, so that

$$|\partial_t \tau/\tau| \ll |\partial_t \mathcal{P}|/2\pi = \omega/2\pi. \tag{50.55}$$

Correspondingly, temporal changes in the angular frequency are assumed to be on the same scale as temporal changes to the string tension

$$|\partial_t \omega/\omega| \sim |\partial_t \tau/\tau| \Longrightarrow |\partial_t \omega| \ll \omega^2/2\pi, \quad \text{or equivalently} \quad |\partial_{tt}\mathcal{P}| \ll (\partial_t \mathcal{P})^2/2\pi. \tag{50.56}$$

Likewise, time changes to the wave amplitude are defined by the background state so that

$$|\partial_t A/A| \sim |\partial_t \tau/\tau|. \tag{50.57}$$

For the length scale, we assume spatial changes in the mass density occur over scales that are large compared to the wavelength

$$|\partial_x \sigma/\sigma| \ll |\partial_x \mathcal{P}|/2\pi = |k|/2\pi, \tag{50.58}$$

and that spatial changes to the wavenumber and wave amplitude are on the same scale as changes to string mass density

$$|\partial_x k/k| \sim |\partial_x \sigma/\sigma| \Longrightarrow |\partial_x k| \ll k^2/2\pi \quad \text{or equivalently} \quad |\partial_{xx}\mathcal{P}| \ll (\partial_x \mathcal{P})^2/2\pi. \tag{50.59}$$

Likewise, space changes to the wave amplitude are defined by the background state so that

$$|\partial_x A/A| \sim |\partial_x \sigma/\sigma|. \tag{50.60}$$

50.5.4 The leading order phase averaged action

The space and time scale separation from Section 50.5.3 motivate the wave ansatz (50.54). Note that a more general ansatz might also consider a space-time dependent phase shift. We do not consider a phase shift since we are concerned with leading order evolution of the wave amplitude, and the extra phase degree of freedom is not directly tied to the amplitude. Furthermore, we could have expanded the amplitude function into an asymptotic series. But again, we are only interested in the leading order, with the ansatz (50.54) sufficient for that purpose.[7]

Leading order contribution to $\sigma\,(\partial_t \psi)^2$

To determine the leading order terms contributing to the Lagrangian (50.49), we start with the squared time tendency of the wave function

$$(\partial_t \psi)^2 = (\partial_t A \cos \mathcal{P})^2 + (A\,\partial_t \mathcal{P} \sin \mathcal{P})^2 - 2\,(A\,\partial_t \mathcal{P}\,\partial_t A \sin \mathcal{P} \cos \mathcal{P}), \tag{50.61}$$

which has a phase average

$$\langle \sigma\,(\partial_t \psi)^2 \rangle = \sigma\,[(\partial_t A)^2 + (A\,\partial_t \mathcal{P})^2]/2. \tag{50.62}$$

To compute the phase average we assumed that σ, $\partial_t A$, and $\partial_t \mathcal{P} = -\omega$ are roughly constant over the course of a 2π change in the phase, with this assumption following from the scaling in

[7] See Section 4 of *Bretherton* (1971) for more details of the phase shift and amplitude expansion.

Section 50.5.3. Further use of the scaling in Section 50.5.3 leads to the leading order contribution

$$\langle \sigma \, (\partial_t \psi)^2 \rangle \approx \sigma \, (A \, \partial_t \mathcal{P})^2 / 2 = \sigma \, A^2 \, \omega^2 / 2. \tag{50.63}$$

Leading order contribution to $\tau \, (\partial_x \psi)^2$

Proceeding just as above, the squared space derivative term in the Lagrangian (50.49) is given by

$$(\partial_x \psi)^2 = (\partial_x A \cos \mathcal{P})^2 + (A \, \partial_x \mathcal{P} \sin \mathcal{P})^2 - 2 \, (A \, \partial_x \mathcal{P} \, \partial_x A \sin \mathcal{P} \cos \mathcal{P}), \tag{50.64}$$

whose phase average is

$$\langle \tau \, (\partial_x \psi)^2 \rangle = \tau \, [(\partial_x A)^2 + (A \, \partial_x \mathcal{P})^2] / 2. \tag{50.65}$$

To compute the phase average we assumed that τ, $\partial_x A$, and $\partial_x \mathcal{P} = k$ are roughly constant over the course of a 2π change in the phase, with this assumption following from the scaling in Section 50.5.3. Further using the scaling in Section 50.5.3 we are led to the leading order contribution

$$\langle \tau \, (\partial_x \psi)^2 \rangle \approx \tau \, (A \, \partial_x \mathcal{P})^2 / 2 = \tau \, A^2 \, k^2 / 2. \tag{50.66}$$

Leading order phase averaged action

The above discussion provides the leading order phase averaged action

$$\langle \mathcal{S} \rangle = \frac{1}{4} \int A^2 \, (\sigma \, \omega^2 - \tau \, k^2) \, \mathrm{d}x \, \mathrm{d}t = \int \langle \mathcal{L} \rangle \, \mathrm{d}x \, \mathrm{d}t. \tag{50.67}$$

This phase averaged Lagrangian is directly analogous to the phase averaged Lagrangian (15.44) for the pendulum whose length is slowly varying.

50.5.5 Whitham's variational principle for the string

Whitham's variational principle states that the phase averaged action, $\langle \mathcal{S} \rangle$, is stationary when $\psi = A \cos \mathcal{P}$ is the physically realized wave function. To find the associated Euler-Lagrange equations requires computing the variation of the action, which in turn requires varying the wave function. Variations in the wave function arise from arbitrary smooth and independent variations (with compact support) of the amplitude, A, and the phase, $\mathcal{P}$. Hence, the phase averaged action must be stationary with respect to independent variations in both A and $\mathcal{P}$. As we see in the following, the dispersion relation is the Euler-Lagrange equation resulting from $\delta_A \langle \mathcal{S} \rangle = 0$, whereas *wave action* conservation results from $\delta_{\mathcal{P}} \langle \mathcal{S} \rangle = 0$.

Vanishing variation with respect to A is equivalent to the dispersion relation

Variation of the phase averaged action (50.67) under variations in the wave amplitude is given by

$$\delta_A \langle \mathcal{S} \rangle = \frac{1}{2} \int (\sigma \, \omega^2 - \tau \, k^2) \, A \, \delta A \, \mathrm{d}x \, \mathrm{d}t, \tag{50.68}$$

and with a zero variation leading to

$$\delta_A \langle \mathcal{S} \rangle = 0 \iff \omega^2 = (\sigma / \tau)^2 \, k^2 = c^2 \, k^2. \tag{50.69}$$

Evidently, satisfying the dispersion relation is equivalent to a zero variation of the phase averaged action with respect to the wave amplitude. Furthermore, since $\langle \mathcal{L} \rangle$ is proportional to the squared wave amplitude, then satisfying the dispersion relation (50.69) means that the phase averaged

Lagrangian vanishes when evaluated with the physical solution,

$$\langle \mathcal{L} \rangle = A^2 \, (\sigma \, \omega^2 - \tau \, k^2)/4 = 0. \tag{50.70}$$

Vanishing variation with respect to $\mathcal{P}$

Variation of the phase averaged action (50.67) under variations in the wave phase function is given by

$$\delta_{\mathcal{P}} \langle \mathcal{S} \rangle = \frac{1}{2} \int A^2 \, (\sigma \, \omega \, \delta\omega - \tau \, k \, \delta k) \, \mathrm{d}x \, \mathrm{d}t = \frac{1}{2} \int A^2 \, [\sigma \, \partial_t \mathcal{P} \, \delta(\partial_t \mathcal{P}) - \tau \, \partial_x \mathcal{P} \, \delta(\partial_x \mathcal{P})] \, \mathrm{d}x \, \mathrm{d}t, \tag{50.71}$$

with rearrangement giving

$$\begin{aligned} \delta_{\mathcal{P}} \langle \mathcal{S} \rangle = \frac{1}{2} \int A^2 \, \left[\partial_t (A^2 \, \sigma \, \partial_t \mathcal{P} \, \delta\mathcal{P}) - \partial_x (A^2 \, \tau \, \partial_x \mathcal{P} \, \delta\mathcal{P}) \right] \mathrm{d}x \, \mathrm{d}t \\ - \frac{1}{2} \int A^2 \left[\partial_t (A^2 \, \sigma \, \partial_t \mathcal{P}) \, \delta\mathcal{P} - \partial_x (A^2 \, \tau \, \partial_x \mathcal{P}) \, \delta\mathcal{P} \right] \mathrm{d}x \, \mathrm{d}t. \end{aligned} \tag{50.72}$$

Assuming $\delta\mathcal{P}$ vanishes on the space-time boundaries, or that it has compact support in space and time, eliminates the first integral to leave

$$\delta_{\mathcal{P}} \langle \mathcal{S} \rangle = -\frac{1}{2} \int A^2 \left[\partial_t (A^2 \, \sigma \, \partial_t \mathcal{P}) - \partial_x (A^2 \, \tau \, \partial_x \mathcal{P}) \right] \delta\mathcal{P} \, \mathrm{d}x \, \mathrm{d}t, \tag{50.73}$$

with Whitham's principle $\delta_{\mathcal{P}} \langle \mathcal{S} \rangle = 0$ producing the conservation law

$$\delta_{\mathcal{P}} \langle \mathcal{S} \rangle = 0 \Longrightarrow \partial_t (A^2 \, \sigma \, \omega) + \partial_x (A^2 \, \tau \, k) = 0. \tag{50.74}$$

Interpretation of this conservation law follows from the discussion in the remainder of this Section.

50.5.6 Phase averaged Hamiltonian

Making use of the eikonal wave ansatz (50.54) renders the leading order phase averaged Hamiltonian (50.50)

$$\langle \mathcal{H} \rangle = A^2 \, (\sigma \, \omega^2 + \tau \, k^2)/4, \tag{50.75}$$

with the dispersion relation (50.69) yielding

$$\langle \mathcal{H} \rangle = A^2 \, \sigma \, \omega^2/2 = A^2 \, \tau \, k^2/2. \tag{50.76}$$

We can use these expressions to write the conservation law (50.74) as

$$\partial_t (\langle \mathcal{H} \rangle / \omega) + \partial_x (\langle \mathcal{H} \rangle / k) = 0. \tag{50.77}$$

This equation is nearly ready for interpretation, but it aided by the discussion in Section 50.5.7.

50.5.7 A general statement of Whitham's variational principle

To help interpret the conservation law (50.77), it is useful to provide a generic expression of Whitham's variational principle, which we write as

$$\delta \int \langle \mathcal{L} \rangle (A, \omega, k; \sigma, \tau) \, \mathrm{d}x \, \mathrm{d}t = \delta \int \langle \mathcal{L} \rangle (A, -\partial_t \mathcal{P}, \partial_x \mathcal{P}; \sigma, \tau) \, \mathrm{d}x \, \mathrm{d}t = \int \delta \langle \mathcal{L} \rangle \, \mathrm{d}x \, \mathrm{d}t = 0. \tag{50.78}$$

The resulting Euler-Lagrange equations follow through variations of the wave amplitude, A, and phase function, $\mathcal{P}$.

Varying the wave amplitude and the dispersion relation

The Euler-Lagrange equation resulting from varying the amplitude is written (see equation (50.41))

$$\frac{\delta \mathcal{S}}{\delta A} = \frac{\partial \langle \mathcal{L} \rangle}{\partial A} - \frac{\partial}{\partial t}\left[\frac{\partial \langle \mathcal{L} \rangle}{\partial (\partial_t A)}\right] - \frac{\partial}{\partial x}\left[\frac{\partial \langle \mathcal{L} \rangle}{\partial (\partial_x A)}\right] = 0. \tag{50.79}$$

Notably, for linear waves the wave amplitude appears in $\langle \mathcal{L} \rangle$ only via its square, A^2, so that the second and third terms in equation (50.79) vanish identically. As a result, the Euler-Lagrange equation resulting from varying A is

$$\frac{\partial \langle \mathcal{L} \rangle}{\partial A} = 0, \tag{50.80}$$

which, as we saw for the stretched string in Section 50.5.5, is equivalaent to the dispersion relation connecting the wave angular frequency to the wavevector. Another way to write the dispersion relation is to note that the phase averaged Lagrangian for linear waves satisfies

$$A\, \partial \langle \mathcal{L} \rangle / \partial A = 2 \langle \mathcal{L} \rangle, \tag{50.81}$$

so that

$$\langle \mathcal{L} \rangle = 0 \Longleftrightarrow \text{dispersion relation}. \tag{50.82}$$

Varying the phase function, group velocity, and conservation of wave action

For linear waves, the phase function only appears in terms of its space and time derivatives, so that $\partial \langle \mathcal{L} \rangle / \partial \mathcal{P} = 0$, in which case the Euler-Lagrange equation resulting from varying the phase function is given by

$$\frac{\delta \mathcal{S}}{\delta \mathcal{P}} = \frac{\partial}{\partial t}\left[\frac{\partial \langle \mathcal{L} \rangle}{\partial (\partial_t \mathcal{P})}\right] + \frac{\partial}{\partial x}\left[\frac{\partial \langle \mathcal{L} \rangle}{\partial (\partial_x \mathcal{P})}\right] = 0 \Longrightarrow -\frac{\partial}{\partial t}\left[\frac{\partial \langle \mathcal{L} \rangle}{\partial \omega}\right] + \frac{\partial}{\partial x}\left[\frac{\partial \langle \mathcal{L} \rangle}{\partial k}\right] = 0. \tag{50.83}$$

We can write this conservation equation in a slightly different form by introducing the group velocity. For this purpose, consider the implications for a zero variation of the phase averaged Lagrangian (another way to state Whitham's principle as in equation (50.78)) so that

$$0 = \delta \langle \mathcal{L} \rangle = \frac{\partial \langle \mathcal{L} \rangle}{\partial A}\, \delta A + \frac{\partial \langle \mathcal{L} \rangle}{\partial \omega}\, \delta \omega + \frac{\partial \langle \mathcal{L} \rangle}{\partial k}\, \delta k = \frac{\partial \langle \mathcal{L} \rangle}{\partial \omega}\, \delta \omega + \frac{\partial \langle \mathcal{L} \rangle}{\partial k}\, \delta k, \tag{50.84}$$

where $\partial \langle \mathcal{L} \rangle / \partial A = 0$ follows from equation (50.80). Rearrangement allows us to write the group velocity in terms of derivatives of the phase averaged Lagrangian

$$c_{\mathrm{g}} = \delta \omega / \delta k = -\frac{\partial \langle \mathcal{L} \rangle / \partial k}{\partial \langle \mathcal{L} \rangle / \partial \omega}, \tag{50.85}$$

so that the Euler-Lagrange equation (50.83) can be written in the form of a traditional conservation law

$$\partial_t \mathcal{A} + \partial_x (c_{\mathrm{g}}\, \mathcal{A}) = 0, \tag{50.86}$$

where we defined the *wave action*

$$\mathcal{A} \equiv \frac{\partial \langle \mathcal{L} \rangle}{\partial \omega}. \tag{50.87}$$

Note that for some applications it is more useful to write the wave action equation (50.86) following the group velocity, so that

$$\frac{\mathrm{D}_{\mathrm{r}}\mathcal{A}}{\mathrm{D}t} = -\mathcal{A}\,\partial_x c_{\mathrm{g}}. \tag{50.88}$$

Hence, the wave action evolves following a ray when moving through regions where the group velocity has a nonzero convergence.

50.5.8 Interpreting the string's wave action conservation equation

For the string, we find

$$\partial\langle\mathcal{L}\rangle/\partial\omega = A^2\,\sigma\,\omega/2 = \langle\mathscr{H}\rangle/\omega = \mathcal{A}, \tag{50.89}$$

so that the wave action conservation law (50.87) can be written in terms of the Hamiltonian

$$\partial_t(\langle\mathscr{H}\rangle/\omega) + \partial_x(c_{\mathrm{g}}\,\langle\mathscr{H}\rangle/\omega) = 0, \tag{50.90}$$

which accords with equation (50.77) given that the string is non-dispersive so that the group velocity is $c_{\mathrm{g}} = \omega/k$.

So in summary, the Euler-Lagrange equation arising from $\delta_{\mathcal{P}}\langle\mathcal{S}\rangle = 0$ leads to the wave action conservation law (50.90). This conservation law is associated with a symmetry of the phase averaged Lagrangian; namely, it is has no explicit dependence on the phase so that $\partial\langle\mathcal{L}\rangle/\partial\mathcal{P} = 0$. Whereas mechanical energy satisfies a conservation law when the background state is time-independent (i.e., the Lagrangian has no explicit time dependence), the wave action satisfies a conservation law since the phase averaged Lagrangian has no explicit dependence on the phase.

50.5.9 Comments

Although the presentation in this section used the relatively simple case of a stretched string, the underlying theory holds for all linear waves. As such, we expand our understanding of the theory when considering waves of more complexity in the following chapters. In particular, the theory proves quite useful for organizing our thinking about group velocity and wave energetics, particularly for dispersive waves whether on a stationary and homogeneous background or more generally.

50.6 Variational methods for self-adjoint wave operators

Our use of variational methods for waves is concerned with the propagation of wave packets through a gently varying and prescribed background state. We assume the packet is prepared at some initial time and fully known at the final time, so that variations of the wave function (as per Hamilton's principle) are nonzero only at intermediate times. Likewise, we assume the packet is specified at the spatial boundaries, so that its variation vanishes there as well. With these assumptions, we here detail a variational method that makes use of the self-adjoint nature of the wave operator. By exploiting the self-adjoint property, we can reformulate Whitham's variational principle from Section 50.5.

50.6.1 Self-adjoint linear wave operators

Assuming Cartesian coordinates, the Euler-Lagrange equations for the acoustic and Klein-Gordon wave equations from Section 46.2.5 can be written

$$\frac{\delta \mathcal{S}}{\delta \psi} = \frac{\partial \mathcal{L}}{\partial \psi} - \frac{\partial}{\partial x^\alpha}\left[\frac{\partial \mathcal{L}}{\partial(\partial_\alpha \psi)}\right] = \widehat{D}\psi = 0, \tag{50.91}$$

where $\widehat{D}$ is the linear partial differential operator,

$$\widehat{D} = -(\partial_{tt} - c^2\,\nabla^2 + \Gamma^2), \tag{50.92}$$

for the Klein-Gordon wave equation with constant c, and with $\Gamma = 0$ for the acoustic wave equation. This result allows us to write the action for this, and other, linear non-dissipative waves in the bilinear form

$$\mathcal{S} = \frac{1}{2}\int_{\mathrm{R}} \psi\,(\widehat{D}\psi)\,\mathrm{d}^3x\,\mathrm{d}t. \tag{50.93}$$

Notably, this action vanishes identically when ψ is a solution to the wave equation, as per equation (50.91), yet the action is non-zero for a general function.

50.6.2 Varying the action

Variation of the action (50.93) can be written

$$2\,\delta\mathcal{S} = \int_{\mathrm{R}} (\delta\psi)\,\widehat{D}\psi\,\mathrm{d}^3x\,\mathrm{d}t + \int_{\mathrm{R}} \psi\,(\widehat{D}\delta\psi)\,\mathrm{d}^3x\,\mathrm{d}t, \tag{50.94}$$

with integration by parts bringing the second right hand side term into the form

$$\begin{aligned}\int_{\mathrm{R}} \psi\,(\widehat{D}\delta\psi)\,\mathrm{d}^3x\,\mathrm{d}t &= \int_{\mathrm{R}} \delta\psi\,(\widehat{D}\psi)\,\mathrm{d}^3x\,\mathrm{d}t \\ &\quad - \int_{\mathrm{R}} \partial_t(\psi\,\partial_t\delta\psi - \delta\psi\,\partial_t\psi)\,\mathrm{d}^3x\,\mathrm{d}t + c^2\int_{\mathrm{R}} \delta^{ab}\partial_b(\psi\,\partial_a\delta\psi - \delta\psi\,\partial_a\psi)\,\mathrm{d}^3x\,\mathrm{d}t.\end{aligned} \tag{50.95}$$

For Hamilton's principle, we assume that $\delta\psi = 0$ at the temporal endpoints, so that

$$\int_{\mathrm{R}} \partial_t(\delta\psi\,\partial_t\psi)\,\mathrm{d}^3x\,\mathrm{d}t = 0. \tag{50.96}$$

Likewise, the term

$$\int_{\mathrm{R}} \delta^{ab}\partial_b(\delta\psi\,\partial_a\psi)\,\mathrm{d}^3x\,\mathrm{d}t = \int_{\mathrm{R}} \nabla\cdot(\delta\psi\,\nabla\psi)\,\mathrm{d}^3x\,\mathrm{d}t, \tag{50.97}$$

vanishes if $\delta\psi = 0$ on the spatial boundaries, or if the physically realized field satisfies the natural boundary conditions

$$\hat{\boldsymbol{n}}\cdot\nabla\psi = 0 \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{50.98}$$

We are thus led to the variation

$$\int_{\mathrm{R}} \psi\,(\widehat{D}\delta\psi)\,\mathrm{d}^3x\,\mathrm{d}t = \int_{\mathrm{R}} \delta\psi\,(\widehat{D}\psi)\,\mathrm{d}^3x\,\mathrm{d}t + \int_{\mathrm{R}} [-\partial_t(\psi\,\partial_t\delta\psi) + c^2\,\delta^{ab}\,\partial_b(\psi\,\partial_a\delta\psi)]\,\mathrm{d}^3x\,\mathrm{d}t. \tag{50.99}$$

We can eliminate the remaining boundary terms as follows. The temporal boundary term vanishes if we assume either ψ or $\delta(\partial_t\psi)$ vanishes at temporal boundaries. We assume either of these conditions holds. Likewise, the spatial boundary term vanishes if ψ or $\delta(\partial_a\psi)$ vanishes at

the spatial boundaries.[8] Assuming the boundary conditions indeed vanish makes $\widehat{D}$ a self-adjoint wave operator, thus bringing about the action variation

$$\delta \mathcal{S} = \int_{\mathrm{R}} (\delta\psi)\, \widehat{D}\psi \, \mathrm{d}^3x \, \mathrm{d}t, \tag{50.100}$$

with Hamilton's principle, $\delta\mathcal{S} = 0$, again leading to the wave equation, $\widehat{D}\psi = 0$.

50.6.3 Comments on the method

The above presentation is a bit circular since we compute the wave operator, $\widehat{D}$, from the Euler-Lagrange equation, and the Euler-Lagrange equation requires the Lagrangian density, $\mathcal{L}$. However, the discussion suggests a complementary means to connect the variational framework of Hamilton's principle to the study of linear waves. Namely, all we need is the linear self-adjoint wave operator, $\widehat{D}$, rather than the Lagrangian density, $\mathcal{L}$. This approach is useful particularly for those cases where the Lagrangian is tricky to determine. For example, the Lagrangian for Rossby waves requires the introduction of auxiliary fields (see page 293 of *Olbers et al.* (2012)). So by writing the action in the form of equation (50.93), we directly connect the variational framework to the study of linear waves via knowledge of the wave operator rather than the wave Lagrangian. We offer examples throughout the chapters in this part of the book. One important caveat is that the action for some wave systems cannot be written in the bilinear form (50.93), such as the interface waves from Chapter 52, in which case distinct methods are needed (see Section 52.2.9).

We also note the need to assume boundary conditions that ensure the wave operator is self-adjoint. These boundary conditions are somewhat restrictive. Even so, they allow us to focus on the form of the waves in the interior of the space-time domain, rather than be concerned with initia-boundary conditions.

[8] In considering these boundary conditions when, recall that δ for Hamilton's principle commutes with space and time derivatives, as detailed in Section 46.2.2.

Chapter 51

Acoustic waves

In this chapter we study the physics of *acoustic waves* in fluids. When reaching the human ear we interpret acoustic waves as sound, hence the synonymous term *sound waves*. The pressure fluctuations associated with standard acoustic waves (those not damaging to the human ear) are a tiny fraction of those arising from, say, a weather disturbance or an atmospheric gravity wave (see Section 51.5.3 for details). Hence, acoustic waves play a negligible role in the geophysical fluid flows forming the focus of this book. Nonetheless, the relative simplicity of acoustic waves, and their ubiquitous presence in the natural environment, make them an ideal pedagogical introduction to the somewhat more complex geophysical waves considered in later chapters. Here, we study acoustic waves in a perfect compressible fluid where the only force arises from pressure, thus ignoring gravity, Coriolis, and viscous friction. We derive the acoustic wave equation using both Lagrangian and Eulerian viewpoints, and thereafter study various properties of acoustic waves, including their energetics.

READER'S GUIDE TO THIS CHAPTER

Development of the linear equations for acoustic waves relies on the momentum dynamics from Chapter 24, and the acoustic energetics makes use of thermodynamics from Chapters 22, 23, and 26. Furthermore, we assume an understanding of wave kinematics from Chapter 49. As a useful conceptual preface, see Sections 15.6 and 15.7 where we study simple harmonic oscillators, as well as Section 46.1 where we take the continuum limit of the oscillators to reveal the acoustic wave equation.

There are many treatments of acoustic waves in the literature, and we made use of Chapter VIII in *Landau and Lifshitz* (1987), Chapter 9 in *Fetter and Walecka* (2003), Section 15.2 of *Kundu et al.* (2016), and Section 16.5 in *Thorne and Blandford* (2017). Additionally, the second half of this video offers a pedagogical introduction to acoustic waves.

51.1 Loose threads

- Need the solution to Exercise 51.3.

51.2 Conceptual introduction to acoustic waves

Physical processes giving rise to acoustic waves

Consider a static background fluid state that is in mechanical and thermodynamic equilibrium. Acoustic waves involve four physical processes within this background state: (i) the density in a compressible fluid changes according to flow divergences and convergences; (ii) density fluctuations lead to pressure fluctuations; (iii) pressure fluctuations lead to fluid particle fluctuations; (iv) for small amplitude fluctuations, fluid particle displacements exhibit space-time coherent oscillatory motion known as linear acoustic waves. Small fluctuations correspond to a fluid particle speed that is much smaller than the acoustic wave speed, with the ratio known as the *Mach number* (we see this relation in Section 51.5.2). Hence, we are concerned only with small Mach number flow in this chapter. As such, acoustic wave properties such as the wave momentum and wave energy are transmitted at a much greater speed than the transport of properties arising from fluid particle motion (e.g., enthalpy and mass transport). Furthermore, we find that fluid particles feeling the passage of an acoustic wave oscillate in the direction of the wave, with the alignment of the fluid velocity and wave direction characterizing *longitudinal waves*.

The alternating compression and rarefaction of fluid elements within an acoustic wave give rise to alternating pressure work that affects the internal energy. For small Mach number flow, acoustic waves can be assumed to be isentropic, so that the pressure work is reversible. We make use of perfect fluid mechanics throughout this chapter, thus ignoring mixing and heating so that fluid elements maintain constant specific entropy. Indeed, we generally assume the fluid

has uniform specific entropy to further isolate the core physical features accounting for acoustic waves.

Comments on compressible, incompressible, and the Boussinesq ocean

All real fluids are compressible and thus support acoustic waves. When compressibility is reduced towards zero, so that the continuous media becomes more rigid, the acoustic wave speed increases. Hence, we generally find acoustic waves travel faster through solids than liquids, and faster through liquids than gases. Taking the mathematical limit of a fully incompressible fluid (where the fluid density is uniform and constant) results in an infinite acoustic wave speed, in which case acoustic waves are absent from incompressible fluid dynamics.

There are occasions where we study incompressible fluids in this book. For example, the shallow water models in Part VI of this book are comprised of incompressible fluid layers with three-dimensional motion, whereas the two-dimensional non-divergent barotropic model in Chapter 38 considers just a two-dimensional velocity (zero vertical motion). The Boussinesq ocean in Chapter 29 offers an important step towards a more realistic fluid. Namely, the Boussinesq ocean is quasi-compressible since the Boussinesq velocity is non-divergent even though the fluid density varies in space and time. The varying density in the Boussinesq ocean gives rise to a divergent velocity that supports acoustic waves. Even so, we commonly ignore the divergent velocity when working with the Boussinesq ocean since this velocity, and the associated acoustic waves, never couple to the Boussineq ocean dynamics that are the concern of the theory.

51.3 Lagrangian perspective

Consider a continuum fluid system whose motion is constrained to one space dimension, $\hat{\boldsymbol{x}}$. Assume that all fluid properties and flow properties are independent of the y and z directions. We assume the only forces acting on fluid elements arise from pressure, so that gravity, electromagnetism, and friction are ignored. Furthermore, all fluid motion remains close to a static background state, where the background state density and pressure are everywhere uniform with values ρ_{e} and p_{e}:

$$\rho_{\text{e}} = \text{background state density} \quad \text{and} \quad p_{\text{e}} = \text{background state pressure.} \tag{51.1}$$

Derivation of the equation for the acoustic waves proceeds in three steps. The first concerns the equation for mass conservation; the second arises from momentum conservation; and the third concerns the equation of state relating pressure, density, and specific entropy. Throughout the derivation in this section, we make use of the Lagrangian displacement field, $\xi(x,t)$, used in Section 46.1 when taking the continuum limit of coupled harmonic oscillators. Recall that this function measures the displacement, at time t, of a fluid element whose equilibrium position is x. We here also introduce the density, $\rho(x,t)$, as the density of a fluid element whose equilibrium position is x, and we maintain the same interpretation for the pressure field, $p(x,t)$.

51.3.1 Mass conservation

In Figure 51.1 we find two configurations for a fluid element, in which the first assumes the fluid is in mechanical equilibrium with constant density, ρ_{e}, and mass per unit area

$$M/A = \rho_{\text{e}}\, \delta x, \tag{51.2}$$

where A is the horizontal cross sectional area. The second configuration has been displaced by $\xi(x,t)$ a small amount so that the fluid element is out of mechanicial equilibrium. In this case its

density, $\rho(x,t)$, is found through mass conservation. Namely, the mass in the original rectangle equals to that in the displaced rectangle

$$\begin{aligned} M/A &= \rho_{\text{e}}\,\delta x && \text{(51.3a)}\\ &= \rho\,[x+\delta x+\xi(x+\delta x,t+\delta t)-x-\xi(x,t+\delta t)] && \text{(51.3b)}\\ &= \rho\,[\delta x+\xi(x+\delta x,t+\delta t)-\xi(x,t+\delta t)] && \text{(51.3c)}\\ &= \rho\,\delta x\left[1+\frac{\partial\xi(x^*,t)}{\partial x}\right] && \text{(51.3d)}\\ &\approx \rho\,\delta x\left[1+\frac{\partial\xi(x,t)}{\partial x}\right]. && \text{(51.3e)} \end{aligned}$$

The penultimate equality made use of the mean value theorem from differential calculus, where x^* is a point between x and $x+\delta x$, whereas the final step involves the approximation that arises when taking the infinitesimal limit allowing us to evaluate $\partial\xi/\partial x$ at the position x. We are thus led to the relation[1]

$$\rho(x,t) = \rho_{\text{e}}\,(1+\partial\xi/\partial x)^{-1} \approx \rho_{\text{e}}\,(1-\partial\xi/\partial x). \tag{51.4}$$

This equation says that the density of a fluid element, $\rho(x,t)$, whose equilibrium position is x, differs from its equilibrium density, ρ_{e}, according to whether the fluid element is expanded ($\partial\xi/\partial x>0$) or contracted ($\partial\xi/\partial x<0$).

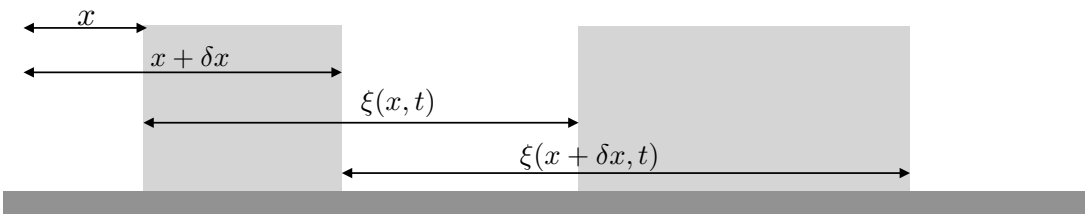

FIGURE 51.1: Schematic of a rectangular fluid element constrained to move just in the $\hat{\boldsymbol{x}}$ direction with uniform properties in the $\hat{\boldsymbol{y}}$ and $\hat{\boldsymbol{z}}$ directions. The fluid element has a constant mass, M, and with density uniform within the element. The equilibrium configuration in the left rectangle has a mass per unit area $M/A=\rho_{\text{e}}\,\delta x$, where A is the fixed cross sectional area, and ρ_{e} is the equilibrium density. The right rectangle shows the fluid element at a displaced non-equilibrium configuration where the density deviates from its equilibrium value. This density, $\rho(x,t)$, is the density of the displaced fluid element (specified by the displacement field $\xi(x,t)$) whose equilibrium position is x. The mass of the fluid element is identical for both the equilibrium and non-equilibrium configurations, which leads to $\rho(x,t)=\rho_{\text{e}}\,(1+\partial\xi/\partial x)^{-1}$. This relation means, for example, if $\partial\xi/\partial x>0$ (fluid element expands relative to equilibrium), then $\rho(x)<\rho_{\text{e}}$.

51.3.2 Momentum conservation

At equilibrium the fluid element experiences a pressure, p_{e}, that is assumed to be spatially uniform.[2] If fluid elements are displaced in a manner that produces nonzero density perturbations, then the pressure field is likewise modified, in which case fluid moves. Recall that we interpret $p(x,t)$ as the pressure acting on a fluid element whose equilibrium position is x. Hence, the net pressure force per area acting on the displaced fluid element is given by the gradient

$$\boldsymbol{F}^{\text{press}} = [-p(x+\delta x,t)+p(x,t)]\,\hat{\boldsymbol{x}} \approx -(\partial p(x,t)/\partial x)\,\delta x\,\hat{\boldsymbol{x}}. \tag{51.5}$$

[1] By assuming small perturbations relative to the background state, we disallow the extreme case where $\partial\xi/\partial x=-1$, in which the fluid becomes so rarefied (vanishing mass density) that we can no longer make use of the continuum description (see Chapter 16 for more on the continuum approximation).

[2] Recall we are ignoring gravity, so there is no hydrostatic pressure that would give rise to a pressure gradient.

The position of the fluid element is fully specified by the deviation function, $\xi(x,t)$, so that the acceleration is its second time derivative, $\partial_{tt}\xi(x,t)$, in which case Newton's equation of motion is given by

$$\frac{\partial}{\partial t}\left[\rho\,\frac{\partial \xi}{\partial t}\right] = -\frac{\partial p}{\partial x}. \tag{51.6}$$

51.3.3 Equation of state and acoustic wave equation

We now assume an equation of state whereby density is a function of pressure and specific entropy[3]

$$\rho = \rho(p, \mathcal{S}). \tag{51.7}$$

Assuming the fluctuations occur with constant specific entropy, $\mathcal{S}$, the equation of motion (51.6) takes the form

$$\frac{\partial}{\partial t}\left[\rho\,\frac{\partial \xi}{\partial t}\right] = -\left[\frac{\partial p}{\partial \rho}\right]_{\mathcal{S}}\frac{\partial \rho}{\partial x}. \tag{51.8}$$

Use of the continuity equation (51.4) allows us to eliminate density in favor of the displacement field

$$\frac{\partial}{\partial t}\left[\rho\,\frac{\partial \xi}{\partial t}\right] = \frac{\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2}{(1+\partial\xi/\partial x)^2}\,\frac{\partial^2 \xi}{\partial x^2}, \tag{51.9}$$

where we introduced the inverse squared speed

$$c_{\mathsf{s}}^{-2} = \left[\frac{\partial \rho}{\partial p}\right]_{\mathcal{S}}, \tag{51.10}$$

where c_{s} is interpreted as the sound speed. We can linearize the acoustic equation (51.9) by dropping all terms with the products of the displacement field and assuming density is approximated by its equilibrium value, ρ_{e}, in which case we recover the acoustic wave equation

$$(\partial_{tt} - c_{\mathsf{s}}^2\,\partial_{xx})\,\xi = 0. \tag{51.11}$$

This equation says that the displacements of the fluid elements relative to their equilibrium position satisfy the linear wave equation, and the displacements travel with the sound speed.

51.3.4 Sound speed

It is important to observe that the pressure derivative in the sound speed equation (51.10) is computed with a fixed entropy, $\mathcal{S}$. We are thus treating acoustic waves as reversible adiabatic waves, which accords with our use of a perfect fluid throughout this chapter.[4] This approach is suitable for those cases where the speed of acoustic waves is much larger than the speed of fluid particles, so that an acoustic wave moves through a fluid far faster than the time for enthalpy to be transferred by fluid particles. In this case, acoustic waves are accurately treated as reversible adiabatic waves.

In Section 23.4.8 we consider the sound speed in an ideal gas, in which

$$c_{\mathsf{s}}^2 = (p/\rho)\,(c_{\mathsf{p}}/c_{\mathsf{v}}) = T\,R^{\mathsf{M}}\,(c_{\mathsf{p}}/c_{\mathsf{v}}), \tag{51.12}$$

where R^{M} is the specific gas constant given by equation (23.49), c_{v} is the specific heat capacity holding specific volume fixed (equation (23.59)), and $c_{\mathsf{p}} = c_{\mathsf{v}} + R^{\mathsf{M}}$ is the specific heat capacity holding pressure fixed. For air we have $c_{\mathsf{s}} \approx 350$ m s^{-1} for $T = 300$ K. We identify these waves as

[3] We study equations of state, including the ideal gas equation, in Chapters 23 and 30.

[4] Matter concentration is also held fixed when considering sound speeds in a fluid with multiple matter constituents.

acoustic (sound) waves due to the agreement of the wave speed (51.12) with the speed of sound measured in the laboratory. Note that LaPlace discovered the relevance of the specific heats ratio, c_p/c_v, in the expression (51.12) for the sound speed. This ratio arises when recognizing acoustic waves to be constant entropy waves, whereas Newton incorrectly assumed they were isothermal, in which case the specific heat ratio does not appear.

A more compressible media, such as the atmosphere, has a smaller sound speed ($c_s \approx 350$ m s^{-1}) than a less compressible media such as the ocean ($c_s \approx 1500$ m s^{-1}). Indeed, the sound speed is infinite when the media is fully incompressible, with the infinite speed a signature that the hyperbolic wave system has converted to an elliptic system (see Chapter 6). We offer further discussion of the sound speed in Sections 22.7.4 and 23.4.8 as part of our study of thermodynamics.

The *Mach number* is the ratio of the fluid particle speed to the sound speed. If a fluid is moving with Mach number greater than unity (supersonic), then there can be discontinuities (shocks) that break the continuum approximation (Chapter 16). In this case, the continuous fluid equations must be supplemented by other physical conditions such as those afforded by molecular dynamics. We have no occasion to study supersonic flow in this book.

51.3.5 Comments and further study

The original calculation of sound speed computed the density derivative holding temperature fixed rather than entropy. This mistake, originally made by Newton in his studies of sound, was corrected by LaPlace by noting that acoustic waves more closely maintain adiabatic conditions, which means they preserve specific entropy. It is perhaps a testament to the genius of Newton that even his mistakes took decades to centuries to correct, and often only after being considered in light of new areas of physics (e.g., thermodynamics) that were totally undeveloped during Newton's time.

Elements of this section were taken from Sections 2.1, 2.2, and 2.3 of *Towne* (1967) and Section 47-3 in Volume I of *Feynman et al.* (1963). See also Section 1.2 of *Lighthill* (1978) for more on the sound speed calculation.

51.4 Eulerian perspective

We here derive the acoustic wave equation using an Eulerian approach, thus offering a complement to the Lagrangian treatment in Section 51.3. Furthermore, we no longer restrict motion to one dimension, so that here the resulting acoustic waves travel in three space dimensions. We also generalize the background state, here allowing for the background density and specific entropy to be static functions of space.

51.4.1 Lagrangian wave equation

Consider a single component perfect fluid that does not feel gravity, Coriolis, or friction, so that the only acceleration acting on a fluid element arises from pressure gradients

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = -\rho^{-1}\,\nabla p. \tag{51.13}$$

This expression of the *Euler equation* is coupled to the mass continuity equation (19.16)

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\rho\,\nabla\cdot\boldsymbol{v}, \tag{51.14}$$

that reflects the material constancy of mass following a fluid element. Furthermore, density and pressure are coupled through the equation of state (51.7), so that the density and pressure

material time derivatives are related by

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = \left[\frac{\partial\rho}{\partial p}\right]_{\mathcal{S}} \frac{\mathrm{D}p}{\mathrm{D}t} + \left[\frac{\partial\rho}{\partial \mathcal{S}}\right]_{p} \frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = c_{\mathrm{s}}^{-2} \frac{\mathrm{D}p}{\mathrm{D}t}, \tag{51.15}$$

where we set $\mathrm{D}\mathcal{S}/\mathrm{D}t = 0$ due to the isentropic nature of the perfect fluid, and introduced the squared sound speed

$$c_{\mathrm{s}}^{-2} = \left[\frac{\partial\rho}{\partial p}\right]_{\mathcal{S}}. \tag{51.16}$$

Combining the continuity equation (51.14) and the material time derivative of the equation of state (51.15) renders

$$\frac{1}{\rho\, c_{\mathrm{s}}^2} \frac{\mathrm{D}p}{\mathrm{D}t} + \nabla\cdot\boldsymbol{v} = 0. \tag{51.17}$$

We can relate the velocity divergence to pressure by taking $\mathrm{D}/\mathrm{D}t$ of this equation and then using the Euler equation (51.13)

$$-\frac{\mathrm{D}(\nabla\cdot\boldsymbol{v})}{\mathrm{D}t} = -(\partial_t + v^n\partial_n)\,(\partial_m v^m) \tag{51.18a}$$

$$= -\nabla\cdot\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + \partial_m v^n\,\partial_n v^m \tag{51.18b}$$

$$= \nabla\cdot(\rho^{-1}\nabla p) + S^m{}_n\,S^n{}_m - R^m{}_n\,R^n{}_m. \tag{51.18c}$$

In the final equality we introduced components to the strain rate tensor, $\boldsymbol{S}$, and the rotation tensor, $\boldsymbol{R}$, both of which were introduced in Section 18.8 when studying the velocity gradient tensor. Furthermore, note that the combination, $S^m{}_n\,S^n{}_m - R^m{}_n\,R^n{}_m$, also appears in the elliptic pressure equation for the Boussinesq ocean in Section 29.3.4. Use of equation (51.18c) along with $\mathrm{D}/\mathrm{D}t$ of equation (51.17) leads to the pressure equation

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{1}{\rho\, c_{\mathrm{s}}^2}\frac{\mathrm{D}p}{\mathrm{D}t}\right] - \nabla\cdot(\rho^{-1}\nabla p) = S^m{}_n\,S^n{}_m - R^m{}_n\,R^n{}_m. \tag{51.19}$$

The left hand side is a *Lagrangian wave equation*, which, when linearized, forms the more familiar acoustic wave equation to be described below. Equation (51.19) describes pressure fluctuations relative to the moving flow, with the nonlinear source on the right hand side arising from strain and rotation within the fluid flow. In Exercise 51.2 we consider the special case of pressure fluctuations when the background flow is a uniform constant.

The pressure equation (51.19) is nonlinear since pressure, density, and velocity are coupled. We garner insight into certain of the physical processes captured by this equation by linearizing around a static background state and examining small amplitude fluctuations, to which we now turn our attention.

51.4.2 Inhomogeneous background state

In Section 51.3 we assumed the background state has zero velocity, uniform density, uniform specific entropy, uniform pressure, and uniform sound speed. This trivial state is itself an exact solution to the perfect fluid equations of motion, thus serving as a suitable state from which to study linear fluctuations. Here we introduce a slightly less trivial background state that is also an exact solution to the equations of motion.

We continue to assume a trivial solution of the Euler equation with vanishing velocity (background $\boldsymbol{v} = 0$) and spatially uniform pressure (p_{e} constant). In this case, the continuity equation (51.14) can be satisfied by a background density that is time independent yet spatially inhomogeneous, $\rho_{\mathrm{e}} = \rho_{\mathrm{e}}(\boldsymbol{x})$. This inhomogeneous density is consistent with the equation of state

(51.7) if the specific entropy is itself inhomogeneous, $\mathcal{S}_e = \mathcal{S}_e(\boldsymbol{x})$, in which case

$$\rho(\boldsymbol{x}) = \rho[p = p_e, \mathcal{S} = \mathcal{S}_e(\boldsymbol{x})]. \tag{51.20}$$

By allowing ρ_e and $\mathcal{S}_e$ to be spatially dependent functions, we extend the applicability of the resulting wave equation to the study of acoustic waves propagating in a static inhomogeneous media. A geophysically relevant example concerns an ocean or atmosphere in exact hydrostatic balance (Section 24.6), with vanishing flow yet density and specific entropy that are functions of geopotential coordinate, z. *Pierce* (1990) considers the even more realistic case with a space and time dependent background flow, and a correspondingly nonuniform pressure field, in which case the acoustic wave equation is modified relative to that considered in this chapter.

51.4.3 Acoustic wave equation

We now linearize the Euler equation (51.13), along with the mass continuity equation in the form of equation (51.17), and perform the linearization relative to a background state of zero motion yet inhomogeneous density. We thus write pressure, density, and velocity as

$$p = p_e + p' \quad \text{and} \quad \rho = \rho_e(\boldsymbol{x}) + \rho' \quad \text{and} \quad \boldsymbol{v} = 0 + \boldsymbol{v}', \tag{51.21}$$

where the pressure and density perturbations are small relative to their background values $|p'| \ll p_e$ and $|\rho'| \ll \rho_e(\boldsymbol{x})$, and where the background density is generally a function of space. A positive p' arises from a local *compression* in the fluid, whereas a negative p' is a local expansion or *rarefaction*.

Wave equation with an inhomogeneous background state

Inserting the perturbations (51.21) into the Euler equation (51.13) leads to

$$(\rho_e + \rho')\,\partial_t \boldsymbol{v}' + (\rho_e + \rho')\,(\boldsymbol{v}' \cdot \nabla)\boldsymbol{v}' = -\nabla p', \tag{51.22}$$

and dropping all products of perturbation fields leads to the linearized Euler equation

$$\rho_e\,\partial_t \boldsymbol{v}' = -\nabla p'. \tag{51.23}$$

Likewise, the linearized continuity equation (51.17) takes the form

$$\partial_t p' + \rho_e\, c_s^2\, \nabla \cdot \boldsymbol{v}' = 0, \tag{51.24}$$

where the squared sound speed is here determined by compressibility of the equilibrum state

$$c_s^{-2} = \left[\left(\frac{\partial \rho}{\partial p}\right)_{\mathcal{S}}\right]_{p=p_e}. \tag{51.25}$$

Taking the divergence of the velocity equation (51.23) and making use of the continuity equation (51.24) renders the acoustic wave equation for the anomalous pressure

$$\frac{1}{\rho_e\, c_s^2}\,\frac{\partial^2 p'}{\partial t^2} - \nabla \cdot (\rho_e^{-1}\,\nabla p') = 0. \tag{51.26}$$

This linear wave equation compares to its fully nonlinear analog in equation (51.19). We can perform analogous manipulations to determine the following wave equation satisfied by the

velocity divergence

$$\partial_{tt}\mathcal{D}' - \nabla\cdot\left[\rho^{-1}\,\nabla(\rho\,c^2\,\mathcal{D}'\right] = 0 \qquad \text{with } \mathcal{D}' = \nabla\cdot\boldsymbol{v}'. \tag{51.27}$$

Finally, note that from the linearized Euler equation (51.23) that the density weighted velocity fluctuation has a static curl

$$\partial_t[\nabla\times(\rho_{\mathsf{e}}\,\boldsymbol{v}')] = 0. \tag{51.28}$$

Wave equation with a homogeneous background state

Equation (51.26) for the pressure, equation (51.27) for the velocity divergence, and equation (51.28) for the curl of the density weighted velocity constitute the suite of equations for acoustic waves in a static yet inhomogeneous background state. In the remainder of this section we study properties of the wave solutions to these equations, yet restricted to the homogeneous and static background state with ρ_{e} a uniform constant and with the sound speed also uniform, in which case we have the linear acoustic wave equations

$$(\partial_{tt}-c_{\mathsf{s}}^2\,\nabla^2)p' = 0 \quad\text{and}\quad (\partial_{tt}-c_{\mathsf{s}}^2\,\nabla^2)\mathcal{D}' = 0 \quad\text{and}\quad \partial_t(\nabla\times\boldsymbol{v}') = 0 \quad\text{with}\quad \mathcal{D}' = \nabla\cdot\boldsymbol{v}'. \tag{51.29}$$

The more realistic, yet complex, case of waves propagating through an inhomogeneous background state requires extra mathematical technology that we develop in Section 51.9.

51.4.4 The velocity potential and acoustic wave properties

The locally static curl (equation (51.29)) means that acoustic waves do not alter vorticity. Hence, if the linear system is initialized with zero vorticity then it stays that way.

Velocity potential for acoustic waves

Assuming zero initial vorticity, as appropriate when considering fluctuations around a state of rest, allows us to introduce a velocity potential (dimensions squared length per time), ψ, so that

$$\boldsymbol{v}' = -\nabla\psi. \tag{51.30}$$

The velocity equation (51.23) thus implies

$$\nabla(p' - \rho_{\mathsf{e}}\,\partial_t\psi) = 0 \Longrightarrow p' = \rho_{\mathsf{e}}\,(\partial_t\psi + K), \tag{51.31}$$

where $K(t)$ is an arbitrary function of time that is independent of space. The velocity potential is itself arbitrary up to a function of time. Hence, we can choose to work with a modified velocity potential, Ψ, that absorbs the function K

$$\Psi = \psi + \int^t K(t')\,\mathrm{d}t', \tag{51.32}$$

so that pressure is determined by the time derivative of Ψ and velocity is determined by the gradient

$$p' = \rho_{\mathsf{e}}\,\partial_t\Psi \quad\text{and}\quad \boldsymbol{v}' = -\nabla\Psi. \tag{51.33}$$

Note that the process of transforming from ψ to Ψ is referred to as a *gauge transformation*. The same approach is used in Section 52.2.2 when studying surface waves.

Making use of the relation (51.33) in the linearized continuity equation (51.24) renders the wave equation for the velocity potential

$$(\partial_{tt} - c_{\mathsf{s}}^2\,\nabla^2)\,\Psi = 0. \tag{51.34}$$

Furthermore, we can take the gradient of this equation to find that each of the three velocity components satisfies the acoustic wave equation

$$-(\partial_{tt} - c_{\mathsf{s}}^2 \nabla^2) \nabla \Psi = (\partial_{tt} - c_{\mathsf{s}}^2 \nabla^2) \boldsymbol{v}' = 0. \tag{51.35}$$

Density fluctuations in an acoustic wave

We determine the density perturbation within an acoustic wave by linearizing the equation of state (51.7) around the background state[5]

$$\rho = \rho(p, \mathcal{S}) \approx \rho_{\mathsf{e}} + c_{\mathsf{s}}^{-2} (p - p_{\mathsf{e}}), \tag{51.36}$$

so that

$$\rho' = \rho - \rho_{\mathsf{e}} = c_{\mathsf{s}}^{-2} p' = \rho_{\mathsf{e}} c_{\mathsf{s}}^{-2} \partial_t \Psi. \tag{51.37}$$

Taking the time derivative and using the wave equation (51.34) reveals the self-consistency of this result with the linearized mass continuity equation (51.24)

$$\partial_t \rho' = \rho_{\mathsf{e}} c_{\mathsf{s}}^{-2} \partial_{tt} \Psi = \rho_{\mathsf{e}} \nabla^2 \Psi = -\rho_{\mathsf{e}} \nabla \cdot \boldsymbol{v}'. \tag{51.38}$$

Temperature fluctuations in an acoustic wave

For an acoustic wave, a differential temperature increment arises just from changes to the pressure while holding entropy fixed

$$\mathrm{d}T = \left[\frac{\partial T}{\partial p}\right]_{\mathcal{S}} \mathrm{d}p. \tag{51.39}$$

In Section 23.2 we referred to this temperature partial derivative is the *adiabatic lapse rate*. Equation (23.26) provides a practical form of the lapse rate

$$\left[\frac{\partial T}{\partial p}\right]_{\mathsf{S}} = \frac{T_{\mathsf{e}} \alpha_{\mathrm{T}}}{\rho_{\mathsf{e}} c_{\mathsf{p}}}, \tag{51.40}$$

with T_{e} the background temperature, c_{p} the specific heat capacity (22.99), and α_T the thermal expansion coefficient (22.103) defined in terms of the *in situ* temperature (α_T and c_{p} are computed for the background state). We thus have a fluctuation of temperature given by

$$T - T_{\mathsf{e}} = T' = \frac{T_{\mathsf{e}} \alpha_{\mathrm{T}} p'}{\rho_{\mathsf{e}} c_{\mathsf{p}}} = (T_{\mathsf{e}} \alpha_{\mathrm{T}} / c_{\mathsf{p}}) \partial_t \Psi. \tag{51.41}$$

Hence, as an acoustic wave propagates it has an associated oscillation of the temperature field due to oscillations in pressure.

51.5 Dispersion relation and flow properties

We now characterize physical properties of acoustic waves, focusing on the properties as realized by a traveling acoustic plane wave in a homogeneous media (i.e., ρ_{e} is a uniform constant). These properties are determined largely through the acoustic wave *dispersion relation*, which provides a functional relation between the wave frequency and the wavevector. After determining the dispersion relation, we derive the pressure, density, and velocity fluctuations in an acoustic wave.

[5] Recall that $\mathcal{S}$ is assumed constant for the background state, so that it plays a passive role in the Taylor expansion (51.36).

51.5.1 Dispersion relation

Not every traveling plane wave is a solution to the acoustic wave equation (51.34). Rather, the wavevector and angular frequency must be related in a specific manner that is dependent on physics of the particular wave. This relation is known as the *dispersion relation*. Plugging in the traveling plane wave (49.18) into the acoustic wave equation (51.34) renders the acoustic wave dispersion relation

$$(\omega^2 - c_s^2 \boldsymbol{k}^2)\,\Psi = 0 \Longrightarrow \omega = c_s\,|\boldsymbol{k}| \Longrightarrow C_p = \omega/|\boldsymbol{k}| = c_s. \tag{51.42}$$

Note that we only consider the positive sign for the angular frequency since $\omega \geq 0$ corresponds to our convention for wave frequencies (Section 49.4). Traveling acoustic plane waves of a given wavevector have their angular frequency specified by the dispersion relation (51.42). The dispersion relation (51.42) reveals that the phase speed for acoustic waves, C_p, equals to the sound speed, c_s.

The sound speed is a function of the background fluid state; it is not a function of wave properties such as the wavelength or wave frequency. Hence, all acoustic waves, regardless their wavelength, travel at the same phase speed, $C_p = c_s$. Correspondingly, we say that acoustic waves are *non-dispersive*. This property accords with common experience, whereby the variety of sound waves with different frequencies from, say, an orchestra are heard together since all sound frequencies travel with the same speed. Furthermore, it is certainly possible for any particular point in space to be comprised of multiple acoustic waves. Since each wave satisfies the wave equation (51.34), and since the wave equation is linear, acoustic waves satisfy the *principle of superposition*. That is, the sum of multiple traveling acoustic waves is also an acoustic wave that satisfies the same wave equation with same speed, c_s.

51.5.2 Flow properties for acoustic plane waves

We here establish expressions for flow fields, such as velocity, pressure, and density, in the presence of an acoustic plane wave. We start with equation (51.33), which relates pressure and velocity to derivatives of the velocity potential. Following our discussion of traveling plane wave kinematics in Section 49.5.1, write the velocity potential for an acoustic plane wave as

$$\Psi(\boldsymbol{x}, t) = A\,\mathrm{Re}[e^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t + \alpha)}] = A\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t + \alpha), \tag{51.43}$$

which leads to the corresponding pressure fluctuation

$$p' = \rho_e\,\partial_t \Psi = \rho_e\,\mathrm{Re}[-\mathrm{i}\,\omega\,\Psi] = \rho_e\,\omega\,A\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t + \alpha). \tag{51.44}$$

Hence, higher frequency acoustic plane waves have higher magnitude for their fluctuating pressure. Likewise, the fluctuating velocity of fluid particles takes on the form

$$\boldsymbol{v}' = -\nabla\Psi = -\,\mathrm{Re}[\mathrm{i}\,\boldsymbol{k}\,\Psi] = A\,\boldsymbol{k}\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t + \alpha). \tag{51.45}$$

This relation means that fluid particles moving in an acoustic plane wave have their velocity aligned with the wave direction

$$\boldsymbol{v}' \times \boldsymbol{k} = 0. \tag{51.46}$$

Furthermore, this relation follows since the vorticity of the linear fluctuations vanish (Section 51.4.4). The alignment of particle velocity and wave vector is a defining feature of *longitudinal waves*.[6] It also means that the squared magnitude of the particle velocity equals to the squared

[6] We later encounter waves in non-divergent flows, $\nabla\cdot\boldsymbol{v} = 0$, which are *transverse waves* whereby $\boldsymbol{k}\cdot\boldsymbol{v} = 0$. That is, for transverse waves the fluid particle motion is perpendicular to the wave direction, whereas for longitudinal

projection of this velocity onto the wave direction

$$|\boldsymbol{v}'|^2 = (\boldsymbol{v}' \cdot \hat{\boldsymbol{k}})^2 = [A\,|\boldsymbol{k}| \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t + \alpha)]^2. \tag{51.47}$$

Finally, the fluctuating density within an acoustic wave is given by the linearized equation of state (51.37), which takes the following form for an acoustic plane wave

$$\rho' = c_s^{-2}\, p' = c_s^{-2}\, \rho_e\, \omega\, A \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t + \alpha). \tag{51.48}$$

Equations (51.44), (51.45), and (51.48) imply the following relations between the fluctuating pressure, velocity, and density in an acoustic plane wave

$$\rho_e\, \omega\, \boldsymbol{v}' = p'\, \boldsymbol{k} \Longrightarrow p' = \rho_e\, c_s\, \boldsymbol{v}' \cdot \hat{\boldsymbol{k}} \Longrightarrow \rho' = \rho_e\, \boldsymbol{v}' \cdot \hat{\boldsymbol{k}}/c_s. \tag{51.49}$$

where we used the dispersion relation (51.42). These relations reveal that pressure, velocity, and density fluctuations are in-phase; i.e., they have the same phase. The density fluctuation in equation (51.49) reveals that its ratio with the background density equals to the ratio of the fluid particle speed to the sound speed. This ratio is the *Mach number*, so that for an acoustic plane wave we have

$$|p'|/(\rho_e\, c_s^2) = |\rho'|/\rho_e = |\boldsymbol{v}' \cdot \hat{\boldsymbol{k}}|/c_s = \mathrm{Ma} \ll 1. \tag{51.50}$$

Hence, small Mach number corresponds to small density fluctuation relative to the background density. We made use of this relation when introducing the Boussinesq ocean at the start of Chapter 29.

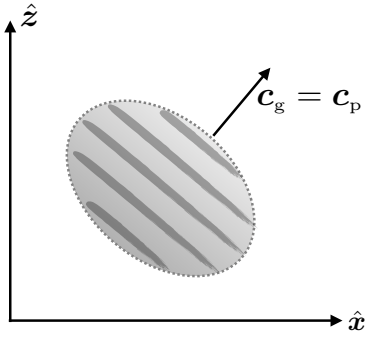

FIGURE 51.2: Example packet of acoustic waves, with the gray shaded lines denoting constant phase surfaces. Acoustic waves are non-dispersive, so that the group and phase velocities are equal, $\boldsymbol{c}_p = \boldsymbol{c}_g$, and all acoustic waves have phase speed given by the speed of sound, $C_p = c_s$. The fluid particle motion is parallel to the phase velocity according to equation (51.45), with such particle motion characterizing longitudinal waves.

51.5.3 Example acoustic pressure perturbations

We noted in the introduction to this chapter that acoustic waves, and their associated pressure perturbations, play a negligible role in large-scale geophysical fluid flows, such as those associated with atmospheric weather patterns. To support that contention, consider some common sounds and examine their pressure perturbations. For that purpose, we make use of the decibel scale (dB) for the sound pressure level (SPL)

$$\mathrm{SPL} = 20 \log_{10}(|p'|/p_{\mathrm{ref}}) \Longrightarrow |p'| = p_{\mathrm{ref}}\, 10^{\mathrm{SPL}/20}. \tag{51.51}$$

waves the particle motion is parallel to the wave direction.

It is conventional to choose the reference pressure, p_{ref}, so that 0 dB is a quiet sound at the threshold of human hearing, with

$$p_{\text{ref}} = 20 \times 10^{-6} \text{ Pa} = 20 \ \mu\text{Pa} \tag{51.52}$$

serving as the international convention. Following equation (51.50), we can determine the Mach number associated with a particular sound pressure level (assuming acoustic plane waves) according to

$$\text{Ma} = |p'|/(\rho_{\text{e}} \, c_{\text{s}}^2) = |p'|/[p \, (c_{\text{p}}/c_{\text{v}})], \tag{51.53}$$

where we made use of the ideal gas relation (23.70) for the sound speed

$$\rho_{\text{e}} \, c_{\text{s}}^2 = p \, c_{\text{p}}/c_{\text{v}}. \tag{51.54}$$

We evaluate the sound speed at the standard sea level atmospheric pressure, $p = p_{\text{stand}} = 101.325 \times 10^3$ Pa, and assume the specific heat capacity ratio, $c_{\text{p}}/c_{\text{v}} = 7/5$, which holds for an ideal diatomic gas, in which case

$$\rho_{\text{e}} \, c_{\text{s}}^2 = p_{\text{stand}} \, (c_{\text{p}}/c_{\text{v}}) = 140 \times 10^3 \text{ Pa}. \tag{51.55}$$

Table 51.1 tabulates the SPL, pressure perturbation, and Mach number for some common sounds. We see that even extremely loud sounds, relative to human hearing, have very small Mach numbers, thus justifying the use of linear acoustic wave dynamics for their description.

To gauge the size of these acoustic pressure fluctuations relative to typical atmospheric pressure fluctuations, consider a middle latitude geostrophic wind, in which case equation (31.15) gives

$$\rho \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{geostrophic}} = -\nabla p_{\text{geostrophic}} \Longrightarrow |p'_{\text{geostrophic}}| \sim \rho \, f \, U \, L, \tag{51.56}$$

where U is the scale of the geostrophic wind speed, and L is the horizontal length scale over which the winds vary. Taking $f = 10^{-4}$ s^{-1}, $U = 10$ m s^{-1}, $\rho = 1$ kg m^{-3}, and $L = 10^6$ m we find a typical pressure fluctuation

$$|p'_{\text{geostrophic}}| \approx 10^3 \text{ Pa}. \tag{51.57}$$

This pressure fluctuation is on the order of that found inside of an automobile exhaust system (see Table 51.1). However, the atmospheric fluctuation associated with this geostrophic wind extends over thousands of kilometers, whereas the sound waves inside of an exhaust system extend over a fraction of a meter. Hence, the energy contained in the atmospheric weather pattern is many orders larger than that for even the loudest sounds extending over typical human length scales. This example further emphasizes the irrelevance of acoustic waves for large-scale geophysical fluid flows.

51.6 Energetics

We here specialize the energetic analysis from Section 26.7 and 26.9 to study the energetics of an acoustic wave in a homogeneous background state. For an acoustic wave, the total energy is the sum of the kinetic energy of the oscillating fluid particles, plus the changes to internal energy of the fluid that arise from pressure work (recall we are ignoring gravity). We thus write the total energy per mass, $\mathcal{E}$, as the sum of the internal energy per mass, $\mathcal{I}$, plus kinetic energy per mass, $\mathcal{K}$,

$$\mathcal{E} = \mathcal{I} + \mathcal{K}. \tag{51.58}$$

SOUND	SPL (dB)	$\lvert p'\rvert$ (Pa)	$\lvert p'\rvert/\lvert p'_{\text{geostrophic}}\rvert$	Ma
soft whisper	30	6.3×10^{-4}	6.3×10^{-7}	4.5×10^{-9}
normal conversation	60	2×10^{-2}	2×10^{-5}	1.4×10^{-7}
noisy factory	90	0.63	6.3×10^{-4}	4.5×10^{-6}
rock concert	115	11	1.1×10^{-2}	8×10^{-5}
aircraft engine	130	63	6.3×10^{-2}	4.5×10^{-4}
automobile exhaust system	160	2×10^{3}	2	1.4×10^{-2}

TABLE 51.1: Acoustic properties of common sounds, following Example 15.2 from *Kundu et al.* (2016). The first column lists the sound, the second column the sound pressure level in dB, the third column the corresponding pressure fluctuation in Pa, the fourth column the ratio of the pressure fluctuation to a pressure fluctuation associated with a geostrophic atmospheric fluctuation, $|p'_{\text{geostrophic}}| \approx 10^3$ Pa (equation (51.57)), and the fifth column the Mach number assuming standard atmospheric sea level pressure, $p_{\text{stand}} = 1.01 \times 10^5$ Pa. Since the Mach number is far smaller than unity even for the loudest sound, we are justified in using linear acoustic wave theory to describe the propagation of these sounds.

The Eulerian form of the total energy equation is given by equation (26.102), which here takes the form

$$\frac{\partial(\rho\,\mathcal{E})}{\partial t} + \nabla\cdot[\rho\,\boldsymbol{v}\,(\mathcal{I} + \mathcal{K} + p/\rho)] = 0, \tag{51.59}$$

where $\mathcal{I} + p/\rho$ is the enthalpy per mass (Section 22.6.4)

$$\mathcal{H} = \mathcal{I} + p/\rho, \tag{51.60}$$

and we set the thermal and chemical fluxes to zero as per a perfect fluid. In the remainder of this section we specialize this energy equation to the case of linear acoustic wave fluctuations.

51.6.1 Expressions for the wave energies

To linearize terms in the energy equation (51.59) requires us to drop third order products of fluctuating quantities while keeping second, first, and zeroth order terms. This procedure is further supported by our ability to develop a self-consistent and closed energy budget for acoustic waves.

Kinetic energy of an acoustic wave

Since velocity is a first order quantity, the kinetic energy per volume is

$$\rho\,\mathcal{K} = (\rho_e + \rho')\,\boldsymbol{v}'\cdot\boldsymbol{v}'/2 \approx \rho_e\,\boldsymbol{v}'\cdot\boldsymbol{v}'/2. \tag{51.61}$$

Internal (potential) energy of an acoustic wave

For the internal energy, recall from Section 22.6.2 that its natural functional dependence for a single-component fluid is

$$\mathcal{I} = \mathcal{I}(\mathcal{S}, \rho). \tag{51.62}$$

Since entropy is held fixed in an acoustic wave, consider the following Taylor series approximation for the internal energy per volume as computed around the background state

$$\rho\,\mathsf{I} \approx \rho\,\mathsf{I}_e + (\rho - \rho_e)\left[\frac{\partial(\rho\,\mathcal{I})}{\partial\rho}\right]_{\rho=\rho_e} + \frac{(\rho-\rho_e)^2}{2}\left[\frac{\partial^2(\rho\,\mathcal{I})}{\partial\rho^2}\right]_{\rho=\rho_e}. \tag{51.63}$$

The first partial derivative is given by

$$\frac{\partial(\rho\,\mathcal{I})}{\partial\rho} = \mathcal{I} + \rho\,\frac{\partial\mathcal{I}}{\partial\rho} = \mathcal{I} + p/\rho = \mathcal{H}, \tag{51.64}$$

where we used identity (22.64) in the penultimate step. The second partial derivative is thus given by

$$\frac{\partial^2(\rho\,\mathcal{I})}{\partial\rho^2} = \frac{\partial\mathcal{H}}{\partial\rho} = \frac{\partial\mathcal{H}}{\partial p}\,\frac{\partial p}{\partial\rho} = c_{\mathrm{s}}^2/\rho, \tag{51.65}$$

where we used the identity (22.76) for the final step. We also used the equation of state (51.7) to convert the density derivative to a pressure derivative in the penultimate step.

Bringing these results together leads to the approximate internal energy per volume

$$\rho\,\mathsf{I} \approx \rho_{\mathrm{e}}\,\mathsf{I}_{\mathrm{e}} + \rho'\,\mathsf{H}_{\mathrm{e}} + (c_{\mathrm{s}}\,\rho')^2/(2\,\rho_{\mathrm{e}}). \tag{51.66}$$

The first term on the right hand side is a constant measuring the internal energy per volume of the background state, and it has no relation to the acoustic wave. The second term is the background enthalpy per mass times the fluctuating density. When integrating over the full domain, the fluctuating density vanishes due to mass conservation. That is, we assume the mass in the domain is the same in the background state as well as when there are acoustic waves, so that

$$\int_{\mathcal{R}} \rho\,\mathrm{d}V = \int_{\mathcal{R}} \rho_{\mathrm{e}}\,\mathrm{d}V \implies \int_{\mathcal{R}} \rho'\,\mathrm{d}V = 0. \tag{51.67}$$

Since the $\rho'\,\mathcal{H}_{\mathrm{e}}$ term drops out from a domain volume integral, it is common to drop this term when studying the energy density for an acoustic wave. However, we choose not to drop it at this point in the discussion. Rather, we find in Section 51.6.3 that $\rho'\,\mathcal{H}_{\mathrm{e}}$ naturally cancels from the flux-form acoustic energy budget equation, at which point we can confidently conclude that it has no significance to the energetic transfers within an acoustic wave. The third term in equation (51.66), $(c_{\mathrm{s}}\,\rho')^2/(2\,\rho_{\mathrm{e}})$, is a potential energy per volume in the acoustic wave that arises from fluid compressibility.

Total energy per volume of an acoustic wave

We conclude that the total energy per volume, accurate to second order in fluctuating acoustic wave fields, is given by

$$\rho\,\mathcal{E} = \rho'\,\mathsf{H}_{\mathrm{e}} + (\rho_{\mathrm{e}}/2)\,[(c_{\mathrm{s}}\,\rho'/\rho_{\mathrm{e}})^2 + \boldsymbol{v}'\cdot\boldsymbol{v}']. \tag{51.68}$$

As a final step, we make use of equations (51.33) and (51.37) to write the wave energy per volume in terms of the velocity potential

$$\rho\,\mathcal{E} = \rho'\,\mathsf{H}_{\mathrm{e}} + (\rho_{\mathrm{e}}/2)\,[(c_{\mathrm{s}}\,\rho'/\rho_{\mathrm{e}})^2 + \boldsymbol{v}'\cdot\boldsymbol{v}'] = \frac{\rho_{\mathrm{e}}}{2\,c_{\mathrm{s}}^2}\left[2\,\mathcal{H}_{\mathrm{e}}\,\partial_t\Psi + (\partial_t\Psi)^2 + c_{\mathrm{s}}^2\,\nabla\Psi\cdot\nabla\Psi\right]. \tag{51.69}$$

51.6.2 Equipartition of energy

Following our study of energy for a simple harmonic oscillator in Section 15.6.3, we here study how energy in an acoustic wave is partitioned between kinetic energy and potential energy. Recall that the simple harmonic oscillator equally partitions energy when time averaging over an oscillation period; i.e., performing the phase average of Section 8.1.2. That result follows from the *virial theorem* considered in Section 12.7.3. We here verify energy equipartition also holds for acoustic waves.

As for the oscillator, we expect energy equipartition for acoustic waves, thus reflecting the alternating exchange of energy between kinetic and potential. Mathematically, equipartition

arises since the potential energy is a homogeneous function of degree two, with details of this property discussed as part of the virial theorem from Section 12.7.3. Here, we show that energy equipartition holds instantaneously for a monochromatic traveling acoustic wave. However, for a general linear acoustic fluctuation, equipartition holds only when averaging over a wave period plus integrating over the closed spatial domain.

Equipartition for a monochromatic traveling acoustic wave

For an acoustic plane wave, the energy density simplifies through use of equation (51.49) to render

$$(c_s\,\rho'/\rho_e)^2 = (\boldsymbol{v}'\cdot\hat{\boldsymbol{k}})^2 = \boldsymbol{v}'\cdot\boldsymbol{v}', \tag{51.70}$$

where the second equality holds since the fluid particle velocity within the plane wave is aligned with the plane wave phase velocity. We thus find that the potential energy per volume and kinetic energy per volume contribute an equal amount to the acoustic plane wave's energy per volume

$$\rho\,\mathcal{E} = \rho'\,\mathsf{H}_e + (\rho_e/2)\,[(c_s\,\rho'/\rho_e)^2 + \boldsymbol{v}'\cdot\boldsymbol{v}'] = \rho'\,\mathcal{H}_e + 2\,\rho_e\,\mathcal{K}. \tag{51.71}$$

Equipartition for an arbitrary periodic linear fluctuation

The general expression (51.69) for the energy in a linear fluctuation does not render energy equipartition at each point in space and time. Rather, being inspired by the oscillator in Section 15.6.3, we here show that a phase and space averaged energy does possess equipartition. For the phase average we integrate the energy density over a single period, and doing so eliminates the background enthalpy term, $2\,\mathcal{H}_e\,\partial_t\Psi$, thus leaving

$$\int_0^{2\pi/\omega} \rho\,\mathcal{E}\,\mathrm{d}t = \frac{\rho_e}{2\,c_s^2}\int_0^{2\pi/\omega}\left[(\partial_t\Psi)^2 + c_s^2\,\nabla\Psi\cdot\nabla\Psi\right]\mathrm{d}t. \tag{51.72}$$

Now integrate by parts and make use of the wave equation (51.34) to find

$$\int_0^{2\pi/\omega} \rho\,\mathcal{E}\,\mathrm{d}t = \frac{\rho_e}{2\,c_s^2}\int_0^{2\pi/\omega}\left[-\Psi\,\partial_{tt}\Psi + c_s^2\,\nabla\Psi\cdot\nabla\Psi\right]\mathrm{d}t \tag{51.73a}$$

$$= \frac{\rho_e}{2}\int_0^{2\pi/\omega}\left[-\Psi\,\nabla^2\Psi + \nabla\Psi\cdot\nabla\Psi\right]\mathrm{d}t \tag{51.73b}$$

$$= \frac{\rho_e}{2}\int_0^{2\pi/\omega}\left[-\nabla\cdot(\Psi\,\nabla\Psi) + 2\,\nabla\Psi\cdot\nabla\Psi\right]\mathrm{d}t. \tag{51.73c}$$

We see that for an arbitrary linear and periodic fluctuation, energy equipartition is realized by time integrating over a wave period and then integrating over a spatially closed or spatially periodic domain

$$\int_{\mathcal{R}}\left[\int_0^{2\pi/\omega}\rho\,\mathcal{E}\,\mathrm{d}t\right]\mathrm{d}V = \rho_e\int_{\mathcal{R}}\left[\int_0^{2\pi/\omega}\nabla\Psi\cdot\nabla\Psi\,\mathrm{d}t\right]\mathrm{d}V = 2\,\rho_e\int_{\mathcal{R}}\left[\int_0^{2\pi/\omega}\mathcal{K}\,\mathrm{d}t\right]\mathrm{d}V. \tag{51.74}$$

This equation says that the phase and domain averaged flow contains an equal amount of kinetic energy as internal energy. This result holds for any periodic acoustic fluctuation, and is not specific to plane acoustic waves.

51.6.3 Energy budget equation

Taking the partial time derivative of the energy per volume, (51.69), leads to

$$\partial_t(\rho\,\mathcal{E}) = \frac{\rho_e}{c_s^2}\left[\partial_{tt}\Psi\,(\mathcal{H}_e + \partial_t\Psi) + c_s^2\,\nabla\Psi\cdot\nabla\partial_t\Psi\right] \tag{51.75a}$$

$$= \rho_e\left[\nabla^2\Psi\,(\mathcal{H}_e + \partial_t\Psi) + \nabla\Psi\cdot\nabla\partial_t\Psi\right] \tag{51.75b}$$

$$= \rho_e\,\nabla\cdot[(\mathcal{H}_e + \partial_t\Psi)\,\nabla\Psi] \tag{51.75c}$$

$$= -\rho_e\,\nabla\cdot[\boldsymbol{v}'\,(\mathcal{H}_e + p'/\rho_e)]. \tag{51.75d}$$

We can thus write the acoustic energy equation in terms of the velocity potential

$$\partial_t\left[2\,\mathsf{H}_e\,\partial_t\Psi + (\partial_t\Psi)^2 + c_s^2\,\nabla\Psi\cdot\nabla\Psi\right] = 2\,c_s^2\,\nabla\cdot[(\mathcal{H}_e + \partial_t\Psi)\,\nabla\Psi]. \tag{51.76}$$

The two $\mathcal{H}_e$ terms cancel identically through use of the wave equation (51.34), thus leaving the acoustic energy equation, here written in two equivalent forms

$$(1/2)\,\partial_t\left[(\partial_t\Psi)^2 + c_s^2\,\nabla\Psi\cdot\nabla\Psi\right] = c_s^2\,\nabla\cdot(\partial_t\Psi\,\nabla\Psi) \tag{51.77a}$$

$$(\rho_e/2)\,\partial_t\left[(c_s\,\rho'/\rho_e)^2 + \boldsymbol{v}'\cdot\boldsymbol{v}'\right] = -\nabla\cdot(\boldsymbol{v}'\,p'). \tag{51.77b}$$

The energy equation (51.77b) identifies $\boldsymbol{v}'\,p'$ as the energy flux for acoustic waves, whose convergence affects a local time change to the wave energy per volume. In this manner we have established the budget equations for acoustic energy, as summarized by[7]

$$\partial_t(\rho_e\,\mathcal{E}) = -\nabla\cdot\boldsymbol{J}_{\mathcal{E}} \tag{51.78a}$$

$$\mathcal{E} = [(c_s\,\rho'/\rho_e)^2 + \boldsymbol{v}'\cdot\boldsymbol{v}']/2 = [c_s^{-2}\,(\partial_t\Psi)^2 + \nabla\Psi\cdot\nabla\Psi]/2 \tag{51.78b}$$

$$\boldsymbol{J}_{\mathcal{E}} = \boldsymbol{v}'\,p' = -\rho_e\,\partial_t\Psi\,\nabla\Psi. \tag{51.78c}$$

Finally, for an acoustic plane wave, use of the relations (51.49) allows us to write the wave energy flux in terms of the wave energy density

$$\boldsymbol{J}_{\mathcal{E}} = \boldsymbol{v}'\,p' = \boldsymbol{v}'\,(\rho_e\,c_s\,\boldsymbol{v}'\cdot\hat{\boldsymbol{k}}) = c_s\,\rho_e\,(\boldsymbol{v}'\cdot\hat{\boldsymbol{k}})^2\,\hat{\boldsymbol{k}} = c_s\,\rho_e\,\mathcal{E}\,\hat{\boldsymbol{k}} = \rho_e\,\mathcal{E}\,\boldsymbol{c}_p \quad \Longleftarrow \text{plane wave.} \tag{51.79}$$

That is, for the acoustic plane wave, the flux of energy moves with the plane wave phase velocity. For dispersive waves in later chapters, we find that the energy flux moves with the group velocity rather than the phase velocity.

51.7 Wave momentum

The linear momentum in a fluid region, $\mathcal{R}$, is given by (see Section 24.2.3)

$$\boldsymbol{P} = \int_{\mathcal{R}} \rho\,\boldsymbol{v}\,\mathrm{d}V, \tag{51.80}$$

so that the linear momentum of acoustic waves is given by

$$\boldsymbol{P} = \int_{\mathcal{R}} (\rho_e + \rho')\,\boldsymbol{v}'\mathrm{d}V \tag{51.81a}$$

$$= -\rho_e\int_{\mathcal{R}} \nabla\Psi\,\mathrm{d}V + \int_{\mathcal{R}} \rho'\,\boldsymbol{v}'\,\mathrm{d}V \tag{51.81b}$$

[7] As shown following equation (51.76), the term $\rho'\,\mathcal{H}_e$ plays no role in energy transformations. Hence, we drop it from $\mathcal{E}$ in equation (51.78b).

$$= -\rho_e \oint_{\partial\mathcal{R}} \Psi\, \hat{\boldsymbol{n}}\, \mathrm{d}V + c_s^{-2} \int_{\mathcal{R}} \boldsymbol{J}_{\mathcal{E}}\, \mathrm{d}V. \tag{51.81c}$$

If the waves are localized to a finite region, such as in a wave packet rather than a plane wave, then we can drop the boundary integral so long as the boundary of the domain extends outside the region where the packet is located. In this case, the integrated energy flux equals to the squared wave speed times the linear momentum

$$c_s^2\, \boldsymbol{P} = \int_{\mathcal{R}} p'\, \boldsymbol{v}'\, \mathrm{d}V = \int_{\mathcal{R}} \boldsymbol{J}_{\mathcal{E}}\, \mathrm{d}V. \tag{51.82}$$

51.8 Acoustic waves radiated from a piston

In this section we introduce the study of acoustic wave radiation, here for the specific case of a circular piston in a flat wall (see Figure 51.3). In addition to exemplifying some of the physical ideas presented earlier in the chapter, this section illustrates the use of the Green's function for the Helmholtz equation that we originally studied in Section 9.6.8. We do not pursue the radiation problem to its entirety as doing so is quite an extensive exercise that is lucidly and thoroughly presented in section 51 of *Fetter and Walecka* (2003). Instead, our goal is mostly to illustrate the style of problems that can be solved using Green's functions for acoustics.

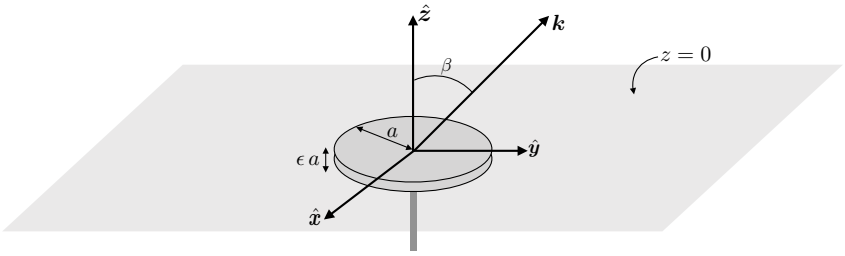

FIGURE 51.3: Illustrating the geometry of a piston radiating acoustic waves as studied in Section 51.8. The piston is circular with radius $r = a$ and situated within an infinite rigid wall along the $z = 0$ plane. We make use of cylindrical-polar coordinates from Section 4.22, with origin at the center of the piston and vertical axis through the origin. The piston oscillates along the vertical axis with a vertical position $z(t) = \epsilon\, a\, \mathrm{e}^{-\mathrm{i}\,\omega\, t}$, where $\epsilon \ll 1$ is small and ω is the angular frequency of the oscillations. The piston generates acoustic waves with angular frequency ω in the surrounding fluid. We depict a single acoustic wavevector, $\boldsymbol{k}$, making an angle, β, with respect to the vertical axis, though note that waves are radiated throughout space. Given the assumed small amplitude of the piston motion, we evaluate boundary conditions on the $z = 0$ plane, which is sufficiently accurate for linear analysis. Our focus concerns waves within the region $z > 0$.

51.8.1 Setting up the physics problem

We are interested in properties of acoustic waves radiated in the $z > 0$ half-plane as depicted in Figure 51.3. If the piston was at rest ($\omega = 0$) at $z = 0$, then we would merely be studying acoustic waves in the $z > 0$ half-plane as described by the boundary value problem for the velocity potential

$$(\partial_{tt} - c_s^2\, \nabla^2)\, \Psi = 0 \quad z > 0 \tag{51.83a}$$

$$\hat{\boldsymbol{z}} \cdot \nabla \Psi = 0 \quad z = 0. \tag{51.83b}$$

Indeed, if there is no wavemaker (i.e., no piston motion), then Ψ would be a space-time constant and so there would be no waves.

Now turn on the piston and write its vertical position as

$$z(t) = \begin{cases} \epsilon\, a\, \mathrm{e}^{-\mathrm{i}\omega t} & r \leq a \\ 0 & r > a, \end{cases} \tag{51.84}$$

where r is the radial distance from the vertical axis and $\epsilon \ll 1$ is a small positive and non-dimensional number. The corresponding vertical velocity of the piston is

$$\dot{z}(t) = \begin{cases} -\mathrm{i}\,\epsilon\, a\, \omega\, \mathrm{e}^{-\mathrm{i}\omega t} & r \leq a \\ 0 & r > a. \end{cases} \tag{51.85}$$

We are thus led to the boundary value problem for the velocity potential

$$(\partial_{tt} - c_{\mathrm{s}}^2\, \nabla^2)\, \Psi = 0 \qquad z > 0 \tag{51.86a}$$

$$\hat{\boldsymbol{z}} \cdot \nabla \Psi = 0 \qquad z = 0 \text{ and } r > a \tag{51.86b}$$

$$\hat{\boldsymbol{z}} \cdot \nabla \Psi = \mathrm{i}\,\epsilon\, a\, \omega\, \mathrm{e}^{-\mathrm{i}\omega t} \qquad z = 0 \text{ and } r \leq a. \tag{51.86c}$$

The time dependent boundary condition generates acoustic waves, and these waves manifest in the velocity potential. We restrict attention to times long enough after the initial setup that allows the wave field to be present throughout the fluid, in which case the velocity potential can be written as a monochromatic field

$$\Psi(\boldsymbol{x}, t) = \Phi(\boldsymbol{x})\, \mathrm{e}^{-\mathrm{i}\omega t}. \tag{51.87}$$

We thus find that the time-independent portion of the velocity potential satisfies the Helmholtz boundary value problem

$$[\nabla^2 + (\omega/c_{\mathrm{s}})^2]\, \Phi = 0 \qquad z > 0 \tag{51.88a}$$

$$\hat{\boldsymbol{z}} \cdot \nabla \Phi = 0 \qquad z = 0, r > a \tag{51.88b}$$

$$\hat{\boldsymbol{z}} \cdot \nabla \Phi = \mathrm{i}\,\epsilon\, a\, \omega \qquad z = 0, r \leq a. \tag{51.88c}$$

51.8.2 Solution in terms of the Green's function

Following our study in Chapter 9, we make use of a Green's function to determine the velocity potential resulting from the oscillating piston. In particular, introduce the Green's function, $G(\boldsymbol{x}|\boldsymbol{x}_0)$, that satisfies the Helmholtz equation with a Dirac source at $\boldsymbol{x}_0$ and a homogeneous Neumann boundary condition

$$[\nabla_{\boldsymbol{x}}^2 + (\omega/c_{\mathrm{s}})^2]\, G(\boldsymbol{x}|\boldsymbol{x}_0) = -\delta(\boldsymbol{x} - \boldsymbol{x}_0) \qquad z > 0 \tag{51.89a}$$

$$\hat{\boldsymbol{z}} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0) = 0 \qquad z = 0. \tag{51.89b}$$

Multiplying the Green's function equation (51.89a) by $\Phi(\boldsymbol{x})$ and integrating over $z \geq 0$ leads to

$$-\Phi(\boldsymbol{x}_0) = \int_{\mathscr{R}} \Phi(\boldsymbol{x})[\nabla_{\boldsymbol{x}}^2 + (\omega/c_{\mathrm{s}})^2]\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V_{\boldsymbol{x}}, \tag{51.90}$$

with integration by parts yielding

$$-\Phi(\boldsymbol{x}_0) = \int_{\mathscr{R}} \left[\nabla_{\boldsymbol{x}} \cdot (\Phi\, \nabla_{\boldsymbol{x}} G - G\, \nabla_{\boldsymbol{x}} \Phi) + G\, (\nabla^2 + (\omega/c)^2)\, \Phi\right] \mathrm{d}V_{\boldsymbol{x}}. \tag{51.91}$$

Setting $\nabla^2 + (\omega/c)^2)\Phi = 0$ as per the Helmholtz equation (51.88a), and use of the divergence theorem, renders

$$-\Phi(\boldsymbol{x}_0) = \int_{\partial\mathcal{R}} \hat{\boldsymbol{n}} \cdot (\Phi\, \nabla_{\boldsymbol{x}} G - G\, \nabla_{\boldsymbol{x}} \Phi)\, \mathrm{d}\mathcal{S}. \tag{51.92}$$

There are two boundaries to consider. The first is at $z = \infty$, at which we assume the fields vanishes so we can ignore this boundary. The second boundary is at $z = 0$, where $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{z}}$ and the Neumann boundary conditions for G and Φ bring about the expression

$$-\Phi(\boldsymbol{x}_0) = \int_0^a \int_0^{2\pi} G\, \hat{\boldsymbol{z}} \cdot \nabla_{\boldsymbol{x}} \Phi\, r\, \mathrm{d}r\, \mathrm{d}\vartheta, \tag{51.93}$$

where ϑ is the polar angle. This is a very tidy result that says we merely need to determine the Green's function over the region of the piston, $r \leq a$ at $z = 0$, in order to determine the velocity potential and hence the acoustic wave field for the $z > 0$ half-space.

51.8.3 Method of images for the Green's function

We can make use of a special trick, known as the *method of images*, to determine the Green's function on the $z \geq 0$ half-space. For this purpose, recall the free space Green's function for the Helmholtz equation from Section 9.6.8, which satisfies

$$[\nabla^2 + (\omega/c)^2]\, \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = -\delta(\boldsymbol{x} - \boldsymbol{x}_0), \tag{51.94}$$

and takes the form

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{\mathrm{e}^{\mathrm{i}\,|\boldsymbol{x}-\boldsymbol{x}_0|\,\omega/c}}{4\,\pi\,|\boldsymbol{x} - \boldsymbol{x}_0|}. \tag{51.95}$$

This Green's function does not satisfy the Neumann boundary condition at $z = 0$. However, to generate a Green's function that does, introduce another Dirac delta point source, $-\delta(\boldsymbol{x} - \overline{\boldsymbol{x}}_0)$, where the source is positioned at

$$\overline{\boldsymbol{x}}_0 = x_0\, \hat{\boldsymbol{x}} + y_0\, \hat{\boldsymbol{y}} - z_0\, \hat{\boldsymbol{z}}. \tag{51.96}$$

This Dirac source is at a position in the $z < 0$ half-space reflected across the $z = 0$ plane from the original source at $\boldsymbol{x}_0$. Notably, the new Dirac source never fires when the field point, $\boldsymbol{x}$, is in the upper, $z > 0$, half-space, just in the same manner that the original Dirac source, $\delta(\boldsymbol{x} - \boldsymbol{x}_0)$, never fires when the field point is in the $z < 0$ half space. Consequently, the Green's function resulting from these two Dirac sources satisfies the following equation set

$$[\nabla^2 + (\omega/c)^2]\, G(\boldsymbol{x}|\boldsymbol{x}_0) = -\delta(\boldsymbol{x} - \boldsymbol{x}_0) \quad z > 0 \tag{51.97a}$$

$$[\nabla^2 + (\omega/c)^2]\, G(\boldsymbol{x}|\boldsymbol{x}_0) = -\delta(\boldsymbol{x} - \overline{\boldsymbol{x}}_0) \quad z < 0 \tag{51.97b}$$

$$\hat{\boldsymbol{z}} \cdot \nabla G = 0 \quad z = 0, \tag{51.97c}$$

and it is given by the sum of the two free space Green's functions,

$$G(\boldsymbol{x}|\boldsymbol{x}_0) = \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) + \mathcal{G}(\boldsymbol{x}|\overline{\boldsymbol{x}}_0) = \frac{\mathrm{e}^{\mathrm{i}\,|\boldsymbol{x}-\boldsymbol{x}_0|\,\omega/c}}{4\,\pi\,|\boldsymbol{x} - \boldsymbol{x}_0|} + \frac{\mathrm{e}^{\mathrm{i}\,|\boldsymbol{x}-\overline{\boldsymbol{x}}_0|\,\omega/c}}{4\,\pi\,|\boldsymbol{x} - \overline{\boldsymbol{x}}_0|}. \tag{51.98}$$

The vanishing Neumann boundary condition (51.97c) results from taking the sum of the original free space Green's function and its image across the $z = 0$ plane, so that the vertical derivative of the two Green's functions cancel at $z = 0$. To verify this result, write

$$\partial_z[\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) + \mathcal{G}(\boldsymbol{x}|\overline{\boldsymbol{x}}_0)] = \partial_z[F(|\boldsymbol{x} - \boldsymbol{x}_0|) + F(|\boldsymbol{x} - |\overline{\boldsymbol{x}}_0|)] \tag{51.99a}$$

$$= F'(|\boldsymbol{x}-\boldsymbol{x}_0|)\frac{z-z_0}{|\boldsymbol{x}-\boldsymbol{x}_0|} + F'(|\boldsymbol{x}-\overline{\boldsymbol{x}}_0|)\frac{z-\overline{z}_0}{|\boldsymbol{x}-\overline{\boldsymbol{x}}_0|} \tag{51.99b}$$

$$= F'(|\boldsymbol{x}-\boldsymbol{x}_0|)\frac{z-z_0}{|\boldsymbol{x}-\boldsymbol{x}_0|} + F'(|\boldsymbol{x}-\overline{\boldsymbol{x}}_0|)\frac{z+z_0}{|\boldsymbol{x}-\overline{\boldsymbol{x}}_0|}, \tag{51.99c}$$

where F' is the derivative of the function. At $z=0$, the two distances are equal so that

$$|\boldsymbol{x}-\boldsymbol{x}_0| = |\boldsymbol{x}-\overline{\boldsymbol{x}}_0| \quad \text{and} \quad F'(|\boldsymbol{x}-\boldsymbol{x}_0|) = F'(|\boldsymbol{x}-\overline{\boldsymbol{x}}_0|) \quad \text{at } z=0, \tag{51.100}$$

which then yields the desired result

$$\partial_z G(\boldsymbol{x}|\boldsymbol{x}_0) = 0 \quad z=0. \tag{51.101}$$

Note that we are only interested in the boundary condition at $z=0$ and the behavior of the Green's function in the half-space $z>0$. We have no concern for what the Green's function does in the region $z<0$. So placement of an image source in the lower half-space is merely a trick to enable proper behavior in the $z\geq 0$ region of interest. This "method of images" constructed Green's function is indeed somewhat magical, as it produces precisely what we need yet without solving any new Green's function equation. Hence, it is a very useful method to construct the Green's function for certain highly symmetric configurations such as given here. However, it is not a general method, so we can only make use of it for certain very special cases. Even so, we accept such gifts when they are available, here providing the Green's function needed to determine the velocity potential, Φ, as per equation (51.93).

51.8.4 Velocity potential

Making use of the Green's function (51.98) within the expression (51.93) leads to the velocity potential

$$-\Phi(\boldsymbol{x}_0) = \frac{\mathrm{i}\,\epsilon\,a\,\omega}{2\pi}\int_0^a \int_0^{2\pi} \frac{\mathrm{e}^{\mathrm{i}\,|\boldsymbol{x}-\boldsymbol{x}_0|\,\omega/c}}{|\boldsymbol{x}-\boldsymbol{x}_0|}\, r\,\mathrm{d}r\,\mathrm{d}\vartheta, \tag{51.102}$$

where the integral is computed at $z=0$ within the region $r\leq a$ of the piston, and where we used the Neumann boundary condition (51.88c) for the velocity potential at $z=0$. Making use of the expression (51.87) for the velocity potential, Ψ, renders

$$\Psi(\boldsymbol{x}_0,t) = \Phi(\boldsymbol{x}_0)\,\mathrm{e}^{-\mathrm{i}\,\omega\,t} = -\frac{\mathrm{i}\,\epsilon\,a\,\omega}{2\pi}\int_0^a \int_0^{2\pi} \frac{\mathrm{e}^{\mathrm{i}\,(|\boldsymbol{x}-\boldsymbol{x}_0|\,\omega/c-\omega\,t)}}{|\boldsymbol{x}-\boldsymbol{x}_0|}\, r\,\mathrm{d}r\,\mathrm{d}\vartheta. \tag{51.103}$$

The velocity potential is constructed by integrating outgoing spherical waves over the area of the piston, with these waves having a strength that is proportional to the piston velocity. As shown in section 51 of *Fetter and Walecka* (2003), further evaluation of this integral reveals that the acoustic energy and power intensity display characteristic lobes as a function of the angle, β, relative to the vertical axis (see Figure 51.3).

51.8.5 Further study

This section is based on section 51 of *Fetter and Walecka* (2003). Further study of acoustic waves from a planar source can be found in section I.12 of *Lighthill* (1978).

51.9 Acoustic waves in a gently varying background

In Section 51.4.3 we developed the acoustic wave equations for linear waves propagating through a static yet inhomogeneous background state with both ρ_e and c_s functions of space. However,

subsequent analysis of acoustic waves was restricted to homogeneous background state whereby ρ_e and c_s are taken to be space and time constants. In this section we extend the geometric optics formalism from Section 50.3 to render equations for the propagation of acoustic wave energy through a spatially inhomogeneous yet static background.[8] We make use of the *WKBJ asymptotic method*, which is a powerful approach for a variety of purposes.[9] We also present Whitham's variational principle, which, as we show, offers a far more streamlined means to deriving the leading order equations. Both the WKBJ and variational methods make use of the *eikonal wave ansatz* (equation (51.124)) rather than a Fourier plane wave ansatz, with the more general ansatz needed since Fourier methods are not suited to inhomogeneous backgrounds.

51.9.1 Scalar potential for density-weighted velocity

Return to the derivation of the acoustic wave equation in Sections 51.4.3 and 51.4.4, now generalizing the velocity potential to include the spatially variable background density. Again, the linearized Euler equation (51.23), its curl, and the linearized continuity equation (51.24) are given by

$$\partial_t(\rho_e\,\boldsymbol{v}') = -\nabla p' \quad \text{and} \quad \partial_t[\nabla\times(\rho_e\,\boldsymbol{v}')] = 0 \quad \text{and} \quad \partial_t p' + \rho_e\, c_s^2\,\nabla\cdot\boldsymbol{v}' = 0. \tag{51.104}$$

Assuming a vanishing initial curl, $\nabla\times(\rho_e\,\boldsymbol{v}') = 0$, as appropriate for a static initial condition, allows us to focus on fluctuations that satisfy $\nabla\times(\rho_e\,\boldsymbol{v}') = 0$ for all time. We are thus led to introduce a scalar potential for the density-weighted velocity

$$\rho_e\,\boldsymbol{v}' = -\nabla\chi, \tag{51.105}$$

with χ having dimensions of density times squared length per time (compare to the velocity potential ψ in equation (51.30)). Use of χ in the linearized Euler equation (first of equation (51.104)) leads to

$$\nabla(\partial_t\chi - p') = 0. \tag{51.106}$$

Following the procedure from Section 51.4.4, we choose a gauge so that

$$p' = \partial_t\chi. \tag{51.107}$$

Using this expression for the pressure in the linearized continuity equation (third of equation (51.104)) renders the wave equation for the velocity potential

$$\frac{1}{\rho_e\,c_s^2}\frac{\partial^2\chi}{\partial t^2} - \nabla\cdot(\rho_e^{-1}\,\nabla\chi) = 0. \tag{51.108}$$

Once we have determined χ, then the pressure field is determined by taking the time derivative in equation (51.107), and the velocity is determined by taking the gradient according to equation (51.105).

51.9.2 Energetics

We studied the energetics of acoustic waves in Section 51.6. Here we provide a terse version of that discussion starting from the wave equation (51.108) and deriving the corresponding

[8] Restricting to static background simplifies the maths. Also, it is sufficient for many applications since acoustic waves are quite fast relative to the slower movement of fluid particles. Finally, as discussed by *Pierce* (1990), the acoustic wave equation picks up extra terms when moving through a time evolving background state, and we are only interested here in the familiar form of the acoustic wave equation.

[9] Chapter 10 of *Bender and Orszag* (1978) presents a thorough discussion of the WKBJ method from an applied mathematical perspective.

energy equation. Multiplying equation (51.108) by $\partial_t\chi$, and recalling that ρ_e and c_s are time independent, brings the first term to

$$[\rho_e\, c_s^2]^{-1}\, \partial_t\chi\, \partial_{tt}\chi = [2\,\rho_e\, c_s^2]^{-1}\, \partial_t(\partial_t\chi\, \partial_t\chi), \tag{51.109}$$

whereas the second term in equation (51.108) gives

$$-\partial_t\chi\, \nabla\cdot(\rho_e^{-1}\, \nabla\chi) = -\nabla\cdot(\rho_e^{-1}\, \partial_t\chi\, \nabla\chi) + \partial_t(\rho_e^{-1}\, \nabla\chi\cdot\nabla\chi)/2. \tag{51.110}$$

We are thus led to the energy conservation law

$$(1/2)\, \partial_t[(\rho_e\, c_s^2)^{-1}\, (\partial_t\chi)^2 + \rho_e^{-1}\, (\nabla\chi)^2] = \nabla\cdot(\rho_e^{-1}\, \partial_t\chi\, \nabla\chi), \tag{51.111}$$

which can be equivalently written

$$(1/2)\, \partial_t[(\rho_e\, c_s^2)^{-1}\, (p')^2 + \rho_e\, \boldsymbol{v}'\cdot\boldsymbol{v}'] = -\nabla\cdot(p'\, \boldsymbol{v}'), \tag{51.112}$$

which compares directly to the energy equation (51.77a) derived for fluctuations around a homogeneous background state.

51.9.3 Stress-energy-momentum tensor

As an aside, we here display the stress-energy-momentum tensor for acoustic waves, following the field theory formalism from Section 50.4.3. The Lagrangian density for acoustic waves can be written as

$$\mathscr{L} = (2\,\rho_e)^{-1}\, [c_s^{-2}\, (\partial_t\chi)^2 - (\nabla\chi)^2], \tag{51.113}$$

whose Euler-Lagrange field equation is the acoustic wave equation (51.108). The corresponding generalized momentum, Hamiltonian density, and energy flux (equation (46.64)) are given by

$$\mathscr{P} = \frac{\partial\mathscr{L}}{\partial(\partial_t\chi)} = (\rho_e\, c_s^2)^{-1}\, \partial_t\chi = p'/(\rho_e\, c_s^2) \tag{51.114a}$$

$$\mathscr{H} = \mathscr{P}\, \partial_t\chi - \mathscr{L} = (2\,\rho_e)^{-1}\, [c_s^{-2}\, (\partial_t\chi)^2 + (\nabla\chi)^2] = (1/2)\, [(\rho_e\, c_s^2)^{-1}\, (p')^2 + \rho_e\, \boldsymbol{v}'\cdot\boldsymbol{v}'] \tag{51.114b}$$

$$F^a = \frac{\partial\mathscr{L}}{\partial(\partial_{x^a}\chi)}\, \frac{\partial\chi}{\partial t} = -\rho_e^{-1}\, \nabla\chi\, \partial_t\chi = \boldsymbol{v}'\, p'. \tag{51.114c}$$

Since the Lagrangian has no explicit time dependence, the Hamiltonian satisfies a source-free continuity equation, which is equivalent to the wave energy equation (51.111)

$$\partial_t\mathscr{H} + \nabla\cdot\boldsymbol{F} = 0. \tag{51.115}$$

Likewise, for a background state that has no dependence on $x = x^1$, the corresponding wave momentum is conserved so that

$$\partial_t T^0{}_1 + \partial_a T^a{}_1 = 0. \tag{51.116}$$

Elements to the stress-energy-momentum tensor are generally given by equation (50.48) and take on the following form for acoustic waves

$$T^0{}_1 = (\rho_e\, c_s^2)^{-1}\, \partial_t\chi\, \partial_x\chi \tag{51.117a}$$

$$T^1{}_1 = -(2\,\rho_e)^{-1}\, [c_s^{-2}\, (\partial_t\chi)^2 - (\partial_x\chi)^2 + (\partial_y\chi)^2 + (\partial_z\chi)^2] \tag{51.117b}$$

$$T^2{}_1 = -(\rho_e)^{-1}\, \partial_y\chi\, \partial_x\chi \tag{51.117c}$$

$$T^3{}_1 = -(\rho_e)^{-1}\, \partial_z\chi\, \partial_x\chi, \tag{51.117d}$$

which can be written in the equivalent form

$$T^0{}_1 = -p'\,u'/c_s^2 \tag{51.118a}$$
$$T^1{}_1 = -[(\rho_e\,c_s^2)^{-1}\,(p')^2 - \rho_e\,(u')^2 + \rho_e\,(v')^2 + \rho_e\,(w')^2]/2 \tag{51.118b}$$
$$T^2{}_1 = -\rho_e\,u'\,v' \tag{51.118c}$$
$$T^3{}_1 = -\rho_e\,u'\,w'. \tag{51.118d}$$

In Exercise 51.3 we verify that the budget equation (51.116) holds for the acoustic waves using elements of the stress-energy-momentum tensor given by equations (51.118a)–(51.118d).

51.9.4 Alternative expression for the action

Following the observation in Sections 50.6 and 50.6, we write the action for acoustic waves in the form

$$\mathcal{S} = \frac{1}{2}\int_R \chi\,\hat{D}\chi\,\mathrm{d}V\,\mathrm{d}t, \tag{51.119}$$

where the acoustic linear operator, $\hat{D}$, is given by

$$-\hat{D} = (\rho_e\,c_s^2)^{-1}\,\partial_{tt} - \nabla(\rho_e^{-1})\cdot\nabla - \rho_e^{-1}\,\nabla^2. \tag{51.120}$$

To verify the expression (51.119), perform an integration by parts to find

$$2\,\mathsf{S} = -\int_R \partial_t[(\rho_e\,c_s^2)^{-1}\,\chi\,\partial_t\chi]\,\mathrm{d}V\,\mathrm{d}t + \int_R \nabla\cdot(\rho_e^{-1}\,\chi\,\nabla\chi)\,\mathrm{d}V\,\mathrm{d}t + 2\int_R \mathcal{L}\,\mathrm{d}V\,\mathrm{d}t, \tag{51.121}$$

where we introduced the Lagrangian density

$$\mathcal{L} = (2\,\rho_e)^{-1}\,[c_s^{-2}\,(\partial_t\chi)^2 - (\nabla\chi)^2], \tag{51.122}$$

from equation (51.113). Dropping boundary terms, which renders $\widehat{D}$ a self-adjoint wave operator, leads to the traditional form of the action

$$\mathcal{S} = \int_R \mathcal{L}\,\mathrm{d}V\,\mathrm{d}t. \tag{51.123}$$

51.9.5 Space and time scale separation

We are motivated by the hypothesis that waves moving through a gently varying inhomogeneous background are locally close to the plane wave form realized for homogeneous background. Asymptotic methods arising from this hypothesis were developed in Chapter 50, and here we apply it to acoustic waves. Rather the traveling plane wave ansatz (49.18) used for homogeneous media, we here consider the *eikonal wave ansatz*

$$\chi(\boldsymbol{x},t) = \mathrm{Re}[A(\boldsymbol{x},t)\,e^{\mathrm{i}\,\mathcal{P}(\boldsymbol{x},t)}] = A(\boldsymbol{x},t)\cos[\mathcal{P}(\boldsymbol{x},t)], \tag{51.124}$$

where $A > 0$ is the real amplitude and $\mathcal{P}$ is the phase introduced in Section 50.2. We assume that spatial variations of the wave amplitude scale according to the length scale, L, introduced by equation (50.3), so that

$$|\nabla A|/A \sim L^{-1} \sim |\nabla\rho_e|/\rho_e. \tag{51.125}$$

The complement assumption is that the phase function varies over a length scale that is much smaller than L, so that the local wavenumber satisfies equation (50.3), here written as

$$|\nabla \mathcal{P}| \gg L^{-1} \implies \frac{1/|\nabla \mathcal{P}|}{L} \ll 1. \tag{51.126}$$

Combined with the definition (51.125), the WKBJ approximation considers a wave amplitude and wave phase that satisfy

$$|\nabla A|/A \ll |\nabla \mathcal{P}| = |\boldsymbol{k}|. \tag{51.127}$$

The same arguments hold for the time scale of the waves, so that

$$|\partial_t A|/A \ll |\partial_t \mathcal{P}| = \omega. \tag{51.128}$$

In developing the WKBJ asymptotic equations from the eikonal wave ansatz, it can be useful to scale the phase by a small non-dimensional parameter, ϵ, in which case

$$\mathcal{P} = \varphi/\epsilon \quad \text{where} \quad |\nabla A|/A \sim |\nabla \varphi|, \tag{51.129}$$

and equation (51.127) then takes on the form

$$|\nabla A|/A \ll |\nabla \varphi|/\epsilon. \tag{51.130}$$

An equivalent means to organize similarly scaled terms is to write the wave function (51.124) in the form

$$\chi = A\, e^{\mathrm{i}\mathcal{P}/\sigma}, \tag{51.131}$$

where $\sigma = 1$ is used to organize the terms, with this approach used in Section 51.9.6.

51.9.6 The WKBJ asymptotic solution

We now plug in the eikonal wave ansatz (51.131) to the wave equation (51.133) to develop the WKBJ asymptotic equations that determine how the amplitude and phase evolve. The manipulations are straightforward but somewhat tedious and uninspired. We expose sufficient details to facilitate checking the maths.

Notation used for the WKBJ asymptotic expansion

In this subsection we find it useful to introduce the following notation

$$W = 1/(\rho_{\mathrm{e}}\, c_{\mathrm{s}}^2) \tag{51.132}$$

so that the wave equation (51.108) is written

$$W \frac{\partial^2 \chi}{\partial t^2} - \nabla \cdot (W\, c_{\mathrm{s}}^2\, \nabla \chi) = 0. \tag{51.133}$$

Likewise, the energy equation (51.111) takes on the form

$$(1/2)\, \partial_t \left[W\, (\partial_t \chi)^2 + W\, c_{\mathrm{s}}^2\, (\nabla \chi)^2 \right] = \nabla \cdot (W\, c_{\mathrm{s}}^2\, \partial_t \chi\, \nabla \chi), \tag{51.134}$$

so that the Hamiltonian density (i.e., the energy) and the energy flux are

$$\mathscr{H} = W\, [(\partial_t \chi)^2 + c_{\mathrm{s}}^2\, (\nabla \chi)^2]/2 \quad \text{and} \quad \boldsymbol{F} = -W\, c_{\mathrm{s}}^2\, \partial_t \chi\, \nabla \chi. \tag{51.135}$$

W does not appear in the dispersion relation derived below, thus motivating its introduction.

The derivatives

The derivatives are given by the following expressions, organized according to powers of σ:

$$e^{-\mathrm{i}\,\mathcal{P}/\sigma}\,\nabla\chi = (\mathrm{i}/\sigma)\,A\,\nabla\mathcal{P} + \nabla A \tag{51.136a}$$

$$e^{-\mathrm{i}\,\mathcal{P}/\sigma}\,\nabla^2\chi = -\sigma^{-2}\,A\,(\nabla\mathcal{P})^2 + (\mathrm{i}/\sigma)\,(2\,\nabla A\cdot\nabla\mathcal{P} + A\,\nabla^2\mathcal{P}) + \nabla^2 A \tag{51.136b}$$

$$e^{-\mathrm{i}\,\mathcal{P}/\sigma}\,\partial_{tt}\chi = -\sigma^{-2}\,A\,(\partial_t\mathcal{P})^2 + (\mathrm{i}/\sigma)\,(2\,\partial_t A\,\partial_t\mathcal{P} + A\,\partial_{tt}\mathcal{P}) + \partial_{tt}A, \tag{51.136c}$$

along with

$$\begin{aligned} e^{-\mathrm{i}\,\mathsf{P}/\sigma}\,\nabla\cdot(W\,c^2\,\nabla\chi) = W\,c_{\mathsf{s}}^2\,\big[-\sigma^{-2}\,A\,(\nabla\mathcal{P})^2 + (\mathrm{i}/\sigma)\,(2\,\nabla A\cdot\nabla\mathcal{P} + A\,\nabla^2\mathcal{P}) + \nabla^2 A\big] \\ + \nabla(W\,c_{\mathsf{s}}^2)\cdot[(\mathrm{i}/\sigma)\,A\,\nabla\mathcal{P} + \nabla A]. \end{aligned} \tag{51.137}$$

$\mathcal{O}(\sigma^{-2})$ terms

As for deriving the quasi-geostrophic equations in Part VIII of this book, when deriving asymptotic equations we balance terms according to powers of the expansion parameter, with σ the parameter for the present analysis. The $\mathcal{O}(\sigma^{-2})$ terms render

$$(\partial_t\mathcal{P})^2 = c_{\mathsf{s}}^2\,\nabla\mathcal{P}\cdot\nabla\mathcal{P} \Longrightarrow \omega^2 = c_{\mathsf{s}}^2\,|\boldsymbol{k}|^2. \tag{51.138}$$

This local dispersion relation is the same as the dispersion relation (51.42) holding for acoustic waves moving in a homogeneous media. Now, however, the angular frequency, wave speed, and wavenumber are each functions of the spatial position. This result accords with our original hypothesis that waves move through the inhomogeneous media with a local plane wave behavior. It also accords with the assumptions built into the ray theory studied in Sections 50.2 and 50.3.

$\mathcal{O}(\sigma^{-1})$ terms

The $\mathcal{O}(\sigma^{-1})$ balance yields

$$W\,(2\,\partial_t A\,\partial_t\mathcal{P} + A\,\partial_{tt}\mathcal{P}) = W\,c_{\mathsf{s}}^2\,(2\,\nabla A\cdot\nabla\mathcal{P} + A\,\nabla^2\mathcal{P}) + A\,\nabla\mathcal{P}\cdot\nabla(W\,c_{\mathsf{s}}^2), \tag{51.139}$$

which can be rearranged to the form

$$(\partial_t + \boldsymbol{c}_{\mathsf{p}}\cdot\nabla)A = -\frac{A}{2\,W\,\omega}\,[W\,\partial_t\omega + \nabla\cdot(\boldsymbol{k}\,W\,c_{\mathsf{s}}^2)]. \tag{51.140}$$

The left hand side is the time derivative of the amplitude computed by following the phase velocity,

$$\boldsymbol{c}_{\mathsf{p}} = c_{\mathsf{s}}\,\hat{\boldsymbol{k}} = (\omega/|\boldsymbol{k}|)\,\hat{\boldsymbol{k}}. \tag{51.141}$$

The right hand side of equation (51.140) is a source term that contributes to the amplitude change following the phase velocity. Furthermore, since the acoustic waves are non-dispersive, in which $\boldsymbol{c}_{\mathsf{p}} = \boldsymbol{c}_{\mathsf{g}}$, equation (51.140) can be written using the time derivative following a ray

$$-\frac{2\,\omega}{A}\,\frac{\mathrm{D}_t A}{\mathrm{D}t} = \partial_t\omega + \nabla\cdot(\boldsymbol{k}\,W\,c_{\mathsf{s}}^2)/W \tag{51.142a}$$

$$= \partial_t\omega + c_{\mathsf{s}}^2\,\nabla\cdot\boldsymbol{k} + \boldsymbol{k}\cdot\nabla c_{\mathsf{s}}^2 + c_{\mathsf{s}}^2\,\boldsymbol{k}\cdot(\nabla W)/W. \tag{51.142b}$$

Massaging the source terms

Terms on the right hand side of the amplitude equation (51.142b) provide sources for the wave amplitude along a ray. We find it useful to rearrange these terms by using the following expression

for the wavevector in an acoustic wave

$$\boldsymbol{k} = \boldsymbol{c}_{\mathsf{p}}\,|\boldsymbol{k}|/c_{\mathsf{s}} = \boldsymbol{c}_{\mathsf{p}}\,\omega/c_{\mathsf{s}}^2 = \boldsymbol{c}_{\mathsf{g}}\,\omega/c_{\mathsf{s}}^2, \tag{51.143}$$

so that

$$\nabla\cdot\boldsymbol{k} = (\omega/c_{\mathsf{s}}^2)\,\nabla\cdot\boldsymbol{c}_{\mathsf{g}} + \boldsymbol{c}_{\mathsf{g}}/c_{\mathsf{s}}^2\cdot\nabla\omega + \omega\,\boldsymbol{c}_{\mathsf{g}}\cdot\nabla c_{\mathsf{s}}^{-2}, \tag{51.144}$$

thus leading to

$$\partial_t\omega + c_{\mathsf{s}}^2\,\nabla\cdot\boldsymbol{k} + \boldsymbol{k}\cdot\nabla c_{\mathsf{s}}^2 = (\partial_t + \boldsymbol{c}_{\mathsf{g}}\cdot\nabla)\omega + \omega\,\nabla\cdot\boldsymbol{c}_{\mathsf{g}} + \omega\,c_{\mathsf{s}}^2\,\boldsymbol{c}_{\mathsf{g}}\cdot\nabla c_{\mathsf{s}}^{-2} + \boldsymbol{k}\cdot\nabla c_{\mathsf{s}}^2 \tag{51.145a}$$

$$= \frac{\mathrm{D}_{\mathsf{r}}\omega}{\mathrm{D}t} + \omega\,\nabla\cdot\boldsymbol{c}_{\mathsf{g}}, \tag{51.145b}$$

where we used

$$\omega\,c_{\mathsf{s}}^2\,\boldsymbol{c}_{\mathsf{g}}\cdot\nabla c_{\mathsf{s}}^{-2} = -2\,(\omega/c_{\mathsf{s}})\boldsymbol{c}_{\mathsf{g}}\cdot\nabla c_{\mathsf{s}} = -\omega\,c_{\mathsf{s}}^{-2}\,(c_{\mathsf{s}}^2\,\boldsymbol{k}/\omega)\cdot\nabla c_{\mathsf{s}}^2 = -\boldsymbol{k}\cdot\nabla c_{\mathsf{s}}^2. \tag{51.146}$$

These results then lead to the amplitude equation

$$\frac{1}{A}\,\frac{\mathrm{D}_{\mathsf{r}}A}{\mathrm{D}t} = -\frac{1}{2\,\omega}\,\frac{\mathrm{D}_{\mathsf{r}}\omega}{\mathrm{D}t} - \nabla\cdot(\boldsymbol{c}_{\mathsf{g}}\,W)/(2\,W). \tag{51.147}$$

The dispersion relation has no explicit time dependence given that the background state is time independent. As a result, equation (50.34) from geometric optics means that the angular frequency remains constant along a ray, so that $\mathrm{D}_{\mathsf{r}}\omega/\mathrm{D}t = 0$. Even so, we retain this term since it hints at the more general case holding for time dependent background states.

For the second term on the right hand side of equation (51.147) we set $W^{-1} = \rho_{\mathsf{e}}\,c_{\mathsf{s}}^2$ from equation (51.132) to have

$$-\nabla\cdot(\boldsymbol{c}_{\mathsf{g}}\,W)/(2\,W) = -(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2/2)\,\nabla\cdot(\boldsymbol{c}_{\mathsf{g}}/\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2) = -\nabla\cdot\boldsymbol{c}_{\mathsf{g}}/2 + \boldsymbol{c}_{\mathsf{g}}\cdot\nabla(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2)/(2\,\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2), \tag{51.148}$$

so that equation (51.147) takes the form

$$\frac{2}{A}\,\frac{\mathrm{D}_{\mathsf{r}}A}{\mathrm{D}t} + \frac{1}{\omega}\,\frac{\mathrm{D}_{\mathsf{r}}\omega}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{c}_{\mathsf{g}} + \boldsymbol{c}_{\mathsf{g}}\cdot\nabla(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2)/(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2). \tag{51.149}$$

Since $\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2$ is assumed to be time independent, we can write this equation as

$$\frac{2}{A}\,\frac{\mathrm{D}_{\mathsf{r}}A}{\mathrm{D}t} + \frac{1}{\omega}\,\frac{\mathrm{D}_{\mathsf{r}}\omega}{\mathrm{D}t} - \frac{\mathrm{D}_{\mathsf{r}}(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2)}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{c}_{\mathsf{g}}, \tag{51.150}$$

which combines to read

$$\frac{\mathrm{D}_{\mathsf{r}}[(A^2\,\omega)/(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2)]}{\mathrm{D}t} = -(A^2\,\omega)/(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2)\,\nabla\cdot\boldsymbol{c}_{\mathsf{g}}, \tag{51.151}$$

which can be written as the flux-form conservation equation

$$\partial_t[A^2\,\omega/(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2)] + \nabla\cdot[\boldsymbol{c}_{\mathsf{g}}\,A^2\,\omega/(\rho_{\mathsf{e}}\,c_{\mathsf{s}}^2)] = 0. \tag{51.152}$$

In Section 51.9.7 we interpret this equation in terms of phase averaged energy and wave action.

51.9.7 Phase averaged energy

We here compute the phase averaged Hamiltonian (energy) consistent with the assumed scaling from Section 51.9.5. Working with the real expression (51.124) leads to

$$\partial_t \chi = A\,[A^{-1}\,\partial_t A \cos\mathcal{P} - \partial_t \mathcal{P} \sin\mathcal{P}] \approx A\,\omega \sin\mathcal{P}, \tag{51.153}$$

where $A^{-1}\,\partial_t A \ll \omega$ as per the assumed scaling (51.128), and $\omega = -\partial_t \mathcal{P}$ as per equation (50.2). Similarly, we compute the gradient as

$$\nabla \chi = A\,[A^{-1}\,\nabla A \cos\mathcal{P} - \nabla\mathcal{P} \sin\mathcal{P}] \approx -A\,\boldsymbol{k} \sin\mathcal{P}, \tag{51.154}$$

which follows from the scaling (51.127) and $\boldsymbol{k} = \nabla\mathcal{P}$ from equation (50.2). We thus have the expression for the Hamiltonian

$$\mathscr{H} = \frac{A^2 \sin^2\mathcal{P}\,(\omega^2 + c_{\mathrm{s}}^2\,|\boldsymbol{k}|^2)}{2\,\rho_{\mathrm{e}}\,c_{\mathrm{s}}^2} = \frac{\omega^2\,A^2 \sin^2\mathcal{P}}{\rho_{\mathrm{e}}\,c_{\mathrm{s}}^2}, \tag{51.155}$$

where we inserted the dispersion relation (51.138). Taking the phase average leads to

$$\langle\mathscr{H}\rangle = \frac{\omega^2\,A^2}{2\,\rho_{\mathrm{e}}\,c_{\mathrm{s}}^2}. \tag{51.156}$$

Making use of the phase averaged energy (51.156) in the amplitude equation (51.152) leads to

$$\partial_t(\langle\mathscr{H}\rangle/\omega) + \nabla\cdot(\boldsymbol{c}_{\mathrm{g}}\,\langle\mathscr{H}\rangle/\omega) = 0. \tag{51.157}$$

The quantity

$$\mathcal{A} = \langle\mathscr{H}\rangle/\omega \tag{51.158}$$

is the *wave action* that we studied in Section 50.5.

51.9.8 Whitham's variational principle

We studied Whitham's variational principle in Section 50.5, where we claimed that it offers a more streamlined means to derive the leading order phase averaged equations than the WKBJ method used in Sections 51.9.6 and 51.9.7. Taking the results from Section 50.5, we write the phase averaged acoustic Lagrangian (51.113)

$$\langle\mathscr{L}\rangle = (4\,\rho_{\mathrm{e}})^{-1}\,A^2\,(c_{\mathrm{s}}^{-2}\,\omega^2 - |\boldsymbol{k}|^2). \tag{51.159}$$

The dispersion relation arises from the Euler-Lagrange equation resulting from a variation of the wave amplitude,

$$\partial\langle\mathscr{L}\rangle/\partial A = 0 \Longrightarrow \omega^2 = c_{\mathrm{s}}^2\,|\boldsymbol{k}|^2. \tag{51.160}$$

Likewise, the Euler-Lagrange equation corresponding to varying the phase function yields the wave action conservation equation

$$\partial_t(\mathcal{A}) + \nabla\cdot(\boldsymbol{c}_{\mathrm{g}}\,\mathcal{A}) = 0, \tag{51.161}$$

where $\boldsymbol{c}_{\mathrm{g}} = c_{\mathrm{s}}\,\hat{\boldsymbol{k}}$ is the group velocity and the wave action is

$$\mathcal{A} = \partial\langle\mathscr{L}\rangle/\partial\omega = \frac{\omega\,A^2}{2\,\rho_{\mathrm{e}}\,c_{\mathrm{s}}^2} = \langle\mathscr{H}\rangle/\omega. \tag{51.162}$$

Evidently, we only needed the phase averaged Lagrangian to leading order when using Whitham's principle to derive both the dispersion relation and the wave action conservation equation. In contrast, the WKBJ method required one order higher in the asymptotics when working with the wave equation to derive wave action conservation, which required a relatively large amount of manipulation.

The relative simplicity of Whitham's variational principle, compared to the WKBJ method, is reminscent of analytic mechanics versus Newtonian mechanics. As shown through a variety of case studies in Chapter 15, analytical mechanics is far more powerful for the study of systems that are generally quite tedious, if not unavailable, using Newtonian mechanics. The price to pay is that analytical mechanics requires some relatively nontrivial theoretical work up front to establish the framework. But once established, exposure of the underlying symmetries and conservation laws is far more streamlined, if not trivial. Likewise, Whitham's variational principle requires some theoretical work up front to derive the framework (Section 50.5). The payoff is that the variational framework is optimized for capturing the leading order physics of phase averaged wave mechanics.

51.9.9 Further study

The WKBJ treatment here followed that given in Section 7.3 of *Thorne and Blandford* (2017). However, we limited attention to the case of a static background state since we only developed the physics for acoustic waves moving in a static inhomogenous background (Section 51.4.2). *Pierce* (1990) considers the more general case with a space and time dependent background, in which the acoustic wave equation contains further terms.

51.10 Exercises

EXERCISE 51.1: ACOUSTIC MODES IN RECTANGULAR CAVITY (PROBLEM 9.1 OF *Fetter and Walecka* (2003))
A rectangular cavity with dimensions $x \in [0, L_x]$, $y \in [0, L_y]$, and $z \in [0, L_z]$ is bounded by rigid material walls on all sides. The fluid is homogeneous within the cavity. Determine the eigenfrequencies and eigenfunctions for the acoustic normal modes in this cavity.

Hint: this exercise requires solving the acoustic wave equation in a closed domain with associated kinematic boundary conditions. The resulting acoustic modes are standing wave modes rather than traveling waves, and the wavenumbers are quantized rather than continuous. Note that standing wave modes can be thought of as the superposition of two oppositvely traveling waves with identical stucture. For example, the sum of a right and left moving wave with equal amplitude, wavenumber, and frequency is given by the standing wave pattern

$$A\cos(k\,x - \omega\,t) + A\cos(k\,x + \omega\,t) = 2\,A\cos(\omega\,t)\cos(k\,x). \tag{51.163}$$

EXERCISE 51.2: PRESSURE FLUCTUATIONS RELATIVE TO A UNIFORM FLOW (PROBLEM 9.4 OF *Fetter and Walecka* (2003))
Consider a homogeneous and compressible fluid with uniform flow, $\boldsymbol{v}$. Show that the pressure fluctuations relative to this fluid flow state satisfy

$$(\partial_t + \boldsymbol{v}\cdot\nabla)^2\,p - c_s^2\,\nabla^2 p = 0. \tag{51.164}$$

Hint: ths solution is a one-liner that results from linearizing equation (51.19) with a nonzero background flow.

EXERCISE 51.3: MOMENTUM BUDGET FOR ACOUSTIC WAVES

Verify that the budget equation (51.116) holds for the acoustic waves, with elements of the stress-energy-momentum tensor given by equations (51.118a)–(51.118d).

Chapter 52

INTERFACIAL WAVES ON POTENTIAL FLOW

In this chapter we study *interfacial waves*, which are waves occuring at the interface between two homogeneous (constant density) fluid layers. We limit the study to the case where the upper layer has zero density, with this idealization motivated by the study of waves on the surface of the ocean under a massless atmosphere, referred to here as *surface waves*. We are here concerned with two restoring forces that affect small amplitude motion relative to a static equilibrium base state. One force arises from gravitation in the presence of a density jump between the two fluid layers; i.e., the buoyancy studied in Chapter 30. The other force arises from surface tension due to molecular forces at the interface (see Section 25.11).

To help understand the basics of surface waves along the ocean's free surface, consider a water parcel that rises above its equilibrium level into an environment where it is heavier than the surrounding atmosphere, in which case the water parcel experiences a downward buoyancy force that returns it to its equilibrium level. However, this motion generally overshoots the equilibrium level, at which point the parcel feels an upward buoyancy force. This up and down motion results in the exchange between kinetic energy and potential energy for the parcel, with the spatio-temporal organization of the oscillations constituting a *surface gravity wave*. A similar picture holds for *capillary waves* that arise from surface tension acting as the restoring force. By ignoring planetary rotation we tacitly focus on ocean surface waves whose lateral extent is too short to be affected by the planetary Coriolis acceleration. That is, we are concerned with surface waves and capillary waves that can be visually observed.

The interfacial waves studied in this chapter do not carry vorticity within the fluid interior, thus enabling use of irrotational fluid mechanics. In this case, the fluid velocity can be written as the gradient of a scalar potential, thus leading to the term *potential flow*. We also pursued the methods of potential flow in Chapter 51 when studying acoustic waves. Yet here the surface waves appear in a fluid with a strictly constant density, thus removing any acoustic modes and rendering non-divergent flow. A flow that is both irrotational and non-divergent is described by a scalar potential that satisfies Laplace's equation (Section 6.5); i.e., the potential is a harmonic function. Waves arise solely through the role of the boundary condition placed at the interface. Furthermore, the waves propagate in the horizontal direction along the interface and exponentially decay in the vertical, with a vertical decay scale directly related to the horizontal wavenumber. Mathematically, this coupling of the horizontal and vertical length scales is a direct result of the scalar potential satisfying Laplace's equation.

Gravity waves along an interface are transverse in the horizontal direction, meaning fluid particles move perpendicular to the wave. Furthermore, the waves do not propagate vertically and they induce vertical particle motion whose amplitude exponentially vanishes with depth in the ocean layer. Although the surface gravity waves we study in this chapter are linear, the depth decay in their amplitude leads to a net drift of fluid particles and hence to the transport of matter. This matter transport is known as *Stokes drift*, which plays an important role in the transport of matter at the ocean surface. Stokes drift provides the canonical example of how averaging at a fixed point in space (Eulerian average) yields distinct behaviors from averaging

on a fixed fluid particle (Lagrangian average).[1]

READER'S GUIDE TO THIS CHAPTER

We make use of dynamical ideas from Chapter 24, elements of the filtered equations from Chapter 27, and salient features of wave kinematics from Chapter 49. The study of capillary waves requires an understanding of surface tension in Section 25.11. We also use ideas from partial differential equations introduced in Chapter 6. The mathematical description of Stokes drift requires an understanding of Eulerian and Lagrangian kinematic descriptions from Chapter 17. Generalizations of Stokes drift appear in Chapter 70 in our study of wave-mean flow interactions, isopycnal averaging, and the corresponding eddy-induced tracer transport. In this chapter we only consider waves at the upper surface of a single massive fluid layer, whereas in Chapter 60 we extend this analysis to the case of two massive fluid layers as part of a study of the Rayleigh-Taylor and Kelvin-Helmholtz instabilities. Finally, note that Chapter 10 in *Fetter and Walecka* (2003) and chapter 13 *Whitham* (1974) work through a number of examples, and in so doing they provide great practice in the mathematical physics of surface waves.

We use Cartesian coordinates throughout this chapter.

[1] Certain treatments of linear waves suggests that they affect a zero drift of matter. However, the Stokes drift by surface gravity waves provides an example where linear waves can transport matter. As noted in Section 52.11.5, the Lagrangian kinematics of particle trajectories introduces nonlinearites that lead to Stokes drift.

52.1 Loose threads

- Waves using Luke's variational principle as per *Miles* (1977) and *Milder* (1977).
- When can we naively use Eulerian coordinates for Hamilton's principle versus the introduction of auxiliary fields? I believe potential flow is quite forgiving on these matters.
- Build on the following ideas. Much more to think about here.

  Potential flow provides an example of a *scalar field theory*, which is distinctively less complex than the vector field theory encountered when the flow is less constrained. In particular, one need not worry about the Lagrangian approach, and can thus use Eulerian coordinates naively, much as done in other areas of field theory.

52.2 Potential flow in a homogeneous fluid layer

Throughout this chapter we assume the fluid is inviscid with constant density and with a flow that has zero vorticity.[2] These assumptions greatly simplify the expression for the velocity field, which is both non-divergent and irrotational. In this section we establish some general results for a perfect homogeneous fluid with a velocity that is non-divergent and irrotational; i.e., for *potential flow*.

We are concerned with a single layer of homogeneous fluid bounded below by a solid material surface and above by a free material surface, and refer to this layer as an "ocean". We depict the flat bottom case in Figure 52.1, showing the material free upper ocean surface at $z = \eta(x, y, t)$

[2] A more general approach can be considered in which the flow is decomposed into a potential flow (irrotational) and a vortical flow. However, for linear fluctuations these two flows are uncoupled. As we are unconcerned with vortical flow in this chapter, we set the vorticity to zero and thus focus on the potential flow.

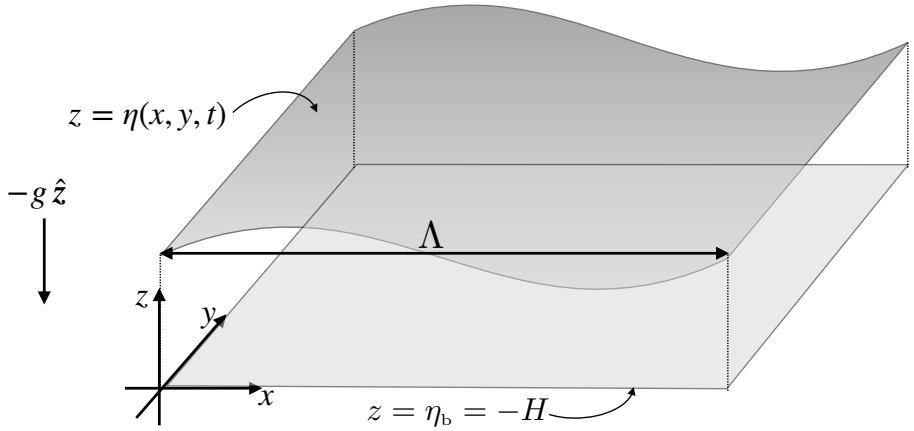

FIGURE 52.1: A depiction of an "ocean" comprised of a homogeneous (i.e., constant density) fluid with an upper free surface that is a moving material interface. The atmosphere applies a pressure to the ocean due to its mass; however, that mass is assumed to be uniform and static so that it does not affect surface motion. Linear fluctuations of the free surface exhibit gravity wave motion due to the restoring effects from a uniform gravitational field, $\boldsymbol{g} = -g\,\hat{\boldsymbol{z}}$, as well as capillary waves due to surface tension. We here depict a single wave with wavelength, Λ, with the wavevector parallel to the $\hat{\boldsymbol{x}}$ direction. We assume the fluid layer retains a fixed volume so that the domain integral of the free surface is constant, $\int \eta \, \mathrm{d}x \, \mathrm{d}y = \text{constant}$. This property follows from the assumption that the free surface is material.

separating a homogeneous ocean from a homogeneous atmosphere. The mass of the atmosphere is assumed to be horizontally uniform and static, even as its bottom boundary (the layer free surface) undulates. This approximation treatment means that atmospheric pressure does not contribute to motion of the ocean fluid layer. The ocean boundaries are material so that the mass of the ocean (equal to the ocean volume times the constant density, ρ) is fixed. Consequently, the domain integral of the free surface is constant,

$$\int \eta \, \mathrm{d}x \, \mathrm{d}y = \int \eta \, \mathrm{d}A = \text{constant}. \tag{52.1}$$

52.2.1 Motivating the irrotational assumption

We are familiar with the non-divergent flow assumption, which is part of the Boussinesq ocean studied in Chapter 29. However, we find it necessary to justify the assumption of irrotational flow, which also appeared in Chapter 51 when studying acoustic waves, and yet is not the case for most other geophysical waves encountered in this book. For this purpose, consider the equation of motion for a perfect non-rotating homogeneous fluid in a gravity field

$$\rho \, \mathrm{D}\boldsymbol{v}/\mathrm{D}t = -\nabla p - \rho \, \nabla \Phi, \tag{52.2}$$

where we assume the simple form of the geopotential (Section 13.10.4),

$$\Phi = g \, z, \tag{52.3}$$

with g the constant and uniform gravitational acceleration. As in our discussion of the Boussinesq ocean in Section 29.1.1, we remove the static background pressure by writing

$$p = -g \, \rho \, z + p_{\mathrm{d}} = -\rho \, \Phi + p_{\mathrm{d}}, \tag{52.4}$$

in which case the velocity equation (52.2) becomes

$$\rho \, \mathrm{D}\boldsymbol{v}/\mathrm{D}t = -\nabla p_{\mathrm{d}}. \tag{52.5}$$

When studying linear waves later in this chapter, this equation is linearized by dropping self-advection so that

$$\rho \, \partial_t \boldsymbol{v} = -\nabla p_{\mathrm{d}}. \tag{52.6}$$

The pressure gradient cannot impart any vorticity to the velocity time tendency since $\nabla \times \nabla p_{\mathrm{d}} = 0$. Evidently, if the velocity is initialized with zero vorticity, then the linearized equations of motion retain that zero vorticity. We thus examine linear fluctuations around a zero vorticity rest state, just as we did for the study of acoustic waves in Chapter 51.

This result offers motivation for studying properties of fluid flow with an irrotational velocity. In the remainder of this section we establish some general results for a perfect homogeneous fluid in non-rotating reference frame feeling a uniform gravity field and with an irrotational velocity. These results hold for the full nonlinear equations of motion and will later be specialized to the linear equations.

52.2.2 Harmonic scalar potential

A velocity field that has zero vorticity

$$\boldsymbol{\omega} = \nabla \times \boldsymbol{v} = 0, \tag{52.7}$$

can be written as the gradient of a scalar potential (see Section 2.3.2)[3]

$$\boldsymbol{v} = -\nabla \psi. \tag{52.8}$$

The scalar potential is unspecified up to an arbitrary function of time. The reason for this arbitrariness is that ψ and $\psi + F(t)$ yield the same velocity field, where $F(t)$ is any spatially constant function of time. We make use of this *gauge* degree of freedom in Section 52.2.3, just like we did for acoustic waves in Section 51.4.4.

Since the fluid is assumed to have uniform density, mass conservation in the form of the continuity equation (19.16) implies that the velocity field is non-divergent. Consequently, the scalar potential satisfies Laplace's equation (Section 2.3.3)

$$\nabla \cdot \boldsymbol{v} = -\nabla \cdot \nabla \psi = -\nabla^2 \psi = 0, \tag{52.9}$$

in which we say that ψ is a *harmonic function*. We develop salient mathematical properties for harmonic functions in Section 6.5.

Harmonic functions do not support spatial oscillations in all three directions since the sum of the curvature in each direction (i.e., second partial derivatives) must vanish. Correspondingly, we will find that the velocity potential supports traveling waves in the horizontal and exponentially decaying in the vertical, with decay when moving away from the surface boundary. It is remarkable that the wavenumber of the horizontally traveling waves also determines the vertical decay scale. That is, the structure of the horizontal waves directly determines the vertical structure.

52.2.3 Equation of motion and Bernoulli's principle

To fully specify the scalar potential requires boundary conditions, which enter the development via the equation of motion. The vector-invariant equation of motion (24.32) for a non-rotating,

[3] The minus sign in equation (52.8) is conventional.

irrotational, inviscid, uniform density fluid is given by

$$\partial_t \boldsymbol{v} = -\nabla(\Phi + \mathcal{K} + p/\rho), \tag{52.10}$$

with

$$\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v}/2 \tag{52.11}$$

the kinetic energy per mass of a fluid element. Inserting the scalar potential, $\boldsymbol{v} = -\nabla\psi$, brings the equation of motion (52.10) to the form

$$\nabla \left(\Phi + \mathcal{K} + p/\rho - \partial_t \psi\right) = 0. \tag{52.12}$$

This equation means that everywhere in the fluid the dynamical fields satisfy

$$\Phi + \mathcal{K} + p/\rho - \partial_t \psi = C(t), \tag{52.13}$$

for some arbitrary time dependent function, $C(t)$. This equation is a particular expression of Bernoulli's theorem studied in Section 26.9.3.

We ascribe no physical significance to the arbitrary function, $C(t)$, appearing in equation (52.13). In fact, it can be completely removed by exploiting the gauge degree of freedom in the scalar potential as noted following equation (52.8). We do so by introducing a modified scalar potential

$$\Psi(\boldsymbol{x}, t) = \psi(\boldsymbol{x}, t) + \int_0^t C(t')\, \mathrm{d}t'. \tag{52.14}$$

Both ψ and Ψ lead to the same velocity vector

$$\boldsymbol{v} = -\nabla\psi = -\nabla\Psi, \tag{52.15}$$

and as such the two scalar potentials are physically indistinguishable. However, Ψ is more convenient for our use since it absorbs the arbitrary time dependent function, $C(t)$, thus rendering the simpler expression for the equation of motion

$$\partial_t \Psi = \Phi + \mathcal{K} + p/\rho. \tag{52.16}$$

In this manner we have dispensed with the need to compute $C(t)$ since it is sufficient to work with Ψ. In the following, we refer to equation (52.16) as the *Bernoulli equation of motion.*

52.2.4 Concerning the pressure field

We here explore facets of the pressure field as decomposed into either its hydrostatic and non-hydrostatic components, or its dynamically active and inactive components.

Two methods for decomposing pressure

In Section 52.2.1 we decomposed the pressure into its dynamically inactive component, $-\rho\, g\, z$, and dynamically active component, p_{d}. We can consider the alternative decomposition into hydrostatic and non-hydrostatic pressure components. As we will see, the dynamically active pressure is partly hydrostatic, due to motion of the free surface, and partly non-hydrostatic. We also considered these two decompositions of pressure when discussing effective buoyancy in Section 30.11, yet the discussion here is far simpler since the fluid has constant density.

Hydrostatic and non-hydrostatic pressures

The Bernoulli equation of motion (52.16) yields the vertical derivative of pressure

$$\partial_z p = -\rho\,\partial_z\Phi + \rho\,\partial_z(\partial_t\Psi - \mathcal{K}) = \partial_z p_{\text{h}} + \partial_z p_{\text{nh}}. \tag{52.17}$$

We here identified two contributions to the pressure. The hydrostatic pressure satisfies

$$\partial_z p_{\text{h}} = -\rho\,\partial_z\Phi = -\rho\,g \Longrightarrow p_{\text{h}} = -\rho\,g\,(z-\eta) = -\rho\,\Phi + \rho\,g\,\eta. \tag{52.18}$$

This expression reveals that part of the hydrostatic pressure is the dynamically inactive pressure, $-\rho\,\Phi = -\rho\,g\,z$, as discussed in Section 52.2.1, plus a dynamically active portion due to undulations of the free surface. The non-hydrostatic pressure has a vertical derivative given by

$$\partial_z p_{\text{nh}} = \rho\,\partial_z(\partial_t\Psi - \mathcal{K}). \tag{52.19}$$

Note that plugging in the hydrostatic pressure (52.18) into the Bernoulli equation of motion (52.16) leads to

$$\partial_t\Psi = \mathcal{K} + g\,\eta + p_{\text{nh}}/\rho, \tag{52.20}$$

whose vertical derivative yields equation (52.19) (recall $\eta = \eta(x,y,t)$ is depth independent).

Equation (52.19) indicates that depth variations in the kinetic energy and depth-time variations in the velocity potential lead the pressure to deviate from locally hydrostatic. We do not generally expect the flow to be hydrostatically balanced for two reasons: (i) the fluid layer has a uniform density so there is no stratification to suppress vertical accelerations that contribute to non-hydrostatic pressures; (ii) the fluid is nonrotating and so there is no vertical stiffening via the Taylor-Proudman result (Section 31.5.3), with vertical stiffening acting to suppress vertical accelerations that cause deviations from hydrostatic balance. Casual observations of surface ocean waves also supports the nontrivial vertical accelerations present in surface gravity waves, thus suggesting a key role for the non-hydrostatic pressure.

Comments on a hydrostatic shallow water layer

For the shallow water model we also consider a homogenous density layer. However, as emphasized in Chapter 35, the hydrostatic balance is fundamental to shallow water dynamics. Indeed, in Section 35.2 we see that the hydrostatic balance over a single homogeneous layer leads to horizontal motion that is depth independent throughout the layer. Hence, $\partial_z(\partial_t\Psi) = 0$ and the kinetic energy contained in the horizontal flow is depth independent, $\partial_z(u^2+v^2) = 0$. Furthermore, the vertical motion has a linear depth dependence across the shallow water layer (Section 35.2.8) and its magnitude is far smaller than horizontal motions. Therfore, we can drop all contributions to $\partial_z\mathcal{K}$ for the shallow water layer, in which case equation (52.17) reduces to the hydrostatic limit

$$\partial_z p = -\rho\,\partial_z\Phi = -\rho\,g \qquad \text{hydrostatic (shallow water) limit.} \tag{52.21}$$

This limit is relevant when the horizontal scales of motion are far larger than the vertical: $L \gg H$, in which case the flow is well approximated as hydrostatic.

So in summary, a homogeneous layer of fluid can have a depth dependence to its horizontal flow, and that depth dependence is driven through non-hydrostatic pressure forces. In contrast, hydrostatic pressure has a depth-independent horizontal gradient within a homogeneous layer

$$\partial_z(\nabla_{\text{h}} p_{\text{h}}) = -g\,\nabla_{\text{h}}\rho = 0 \qquad \text{homogeneous density layer.} \tag{52.22}$$

Consequently, a hydrostatic pressure cannot drive depth dependence to the horizontal velocity

field in a homogeneous fluid.

52.2.5 Bernoulli equation of motion and boundary conditions

Decompositions of the pressure discussed in Sections 52.2.1 and 52.2.4 render the following equivalent expressions for the Bernoulli equation of motion

$$\partial_t \Psi = \mathcal{K} + g\, z + p/\rho \qquad \text{full pressure form} \tag{52.23a}$$
$$\partial_t \Psi = \mathcal{K} + p_{\mathsf{d}}/\rho \qquad \text{dynamically active/inactive pressure split} \tag{52.23b}$$
$$\partial_t \Psi = \mathcal{K} + g\, \eta + p_{\mathsf{nh}}/\rho \qquad \text{hydrostatic/non-hydrostatic pressure split.} \tag{52.23c}$$

With the velocity given by $\boldsymbol{v} = -\nabla\Psi$, we take the gradient of equations (52.23a)-(52.23c) to render the velocity equations

$$\partial_t \boldsymbol{v} = -\nabla(\mathcal{K} + g\, z + p/\rho) \qquad \text{full pressure form} \tag{52.24a}$$
$$\partial_t \boldsymbol{v} = -\nabla(\mathcal{K} + p_{\mathsf{d}}/\rho) \qquad \text{dynamically active/inactive pressure split} \tag{52.24b}$$
$$\partial_t \boldsymbol{v} = -\nabla(\mathcal{K} + g\, \eta + p_{\mathsf{nh}}/\rho) \qquad \text{hydrostatic/non-hydrostatic pressure split.} \tag{52.24c}$$

A complete specification of the mathematical physics for this system requires the kinematic and dynamic boundary conditions given by the following.

Kinematic free surface boundary condition

The free surface is a moving material interface, so that its kinematics are described by the surface kinematic boundary condition (19.66) holding for a non-divergent flow at a material boundary

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\eta = w \qquad \text{kinematic b.c. at } z = \eta(x, y, t). \tag{52.25}$$

When $\hat{\boldsymbol{n}}$ has a nonzero vertical component (always assumed to hold in this chapter), the surface kinematic boundary condition can be written in the equivalent form

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = \frac{\partial_t \eta}{|\nabla(z - \eta)|}, \tag{52.26}$$

where the outward normal is

$$\hat{\boldsymbol{n}} = \frac{\nabla(z - \eta)}{|\nabla(z - \eta)|} = \frac{\hat{\boldsymbol{z}} - \nabla\eta}{\sqrt{1 + \nabla\eta \cdot \nabla\eta}}. \tag{52.27}$$

It is furthermore convenient to make use of the relation between the area elements on the free surface given by equation (19.91)

$$\mathrm{d}\mathcal{S} = |\nabla(z - \eta)|\, \mathrm{d}A \quad \text{with} \quad \mathrm{d}A = \mathrm{d}x\, \mathrm{d}y, \tag{52.28}$$

where $\mathrm{d}A$ is the horizontal projection of $\mathrm{d}\mathcal{S}$. Consequently, we are led to the expression of the kinematic boundary condition

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \boldsymbol{v} \cdot \nabla(z - \eta)\, \mathrm{d}A = \partial_t \eta\, \mathrm{d}A. \tag{52.29}$$

Dynamic free surface boundary condition

At the ocean free surface we assume zero atmospheric pressure,[4] in which case the ocean pressure must also vanish there. We are thus led to the following pressure boundary conditions

$$p = 0 \quad \text{and} \quad p_{\mathsf{d}} = g\,\eta\,\rho \quad \text{and} \quad p_{\mathsf{nh}} = 0 \quad \text{at } z = \eta, \tag{52.30}$$

each of which leads to the surface boundary condition for the velocity potential

$$\partial_t \Psi = \mathcal{K} + g\,\eta \quad \text{at } z = \eta. \tag{52.31}$$

Kinematic bottom boundary condition

The bottom is a rigid material surface so that the bottom kinematic boundary condition (Section 19.6.1) is the no-normal flow condition

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{v} = -\nabla\Psi \cdot \hat{\boldsymbol{n}} = 0 \quad \text{at } z = \eta_{\mathsf{b}}(x, y). \tag{52.32}$$

When studying surface waves later in this chapter, we only consider the flat bottom ($\hat{\boldsymbol{n}} = -\hat{\boldsymbol{z}}$), in which case $w = 0$ at the bottom

$$w = -\partial_z \Psi = 0 \quad \text{at } z = \eta_{\mathsf{b}} = -H. \tag{52.33}$$

Dynamic bottom boundary condition

To develop the pressure boundary condition at the bottom, recall that a static material bottom has a static outward normal, $\hat{\boldsymbol{n}}$, so that

$$\hat{\boldsymbol{n}} \cdot \partial_t \boldsymbol{v} = \partial_t(\hat{\boldsymbol{n}} \cdot \boldsymbol{v}) = 0, \tag{52.34}$$

which then brings equations (52.24a)-(52.24c) to the form

$$\hat{\boldsymbol{n}} \cdot \nabla\mathcal{K} = -\hat{\boldsymbol{n}} \cdot \nabla(g\,z + p/\rho) \tag{52.35a}$$
$$\hat{\boldsymbol{n}} \cdot \nabla\mathcal{K} = -\hat{\boldsymbol{n}} \cdot \nabla p_{\mathsf{d}}/\rho \tag{52.35b}$$
$$\hat{\boldsymbol{n}} \cdot \nabla\mathcal{K} = -\hat{\boldsymbol{n}} \cdot \nabla(g\,\eta + p_{\mathsf{nh}}/\rho). \tag{52.35c}$$

Specializing to the flat bottom with $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{z}}$ yields the bottom boundary conditions

$$\partial_z\mathcal{K} = -g - \rho^{-1}\,\partial_z p \tag{52.36a}$$
$$\partial_z\mathcal{K} = -\rho^{-1}\,\partial_z p_{\mathsf{d}} \tag{52.36b}$$
$$\partial_z\mathcal{K} = -\rho^{-1}\,\partial_z p_{\mathsf{nh}}, \tag{52.36c}$$

where $\partial_z\eta = 0$. In the linearized theory, $\partial_z\mathcal{K}$ is far smaller than g or $\rho^{-1}\,\partial_z p$, which means that the balance in equation (52.36a) must be hydrostatic, $\partial_z p = -\rho\,g$. This result then means that the non-hydrostatic boundary condition is $\partial_z p_{\mathsf{nh}} = 0$. Likewise, with $p = -\rho\,g\,z + p_{\mathsf{d}}$, and $\partial_z p = -\rho\,g$ at the bottom, we must have $\partial_z p_{\mathsf{nh}} = 0$. These results are thus summarized as

$$\partial_z p = -g\,\rho \quad \text{and} \quad \partial_z p_{\mathsf{d}} = 0 \quad \text{and} \quad \partial_z p_{\mathsf{nh}} = 0 \quad \text{at } z = \eta_{\mathsf{b}} = -H. \tag{52.37}$$

[4] In Section 52.3.2 we show that a uniform and constant atmospheric pressure plays no role in the physics of concern here since the fluid density is itself a uniform constant.

Comments on the need for two boundary conditions

Mathematically, the solution to Laplace's equation requires only a single boundary condition when posed in a domain with specified boundaries (e.g., see Section 6.5). For the current setup, however, the free surface is a moving boundary, thus offering one more dynamical degree of freedom that necessitates an extra boundary condition. Physically, there are two dynamical fields that describe the fluid layer, the velocity potential, Ψ, and the free surface height, η. Consequently, there are two boundary conditions that arise when specifying these fields: one from kinematics (the boundary interfaces are material) and one from dynamics (forces on both sides of the boundary interfaces must balance as per Newton's third law).

52.2.6 Local energetic balances

Since the fluid has a constant density, the only energy arises from mechanical energy due to motion (kinetic energy) plus the gravity field (gravitational potential energy)

$$\mathcal{E} = \mathcal{K} + \Phi = \boldsymbol{v} \cdot \boldsymbol{v}/2 + g\, z. \tag{52.38}$$

The internal energy is a constant and so plays no role in the energetic analysis. Also, we ignore dissipation and heat transfer so that energy is modified only through reversible processes. Local energetic budget equations are readily computed by taking the scalar product of the velocity with the velocity tendency. We consider here the three forms of the velocity equation (52.24a)-(52.23c) and their corresponding energy equations.

Velocity equation with unsplit pressure

With $\partial_t \boldsymbol{v}$ written in the form of equation (52.24a) we have

$$\partial_t \mathcal{K} = -\boldsymbol{v} \cdot \nabla(\mathcal{K} + \Phi + p/\rho) = -\nabla \cdot [\boldsymbol{v}\,(\mathcal{K} + \Phi + p/\rho)], \tag{52.39}$$

where we used $\nabla \cdot \boldsymbol{v} = 0$ for the second equality. Since the geopotential has a zero Eulerian time derivative, the kinetic energy equation readily leads to the total mechanical energy equation

$$\partial_t \mathcal{E} = -\nabla \cdot [\boldsymbol{v}\,(\mathcal{E} + p/\rho)] \Longrightarrow \rho\, \mathrm{D}\mathcal{E}/\mathrm{D}t = -\nabla \cdot (\boldsymbol{v}\, p). \tag{52.40}$$

Evidently, convergence of the pressure flux, $\boldsymbol{v}\, p$, leads to a material time change in the total energy.

Dynamically active/inactive pressure split

An equivalent form of the energy equation can be found by making use of the pressure split into dynamically active and inactive components according to the velocity equation (52.24b), which yields

$$\partial_t \mathcal{K} = -\nabla \cdot [\boldsymbol{v}\,(\mathcal{K} + p_{\mathsf{d}}/\rho)] \Longrightarrow \rho\, \mathrm{D}\mathcal{K}/\mathrm{D}t = -\nabla \cdot (\boldsymbol{v}\, p_{\mathsf{d}}). \tag{52.41}$$

We here find that convergence of the dynamic pressure flux, $\boldsymbol{v}\, p_{\mathsf{d}}$, leads to a material time change in the kinetic energy.

Hydrostatic/non-hydrostatic pressure split

We now develop the energetics with the hydrostatic/non-hydrostatic pressure decomposition (52.23c) to render

$$\partial_t \mathcal{K} = -\nabla \cdot [\boldsymbol{v}\,(\mathcal{K} + g\,\eta + p_{\mathsf{nh}}/\rho)]. \tag{52.42}$$

This form only lends itself to a total energy budget written in the form

$$\partial_t \mathcal{E} = -\nabla \cdot [\boldsymbol{v}\,(\mathcal{E} + p/\rho)] \Longrightarrow \rho\, \mathrm{D}\mathcal{E}/\mathrm{D}t = -\nabla \cdot [\boldsymbol{v}\,(p_{\mathsf{h}} + p_{\mathsf{nh}})]. \tag{52.43}$$

52.2.7 Expressions for the globally integrated kinetic energy

The kinetic energy per mass can be written in terms of the scalar potential

$$2\,\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v} = \nabla\Psi \cdot \nabla\Psi = \nabla \cdot (\Psi\, \nabla\Psi), \tag{52.44}$$

where we used $\nabla^2\Psi = 0$ for the final equality. This divergence form of the kinetic energy means that its global integral is fully determined by properties at the boundaries.

Domain integrated kinetic energy is just due to surface properties

Integration of the kinetic energy in the form of equation (52.44) over the full ocean domain, $\mathcal{R}$, leads to the total kinetic energy

$$E_{\mathrm{KE}} = \int_{\mathcal{R}} \rho\, \mathcal{K}\, \mathrm{d}V = \frac{\rho}{2} \int_{\mathcal{R}} \nabla \cdot (\Psi\, \nabla\Psi)\, \mathrm{d}V = \frac{\rho}{2} \int_{\partial\mathcal{R}} \Psi\, \nabla\Psi \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{52.45}$$

where we made use of the divergence theorem. The ocean bottom is material so that the flow satisfies the no-normal flow condition at each point along the bottom (Section 19.6.1)

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = -\nabla\Psi \cdot \hat{\boldsymbol{n}} = 0, \tag{52.46}$$

where $\hat{\boldsymbol{n}}$ is the outward normal on the rigid material boundaries. Lateral boundaries are either periodic or rigid material walls. We thus find the remarkable result that the domain integrated kinetic energy arises solely from properties integrated over the free surface

$$E_{\mathrm{KE}} = \frac{\rho}{2} \int_{z=\eta} \Psi\, \nabla\Psi \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = -\frac{\rho}{2} \int_{z=\eta} \Psi\, \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{52.47}$$

Evidently, contributions from interior motion play no role in the domain integrated kinetic energy. Furthermore, the kinetic energy is a non-negative number, so that the right hand side of equation (52.47) is non-negative although it is not obvious without noting that Ψ is a harmonic function in the domain interior. That is, the nature of the kinetic energy is fundamentally related to the harmonic nature of the velocity potential that allows the kinetic energy to be written as the total divergence in equation (52.44). We encountered a similar feature of harmonic functions in Section 6.5.2 when studying their mean-value property.

Gauge invariance of the domain integrated kinetic energy

The kinetic energy per mass, $\mathcal{K} = \nabla\Psi \cdot \nabla\Psi/2$, is manifestly gauge invariant since it remains unchanged if Ψ is shifted by a spatial constant. This property also holds for the domain integrated kinetic energy, (52.47), as follows from use of the divergence theorem and then the non-divergence of the velocity field

$$\int_{z=\eta} \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\partial\mathcal{R}} \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \nabla \cdot \boldsymbol{v}\, \mathrm{d}V = 0. \tag{52.48}$$

Evidently, if the scalar potential is shifted by a function of time that is spatially independent, then the globally integrated kinetic energy (52.47) remains unchanged and so is gauge invariant. An alternative derivation makes use of the surface kinematic boundary condition (52.29) that

leads to the identity

$$\int_{z=\eta} \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, d\mathcal{S} = \int \partial_t \eta \, dA = - \int \nabla \cdot \boldsymbol{U} \, dA = 0, \tag{52.49}$$

where we set $\partial_t \eta = -\nabla \cdot \boldsymbol{U}$ as per the free surface equation (21.81) holding for a volume conserving fluid, with $\boldsymbol{U} = \int_{-H}^{\eta} \boldsymbol{u} \, dz$ the depth integrated horizontal velocity.[5]

Kinetic energy in terms of time tendencies

We write yet another form for the domain integrated kinetic energy, which proves of use when studying Hamilton's principle in Section 52.2.9. For this purpose, make use of the free surface kinematic boundary condition (52.29) to bring the kinetic energy equation (52.47) into the form

$$E_{\text{KE}} = -\frac{\rho}{2} \int_{z=\eta} \Psi \, \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, d\mathcal{S} = -\frac{\rho}{2} \int_{z=\eta} \Psi \, \partial_t \eta \, dA. \tag{52.50}$$

Now reintroduce the vertical integral via Leibniz's rule (Section 20.2.4) to write

$$\int_{z=\eta} \Psi \, \partial_t \eta \, dA = \int \left[\frac{\partial}{\partial t} \int_{\eta_b}^{\eta} \Psi \, dz \right] dA - \int \left[\int_{\eta_b}^{\eta} \partial_t \Psi \, dz \right] dA. \tag{52.51}$$

If the horizontal extent of the domain has a static extent, such as when the horizontal domain is periodic or it is bounded by rigid vertical walls (e.g., see Figure 28.6), then the time derivative commutes with the area integral so that equation (52.51) becomes

$$\int_{z=\eta} \Psi \, \partial_t \eta \, dA = \frac{d}{dt} \left[\int \int_{\eta_b}^{\eta} \Psi \, dz \, dA \right] - \int \int_{\eta_b}^{\eta} \partial_t \Psi \, dz \, dA = \frac{d}{dt} \int \Psi \, dV - \int \partial_t \Psi \, dV. \tag{52.52}$$

We make use of this identity in the discussion of Hamilton's principle in Section 52.2.9.

52.2.8 Kelvin's minimum kinetic energy theorem

The domain integrated kinetic energy equation (52.47) points to the central role of boundary conditions. We here expose a property of the kinetic energy associated with *Kelvin's minimum kinetic energy theorem*.

Basic formulation

Following Kelvin (as detailed in Section 45 of *Lamb* (1993)), consider a non-divergent flow, $\boldsymbol{v}^{\text{tot}}$, built from the sum of an irrotational and non-divergent velocity field (i.e., potential flow), $\boldsymbol{v}$, plus a non-divergent and rotational flow, $\boldsymbol{v}_{\text{r}}$

$$\boldsymbol{v}_{\text{tot}} = \boldsymbol{v} + \boldsymbol{v}_{\text{r}} \quad \text{with} \quad \nabla \cdot \boldsymbol{v} = \nabla \cdot \boldsymbol{v}_{\text{r}} = 0 \quad \text{and} \quad \nabla \times \boldsymbol{v}_{\text{tot}} = \nabla \times \boldsymbol{v}_{\text{r}}. \tag{52.53}$$

The domain integrated kinetic energy of this flow,

$$E^{\text{tot}}_{\text{KE}} = \frac{\rho}{2} \int_{\mathcal{R}} \boldsymbol{v}_{\text{tot}} \cdot \boldsymbol{v}_{\text{tot}} \, dV, \tag{52.54}$$

has three terms

$$E^{\text{tot}}_{\text{KE}} = \frac{\rho}{2} \int_{\mathcal{R}} \boldsymbol{v} \cdot \boldsymbol{v} \, dV + \frac{\rho}{2} \int_{\mathcal{R}} \boldsymbol{v}_{\text{r}} \cdot \boldsymbol{v}_{\text{r}} \, dV + \rho \int_{\mathcal{R}} \boldsymbol{v} \cdot \boldsymbol{v}_{\text{r}} \, dV. \tag{52.55}$$

[5] See also Exercise 21.10.

The domain integrated kinetic energy for the irrotational flow equals to the boundary integral from equation (52.47)

$$\frac{\rho}{2}\int_{\mathcal{R}} \boldsymbol{v}\cdot\boldsymbol{v}\,\mathrm{d}V = -\frac{\rho}{2}\int_{\partial\mathcal{R}} \Psi\,\boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{52.56}$$

The cross-term also takes the form of a boundary integral

$$\int_{\mathcal{R}} \boldsymbol{v}\cdot\boldsymbol{v}_{\mathrm{r}}\,\mathrm{d}V = -\int_{\mathcal{R}} \nabla\Psi\cdot\boldsymbol{v}_{\mathrm{r}}\,\mathrm{d}V = -\int_{\mathcal{R}} \nabla\cdot(\Psi\,\boldsymbol{v}_{\mathrm{r}})\,\mathrm{d}V = -\int_{\partial\mathcal{R}} \Psi\,\boldsymbol{v}_{\mathrm{r}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{52.57}$$

so that the domain integrated kinetic energy is

$$E^{\mathrm{tot}}_{\mathrm{KE}} = \frac{\rho}{2}\int_{\mathcal{R}} (\boldsymbol{v}_{\mathrm{r}}\cdot\boldsymbol{v}_{\mathrm{r}} + \boldsymbol{v}\cdot\boldsymbol{v})\,\mathrm{d}V - \rho\int_{\partial\mathcal{R}} \Psi\,\boldsymbol{v}_{\mathrm{r}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{52.58a}$$

$$= \frac{\rho}{2}\int_{\mathcal{R}} \boldsymbol{v}_{\mathrm{r}}\cdot\boldsymbol{v}_{\mathrm{r}}\,\mathrm{d}V - \frac{\rho}{2}\int_{\partial\mathcal{R}} \Psi\,(\boldsymbol{v}+2\,\boldsymbol{v}_{\mathrm{r}})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{52.58b}$$

Kelvin's minimum kinetic energy theorem

Consider the case where the flow is irrotational and so it satisfies the boundary conditions appropriate for potential flow in a homogeneous fluid layer with a free surface

$$\boldsymbol{v}\cdot\hat{\boldsymbol{n}} = 0 \qquad \text{at solid bottom boundary, } z=\eta_{\mathrm{b}}(x,y) \tag{52.59a}$$

$$\boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \partial_t\eta\,\mathrm{d}A \quad \text{at free surface boundary, } z=\eta(x,y,t). \tag{52.59b}$$

The free surface condition (52.59b) arises from equation (52.26) as well as the area relation in equation (52.28). Now add a rotational flow, and assume the rotational flow leaves the potential flow's boundary conditions (52.59a) and (52.59b) unaffected, which can be ensured if the rotational flow satisfies the no-normal flow condition at all boundaries

$$\boldsymbol{v}_{\mathrm{r}}\cdot\hat{\boldsymbol{n}} = 0 \quad \boldsymbol{x}\in\partial\mathcal{R}. \tag{52.60}$$

Kelvin's minimum kinetic energy theorem follows from equation (52.58a) with $\boldsymbol{v}_{\mathrm{r}}\cdot\hat{\boldsymbol{n}}=0$, in which case

$$E^{\mathrm{tot}}_{\mathrm{KE}} = \frac{\rho}{2}\int_{\mathcal{R}} (\boldsymbol{v}\cdot\boldsymbol{v} + \boldsymbol{v}_{\mathrm{r}}\cdot\boldsymbol{v}_{\mathrm{r}})\,\mathrm{d}V, \tag{52.61}$$

so that kinetic energy of the pure irrotational flow is less than that for the flow based on the same irrotational flow plus a rotational perturbation. Evidently, the irrotational flow minimizes the kinetic energy for the simply connected material domain.

In formulating the theorem (52.61), we considered the rotational component to the flow as a perturbation to the original irrotational flow, with the perturbation not altering the boundary conditions satisfied by the irrotational flow. In this manner, the rotational flow is akin to a variation added to the irrotational flow in the sense used for Hamilton's principle (e.g., Sections 46.2 and 52.2.9), in which variations do not touch boundary (or initial) conditions.

Material boundary condition for $\boldsymbol{v}_r + \boldsymbol{v}$

Now consider the material boundary conditions at the bottom and surface to be satisfied by the full flow

$$(\boldsymbol{v}+\boldsymbol{v}_{\mathrm{r}})\cdot\hat{\boldsymbol{n}} = 0 \qquad \text{at solid bottom boundary, } z=\eta_{\mathrm{b}}(x,y) \tag{52.62a}$$

$$(\boldsymbol{v}+\boldsymbol{v}_{\mathrm{r}})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \partial_t\eta\,\mathrm{d}A \quad \text{at free surface boundary, } z=\eta(x,y,t), \tag{52.62b}$$

so that these boundary conditions couple the rotational and irrotational components. The kinetic energy equation (52.58b) now takes the form

$$E^{\text{tot}}_{\text{KE}} = \frac{\rho}{2}\int_{\mathscr{R}} \boldsymbol{v}_{\text{r}}\cdot\boldsymbol{v}_{\text{r}}\,\text{d}V - \frac{\rho}{2}\int_{z=\eta}\Psi\,\partial_t\eta\,\text{d}A - \frac{\rho}{2}\int_{\partial\mathscr{R}}\Psi\,\boldsymbol{v}_{\text{r}}\cdot\hat{\boldsymbol{n}}\,\text{d}\mathcal{S} \tag{52.63a}$$

$$= \frac{\rho}{2}\int_{\mathscr{R}}(\boldsymbol{v}_{\text{r}}\cdot\boldsymbol{v}_{\text{r}} - \boldsymbol{v}\cdot\boldsymbol{v})\,\text{d}V - \rho\int_{z=\eta}\Psi\,\partial_t\eta\,\text{d}A \tag{52.63b}$$

For a rigid material upper boundary, so that $\partial_t\eta = 0$, the domain integrated kinetic energy in the irrotational flow is less than that in the rotational flow. Any further general statements are unavailable for the case with a time dependent free surface. The absence of a general theorem can be traced to coupling between the rotational and irrotational flow as realized via the boundary conditions. This situation contrasts to the case of Kelvin's minimum kinetic energy theorem, where there we purposely disabled any coupling.

52.2.9 Hamilton's principle and Luke's variational principle

Following the discussion of classical field theory in Chapter 46, we here consider the Lagrangian density functional and the corresponding equations of motion that follow from *Hamilton's principle*. The special nature of the dynamical free surface boundary condition prompts a modified version of the action that allows for a treatment of both the interior potential flow and the nonlinear surface boundary conditions. This modification is due to *Luke* (1967), prompting the name *Luke's variational principle*.[6]

Conventional form of the Lagrangian density

The Lagrangian density (dimensions of energy per unit volume) is the kinetic energy per volume minus the gravitational potential energy per volume, which takes the following form for potential flow of a homogeneous fluid layer

$$\mathscr{L} = \rho\,(\boldsymbol{v}\cdot\boldsymbol{v}/2 - g\,z) = \rho\,(\nabla\Psi\cdot\nabla\Psi - g\,z)/2. \tag{52.64}$$

The corresponding action is

$$\mathcal{S} = \int_R \mathscr{L}\,\text{d}V\,\text{d}t, \tag{52.65}$$

where R is the space-time domain. Hamilton's principle says that variation of the action vanishes for the physically realized fields

$$\delta\mathcal{S} = \int_R \delta\mathscr{L}\,\text{d}V\,\text{d}t = 0, \tag{52.66}$$

where the variation operator, δ, does not touch space or time and so it commutes with integrals and derivatives (see Sections 46.2.2 and 46.2.3).

The puzzle we have, however, is that the free surface does not explicitly appear in the Lagrangian (52.64). Rather, it only appears as a boundary in the action integral (52.66). That is not a problem *per se*, but the problem is that varying the action using the Lagrangian (52.64) fails to produce the dynamical boundary condition at the free surface. To resolve this puzzle we follow *Luke* (1967) by transforming the action into a modified form that differs from the original action by a time derivative which, as shown in Section 46.3.5, does not alter the mechanics.

[6] Elements of this section follow from *Luke* (1967), Section 13.2 of *Whitham* (1974), and Exercise 10.14 of *Fetter and Walecka* (2003). See also *Miles* (1977) and *Milder* (1977).

Furthermore, the appropriate action turns out to be, quite remarkably, the space-time integral of the pressure.

Surface Lagrangian density

Before considering the approach of *Luke* (1967), observe that the Lagrangian density (52.64) can be written

$$\rho^{-1} \int_{\mathcal{R}} \mathcal{L} \, \mathrm{d}V = \int_{\mathcal{R}} (\boldsymbol{v} \cdot \boldsymbol{v}/2 - g\, z) \, \mathrm{d}V = -\frac{1}{2} \int [\Psi_{\mathrm{s}} \, \partial_t \eta + g \, (\eta^2 - \eta_{\mathrm{b}}^2)] \, \mathrm{d}A, \tag{52.67}$$

where we made use of the kinematic boundary conditions (52.59a) and (52.59b), in which case the action is

$$\mathsf{S} = -\frac{\rho}{2} \int [\Psi_{\mathrm{s}} \, \partial_t \eta + g \, (\eta^2 - \eta_{\mathrm{b}}^2)] \, \mathrm{d}A \, \mathrm{d}t \equiv \int \mathcal{L}_{\mathrm{s}} \, \mathrm{d}A \, \mathrm{d}t. \tag{52.68}$$

In this equation we introduced the velocity potential evaluated at the free surface

$$\Psi_{\mathrm{s}} = \Psi(x, y, z = \eta, t), \tag{52.69}$$

and the surface Lagrangian density (dimensions of energy per unit area)

$$\mathcal{L}_{\mathrm{s}} = -\rho [\Psi_{\mathrm{s}} \, \partial_t \eta + g \, (\eta^2 - \eta_{\mathrm{b}}^2)]/2. \tag{52.70}$$

This Lagrangian forms the starting point for *Milder* (1977).

Transforming the action into the integral of pressure

We transform the action through use of equation (52.52) for the kinetic energy, in which

$$\int \left[\int \nabla \Psi \cdot \nabla \Psi \, \mathrm{d}V \right] \mathrm{d}t = - \int \left[\int [\Psi \, \partial_t \eta]_{z=\eta} \, \mathrm{d}A \right] \mathrm{d}t \tag{52.71a}$$

$$= - \int \left[\frac{\partial}{\partial t} \int \Psi \, \mathrm{d}V \right] \mathrm{d}t + \int \partial_t \Psi \, \mathrm{d}V \, \mathrm{d}t. \tag{52.71b}$$

As noted in deriving equation (52.52), we assumed here that the horizontal bounds for the domain are static. For the more general case of sloping side boundaries (e.g., see Figure 28.6), then we need to introduce yet another dynamical field, namely the moving horizontal bounds. That added dynamical degree of freedom is not the focus here, so that we assume the domain has static horizontal boundaries, thus allowing the time derivative to commute with the area integral.

Use of equation (52.71b) brings the action to the form

$$\mathcal{S} = -\frac{\rho}{2} \int \left[\frac{\partial}{\partial t} \int \Psi \, \mathrm{d}V \right] \mathrm{d}t + \rho \int \left[\frac{1}{2} \frac{\partial \Psi}{\partial t} - g\, z \right] \mathrm{d}V \, \mathrm{d}t. \tag{52.72}$$

Following the discussion in Section 46.3.5, the first term on the right hand side is mechanically irrelevant since it evaluates to the time bounds, during which the velocity potential has zero variation. We can thus drop the first right hand side term in equation (52.72) to focus on the modified action

$$\mathcal{S}^{\mathrm{mod}} = \rho \int \left[\frac{1}{2} \frac{\partial \Psi}{\partial t} - g\, z \right] \mathrm{d}V \, \mathrm{d}t. \tag{52.73}$$

Making use again of equation (52.52) along with the mechanical equivalence (52.72) gives

$$\mathcal{S}^{\text{Luke}} = \rho \int \left[\frac{\partial \Psi}{\partial t} - \frac{1}{2} \frac{\partial \Psi}{\partial t} - g\, z \right] \mathrm{d}V\, \mathrm{d}t = \rho \int \left[\frac{\partial \Psi}{\partial t} - \frac{1}{2} \nabla \Psi \cdot \nabla \Psi - g\, z \right] \mathrm{d}V\, \mathrm{d}t. \tag{52.74}$$

Variation of the action with respect to η

Exposing the vertical integration limits on the action (52.74) yields

$$\mathsf{S}^{\text{Luke}} = \rho \int \int \int_{\eta_{\mathsf{b}}}^{\eta} \left[\frac{\partial \Psi}{\partial t} - \frac{1}{2} \nabla \Psi \cdot \nabla \Psi - g\, z \right] \mathrm{d}z\, \mathrm{d}A\, \mathrm{d}t, \tag{52.75}$$

so that the variation arising from $\delta\eta$ is straightforward to compute. In so doing we find

$$\frac{\delta \mathcal{S}^{\text{Luke}}}{\delta \eta} = 0 \Longrightarrow \partial_t \Psi = \frac{1}{2} \nabla \Psi \cdot \nabla \Psi + g\, \eta \quad \text{at } z = \eta, \tag{52.76}$$

which is the dynamic boundary condition (52.31).

Variation of the action with respect to Ψ

Variation of the action with respect to the velocity potential leads to

$$\delta_\Psi \mathcal{S}^{\text{Luke}} = \frac{\rho}{2} \int \partial_t(\delta \Psi)\, \mathrm{d}V\, \mathrm{d}t - \rho \int \delta \Psi\, \nabla \Psi \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}\, \mathrm{d}t + \rho \int \nabla^2 \Psi\, \delta \Psi\, \mathrm{d}V\, \mathrm{d}t, \tag{52.77}$$

where we noted that $\delta(\partial_t \Psi) = \partial_t(\delta \Psi)$, and integrated by parts to get the second and third terms on the right hand side. For the time derivative term we write

$$\int \partial_t(\delta \Psi)\, \mathrm{d}V = \int \left[\int_{\eta_{\mathsf{b}}}^{\eta} \partial_t(\delta \Psi)\, \mathrm{d}z \right] \mathrm{d}A = \int \left[\frac{\partial}{\partial t} \int_{\eta_{\mathsf{b}}}^{\eta} \delta \Psi\, \mathrm{d}z - \partial_t \eta\, \delta \Psi_{\mathrm{s}} \right] \mathrm{d}A, \tag{52.78}$$

whereas the kinematic boundary conditions (equations (52.59a) and (52.59b)) bring the spatial boundary term to

$$- \int \delta \Psi\, \nabla \Psi \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int \partial_t \eta\, \delta \Psi_{\mathrm{s}}\, \mathrm{d}A, \tag{52.79}$$

thus leading to the action variation

$$\delta_\Psi \mathcal{S}^{\text{Luke}} = \int \nabla^2 \Psi\, \delta \Psi\, \mathrm{d}V\, \mathrm{d}t. \tag{52.80}$$

The action variation vanishes so long as $\nabla^2 \Psi = 0$ within the fluid domain. Bringing everything together leads to the boundary value problem for the velocity potential and the free surface

$$\nabla^2 \Psi = 0 \qquad \boldsymbol{x} \in \mathcal{R} \tag{52.81a}$$

$$\hat{\boldsymbol{n}} \cdot \nabla \Psi = 0 \qquad \boldsymbol{x} \in \partial \mathcal{R} \text{ kinematic rigid condition} \tag{52.81b}$$

$$(\nabla \eta - \hat{\boldsymbol{z}}) \cdot \nabla \Psi = \partial_t \eta \qquad z = \eta \text{ kinematic free surface condition} \tag{52.81c}$$

$$\partial_t \Psi = \frac{1}{2} \nabla \Psi \cdot \nabla \Psi + g\, \eta \qquad z = \eta \text{ dynamic free surface condition.} \tag{52.81d}$$

Comments

Remarkably, the Bernoulli equation of motion (52.16) means that the Lagrangian functional appearing in the action (52.74) equals to the pressure

$$\mathcal{S}^{\text{Luke}} = \rho \int \left[\frac{\partial \Psi}{\partial t} - \frac{1}{2} \nabla \Psi \cdot \nabla \Psi - g\, z \right] \mathrm{d}V\, \mathrm{d}t = \int p\, \mathrm{d}V\, \mathrm{d}t. \tag{52.82}$$

Starting from this form of the action, Hamilton's principle extremizes the space-time integral of the pressure. *Seliger and Whitham* (1968) provide some discussion of pressure as the action within the context of the Boussinesq approximation, where the same result holds.

A free surface certainly adds subtleties to the use of Hamilton's principle. The presentation given in this subsection proceeds in the opposite order to that given by *Luke* (1967) as well as section 13.2 of *Whitham* (1974). Here, we started with the conventional form of the Lagrangian (52.64) written as the difference between kinetic energy and potential energy, and then showed how to transform the action into the pressure action integral (52.82) that captures the dynamical boundary condition. In that transformation we made use of the kinematic boundary conditions at both the static bottom boundary (equation (52.59a)) and the free surface (equation (52.59b)). The alternative approach taken by *Luke* (1967) starts from the inspired guess of a pressure based action integral (52.82), and shows that it indeed produces the proper dynamical equations so long as the kinematic boundary conditions are satisfied. The present approach is thus offered as a complement to that from *Luke* (1967) and *Whitham* (1974)

52.3 Linearized dynamics

We here develop the boundary value problem describing linear surface gravity wave motions of the free surface, and characterize physical aspects of the waves. Surface tension is ignored so that pressure is continuous across the free surface. In Section 52.10 we remove this assumption by considering the pressure jump at the ocean surface due to surface tension, with this pressure jump leading to capillary waves. The fundamental parameter measuring nonlinearity concerns the ratio of the free surface undulation to the length of a wave disturbance. A small value for this non-dimensional ratio allows us to confidently make use of the linear equations.

Note that we focus on the velocity potential in our analysis of linear surface gravity waves. A directly analogous approach focuses on the dynamic pressure, p_{d}, which is a harmonic function for the linearized system (take the divergence of the linearized velocity equation (52.6)). Section 7.1 of *Vallis* (2017) takes the pressure approach. The two methods are equivalent, with the velocity potential and pressure closely connected.

52.3.1 Linear relations between the velocity potential and pressure

The Bernoulli equations of motion (52.23a)-(52.23c) provide an expression for the time tendency of the velocity potential. When linearizing the equations we drop the contribution from the kinetic energy since it is second order in the velocity field.[7] We are thus led to the linear relations

$$\partial_t \Psi = g\, z + p/\rho = p_{\text{d}}/\rho = g\, \eta + p_{\text{nh}}/\rho. \tag{52.83}$$

This equation provides the linearized relation between the velocity potential and the various pressure fields.

[7] We do *not* drop kinetic energy when studying the energetics of linear waves. But here we are studying their momentum, in which we linearize by dropping all second and higher order terms.

52.3.2 Dynamic boundary condition at the free surface

The equation of motion (52.16) applies to any point within the fluid and at any time. In particular, it applies at the free surface, $z = \eta(x, y, t)$, where pressure equals to the atmospheric pressure. As stated earlier, we assume that the atmospheric pressure is constant in space and time so that

$$g\,\eta + \mathcal{K} - \partial_t \Psi = -p_a/\rho = \text{constant}. \tag{52.84}$$

Without loss of generality we can set this constant to zero,[8] thus leaving the boundary condition

$$g\,\eta + \mathcal{K} - \partial_t \Psi = 0 \qquad \text{linearized dynamic b.c. at } z = \eta. \tag{52.85}$$

We now linearize relative to a state of rest with $\eta = 0$, $\boldsymbol{v} = 0$, and $\partial_t \Psi = 0$. Linear fluctuations about this rest state have small velocities. Consequently, the kinetic energy, which is second order in velocity, is small relative to the remaining terms and so we arrive at the linearized dynamic boundary condition

$$g\,\eta = \partial_t \Psi \qquad \text{linearized dynamic b.c. at } z = \eta. \tag{52.86}$$

This boundary condition directly connects the free surface to time tendencies of the velocity potential. The free surface fluctuates upward when the velocity potential has a positive tendency, and vice versa. Also note that we arrive at this boundary condition by making use of the pressure boundary conditions (52.30) within equation (52.83).

52.3.3 Kinematic boundary conditions

The free surface is assumed to be a material interface, meaning that there is no matter transported across this surface. Consequently, following the discussion of kinematic boundary conditions in Section 19.6.2, we have

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\eta = w \qquad \text{kinematic b.c. at } z = \eta. \tag{52.87}$$

Linearizing this boundary condition about the state of rest, and introducing the scalar potential, leads to

$$\partial_t \eta = w = -\partial_z \Psi \qquad \text{linearized kinematic b.c. at } z = \eta. \tag{52.88}$$

This is yet another constraint that links the free surface to the velocity potential.

52.3.4 Summary of the linear equations

The boundary value problem for the velocity potential and free surface is given by

$$\boldsymbol{v} = -\nabla\Psi \qquad \text{velocity potential} \tag{52.89a}$$

$$\nabla^2 \Psi = 0 \qquad \text{irrotational and non-divergent velocity for } \boldsymbol{x} \in \text{ocean} \tag{52.89b}$$

$$\partial_t \Psi = g\,\eta \qquad \text{linearized dynamic b.c. at } z = \eta \tag{52.89c}$$

$$\partial_z \Psi = -\partial_t \eta \qquad \text{linearized kinematic b.c. at } z = \eta \tag{52.89d}$$

$$\hat{\boldsymbol{n}} \cdot \nabla\Psi = 0 \qquad \text{no-normal flow kinematic b.c. on rigid boundaries.} \tag{52.89e}$$

Equations (52.89a) and (52.89b) hold throughout the fluid whereas the remaining equations hold only at the boundaries.

Although the equations (52.89b)-(52.89e) were derived through linearization, there is one remaining nonlinearity that needs to be removed to enable a fully linear analytical treatment.

[8] Alternatively, can use a gauge transformation $\Psi' = \Psi - t\,(p_a/\rho)$ to eliminate the constant.

Namely, when combining the boundary conditions into a single equation we compute the time derivative of equation (52.89c) according to

$$g \frac{\partial \eta}{\partial t} = \left[\frac{\partial}{\partial t} + \frac{\partial \eta}{\partial t} \frac{\partial}{\partial z} \right] \frac{\partial \Psi}{\partial t}, \tag{52.90}$$

which follows since $\Psi = \Psi(x, y, z = \eta(x, y, t), t)$ at the surface boundary. Combining with equation (52.89d) renders

$$\left[\frac{\partial}{\partial t} + \frac{\partial \eta}{\partial t} \frac{\partial}{\partial z} \right] \frac{\partial \Psi}{\partial t} = -g \frac{\partial \Psi}{\partial z}. \tag{52.91}$$

With $w \approx \partial \eta / \partial t$ at the free surface, we identify $(\partial \eta / \partial t)\, \partial_z$ as a vertical advection operator. The corresponding term $(\partial \eta / \partial t)\, \partial_{zt} \Psi$ is nonlinear and second order in fluctuating fields. Hence, we drop this term as part of the linearization process. An equivalent means to realize this linearization is to evaluate the free surface boundary condition at $z = 0$ rather than at $z = \eta(x, y, t)$. For this approximation to be self-consistent requires the amplitude of free surface undulations to be much smaller than the typical wavelengths of the fluctuations, in which case

$$|\eta| / \Lambda \ll 1, \tag{52.92}$$

with this condition holding for the waves considered here.

In summary, the fully linearized equation set takes the form

$$\boldsymbol{v} = -\nabla \Psi \qquad \text{velocity potential} \tag{52.93a}$$

$$\nabla^2 \Psi = 0 \qquad \text{irrotational and non-divergent velocity for } \boldsymbol{x} \in \text{ocean} \tag{52.93b}$$

$$\partial_t \Psi = g\, \eta \qquad \text{linearized dynamic b.c. at } z = 0 \tag{52.93c}$$

$$\partial_z \Psi = -\partial_t \eta \qquad \text{linearized kinematic b.c. at } z = 0 \tag{52.93d}$$

$$\hat{\boldsymbol{n}} \cdot \nabla \Psi = 0 \qquad \text{no-normal flow kinematic b.c. on rigid boundaries.} \tag{52.93e}$$

Observe that these equations for surface gravity waves involve a harmonic scalar potential, Ψ, defined throughout the full fluid domain (equation (52.93b)), whereas the time tendencies are determined by the kinematic boundary condition (equation (52.93d)) and dynamic boundary condition (equation (52.93c)). Mathematically, the free surface, η, lives on a two-dimensional manifold of the surface interface, whereas the velocity potential, Ψ, lives on a three-dimensional manifold defined by the ocean domain. The velocity potential and free surface are coupled by the kinematic and dynamic boundary conditions, thus requiring the velocity potential to be determined throughout the three-dimensional ocean domain even if we might only care about fluctuations of the free surface. These features of surface gravity waves make them inherently more complex, and rich, than surface fluctuations of a membrane[9], or the volume fluctuations of a compressible fluid leading to acoustic waves (Chapter 51). The surface gravity wave system provides a canonical example of a surface boundary dynamical system, with surface quasi-geostrophy another prominent geophysical example.[10]

52.4 Energetics for the linearized equations

We here specialize the energetic analysis from Section 52.2.6 to study the energetics of the linearized equations in a manner analogous to the acoustic wave energetics considered in Section

[9] A drumhead provides the canonical example of a vibrating membrane. For determining waves moving on a drumhead, we focus exclusively on the drumhead without also considering dynamics of the surrounding fluid. See Chapter 8 of *Fetter and Walecka* (2003) for details.

[10] See *Held et al.* (1995) for a classic treatment of surface quasi-geostrophy. *Yassin* (2021) and *Yassin and Griffies* (2022) provide further studies of surface quasi-geostrophy in the context of normal mode theory.

51.6.

52.4.1 Domain integrated kinetic energy

The surface integral (52.50) for the domain integrated kinetic energy is computed at $z = \eta(x, y, t)$. For the linearized system, this integral is approximated at $z = 0$, so that the domain integrated kinetic energy is

$$E_{\text{KE}} = -\frac{\rho}{2} \int [\Psi \, \partial_t \eta]_{z=0} \, \mathrm{d}A = \frac{\rho}{2} \int [\Psi \, \partial_z \Psi]_{z=0} \, \mathrm{d}A = -\frac{\rho}{2} \int [\Psi \, w]_{z=0} \, \mathrm{d}A, \tag{52.94}$$

where we made use of the kinematic boundary condition (52.93d).

52.4.2 Domain integrated potential and available potential energies

Measuring the zero of gravitational potential energy at $z = -H$ (see Figure 52.1), yields the domain integrated gravitational potential energy

$$g \, \rho \int_{z=0} \left[\int_{-H}^{\eta} z \, \mathrm{d}z \right] \mathrm{d}A = \frac{g \, \rho}{2} \int (\eta^2 - H^2) \, \mathrm{d}A. \tag{52.95}$$

The available potential energy (see Sections 29.9 and 36.5.6) is the difference between the gravitational potential energy and that contained in an ocean at rest with $\eta = 0$, so that

$$E_{\text{APE}} = g \, \rho \int \left[\int_{-H}^{\eta} z \, \mathrm{d}z \right] \mathrm{d}A - g \, \rho \int \left[\int_{-H}^{0} z \, \mathrm{d}z \right] \mathrm{d}A = \frac{g \, \rho}{2} \int \eta^2 \, \mathrm{d}A = \frac{\rho}{2 \, g} \int (\partial_t \Psi)^2 \, \mathrm{d}A, \tag{52.96}$$

where the final step made use of the dynamic boundary condition (52.93c). Hence, a non-negative available potential energy is associated with any undulation of the free surface, whether the undulation is positive or negative.

In Section 36.5.6 we computed the available potential energy for a single layer of shallow water fluid. In that discussion we chose to set $z = 0$ at the resting free surface (Figure 35.1), whereas in the current discussion we chose $z = 0$ at the flat bottom (Figure 52.1). Even so, the available potential energy (52.96) is identical to the shallow water case, which we see by noting that the area average of η vanishes for the current choice in Figure 52.1 (due to volume conservation)

$$\overline{\eta} = \frac{1}{A_{\text{ocn}}} \int \eta \, \mathrm{d}A = 0, \tag{52.97}$$

where

$$A_{\text{ocn}} = \int \mathrm{d}A \tag{52.98}$$

is the surface area of the ocean. We thus find

$$E_{\text{APE}} = \frac{g \, \rho}{2} \int \eta^2 \, \mathrm{d}A = \frac{g \, \rho}{2} \int (\eta - \overline{\eta})^2 \, \mathrm{d}A = \frac{g \, \rho}{2} \int (\eta')^2 \, \mathrm{d}A, \tag{52.99}$$

which agrees with equation (36.131) derived for the shallow water layer. We expect the two energies to agree since the gravitational energy depends only on the density and the position within the gravity field; it has no concern for dynamical assumptions such as whether the fluid motion is approximately hydrostatic (as for the shallow water model) or general (as considered here).

52.4.3 Equipartition for the phase averaged domain integrated energies

The expression (52.96) for the available potential energy can be written

$$E_{\text{APE}} = \frac{\rho}{2} \int \eta \, \partial_t \Psi \, \mathrm{d}A = \frac{\rho}{2} \int [-\Psi \, \partial_t \eta + \partial_t(\eta \, \Psi)] \, \mathrm{d}A = E_{\text{KE}} + \frac{\rho}{2} \int \partial_t(\eta \, \Psi) \, \mathrm{d}A, \tag{52.100}$$

where we made use of equation (52.94) for the total kinetic energy. If the fields exhibit periodicity in time, such as for a surface gravity wave field, then integration over an integer multiple of the wave period results in an equipartition between the phase averaged available potential energy and phase averaged kinetic energy

$$\langle E_{\text{APE}} \rangle = \langle E_{\text{KE}} \rangle \quad \text{with} \quad \langle E_{\text{APE}} \rangle = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} E_{\text{APE}} \, \mathrm{d}t, \tag{52.101}$$

where $2\pi/\omega$ is the wave period. We found a similar equipartition of energy in Section 51.6.2 for acoustic waves.

52.4.4 Energetics for the depth integrated linear flow

We here study the mechanical energy contained in the fluid layer within the linear theory. Notably, when computing the kinetic energy in the depth integrated flow, we only integrate to $z = 0$ since going to $z = \eta$ involves third order terms that are neglected in the linear theory. Hence, the time derivative of the depth integrated kinetic energy per mass is

$$\frac{\partial}{\partial t} \int_{-H}^{0} \mathcal{K} \, \mathrm{d}z = \frac{1}{2} \frac{\partial}{\partial t} \int_{-H}^{0} \nabla\Psi \cdot \nabla\Psi \, \mathrm{d}z = \int_{-H}^{0} \nabla(\partial_t \Psi) \cdot \nabla\Psi \, \mathrm{d}z, \tag{52.102}$$

which follows since the integral bounds are static so that the time derivative commutes with the integral. Note that we used the partial time derivative operator, $\partial/\partial t$, as it is computed holding the horizontal position fixed. We next make use of the harmonic nature of the velocity potential ($\nabla^2 \Psi = 0$) to write

$$\frac{\partial}{\partial t} \int_{-H}^{0} \mathcal{K} \, \mathrm{d}z = \int_{-H}^{0} \nabla \cdot (\partial_t \Psi \, \nabla\Psi) \, \mathrm{d}z = [\partial_t \Psi \, \partial_z \Psi]_{z=0} + \nabla_{\!\mathrm{h}} \cdot \int_{-H}^{0} \partial_t \Psi \, \nabla_{\!\mathrm{h}} \Psi \, \mathrm{d}z, \tag{52.103}$$

where we used the bottom kinematic boundary condition, $\partial_z \Psi = 0$ at $z = -H$, and noted that H is a constant (flat bottom) so that the horizontal derivative commutes with the integral. For the boundary term we use the linearized dynamic boundary condition (52.93c) and linearized kinematic boundary condition (52.93d) to yield

$$\frac{\partial}{\partial t} \int_{-H}^{0} \mathcal{K} \, \mathrm{d}z = -g \, \eta \, \partial_t \eta + \nabla_{\!\mathrm{h}} \cdot \int_{-H}^{0} \partial_t \Psi \, \nabla_{\!\mathrm{h}} \Psi \, \mathrm{d}z. \tag{52.104}$$

Observe that the boundary term is the time tendency of the depth integrated potential energy per mass

$$\int_{-H}^{\eta} \Phi \, \mathrm{d}z = \int_{-H}^{\eta} g \, z \, \mathrm{d}z = (g/2) \, (\eta^2 - H^2) \implies \frac{\partial}{\partial t} \int_{-H}^{\eta} g \, z \, \mathrm{d}z = g \, \eta \, \partial_t \eta. \tag{52.105}$$

The potential energy in the column is computed by integrating all the way to the free surface, even for the linear theory. That integration limit is needed since changes in the potential energy over a column of constant density fluid arise solely through changes in the free surface. Bringing the pieces together allows us to write the time derivative of the depth integrated mechanical

energy per mass in the linear theory

$$\frac{\partial}{\partial t}\left[\frac{1}{2}\int_{-H}^{0}\boldsymbol{v}\cdot\boldsymbol{v}\,\mathrm{d}z+\int_{-H}^{\eta}g\,z\,\mathrm{d}z\right]=\nabla_{\mathsf{h}}\cdot\int_{-H}^{0}\partial_t\Psi\,\nabla_{\mathsf{h}}\Psi\,\mathrm{d}z. \tag{52.106}$$

Finally, set $\boldsymbol{u}=-\nabla_{\mathsf{h}}\Psi$, and use the linear theory identity, $\partial_t\Psi=p_{\mathsf{d}}/\rho$ from equation (52.83), thus leading to

$$\frac{\partial}{\partial t}\left[\int_{-H}^{0}\rho\,\mathcal{K}\,\mathrm{d}z+\int_{-H}^{\eta}\rho\,\Phi\,\mathrm{d}z\right]=-\nabla_{\mathsf{h}}\cdot\int_{-H}^{0}p_{\mathsf{d}}\,\boldsymbol{u}\,\mathrm{d}z. \tag{52.107}$$

Evidently, it is the horizontal convergence of the layer integrated flux of dynamical pressure, $p_{\mathsf{d}}\,\boldsymbol{u}$, that affects a time change to the layer integrated mechanical energy for the linear theory. That is, the layer integrated mechanical energy has a time tendency due to work by the dynamical pressure. Recall we saw the importance of pressure work in Section 52.2.6 when considering the local energy balances for the fully nonlinear system. We also saw the importance of pressure work for acoustic wave energetics in Section 51.6.3. Other wave systems we encounter in this part of the book also have pressure work central to their energetics.

52.5 Traveling gravity waves in a flat domain

We now study a traveling plane wave solution to the equations (52.93b)-(52.93e) as posed in a flat bottom domain such as illustrated in Figure 52.1. The waves are assumed to travel horizontally, with the example in Figure 52.1 showing waves in the $\pm\hat{\boldsymbol{x}}$ direction. There are no lateral boundaries. The waves also contain a vertical profile that, as we shall see, exponentially decays from the surface into the interior.

Besides providing an explicit realization of surface gravity waves, our analysis offers experience with the *separation of variables* method for solving certain partial differential equations. In our analysis, we are not interested in the most general wave solution. Instead, we aim to determine a particular solution of sufficient generality to expose the underlying physics of the linear wave fluctuations, and in particular to expose the exponential decay of the wave amplitude with depth. Furthermore, given linearity, the *superposition principle* holds whereby the sum or integral of particular solutions are also solutions.

52.5.1 Horizontally traveling plane wave

We seek a traveling plane wave solution with angular frequency, $\omega>0$, and horizontal wavevector and wave direction

$$\boldsymbol{k}=k_x\,\hat{\boldsymbol{x}}+k_y\,\hat{\boldsymbol{y}}\quad\text{and}\quad\hat{\boldsymbol{k}}=\boldsymbol{k}/|\boldsymbol{k}|. \tag{52.108}$$

For this purpose we assume the waves appear in the velocity potential in the shape of a cosine modulated by a vertical structure function[11]

$$\Psi(x,y,z,t)=\Psi_0\,\Gamma(z)\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t). \tag{52.109}$$

Plugging this ansatz into Laplace's equation, $\nabla^2\Psi=0$, leads to the ordinary differential equation satisfied by the non-dimensional vertical structure function

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}z^2}=|\boldsymbol{k}|^2\,\Gamma\qquad -H\le z\le 0 \tag{52.110a}$$

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}z}=0\qquad\text{at } z=-H, \tag{52.110b}$$

[11] We could use complex exponentials for the traveling wave, as discussed in Chapter 49. We here work with the real trigonometric functions to exemplify their use.

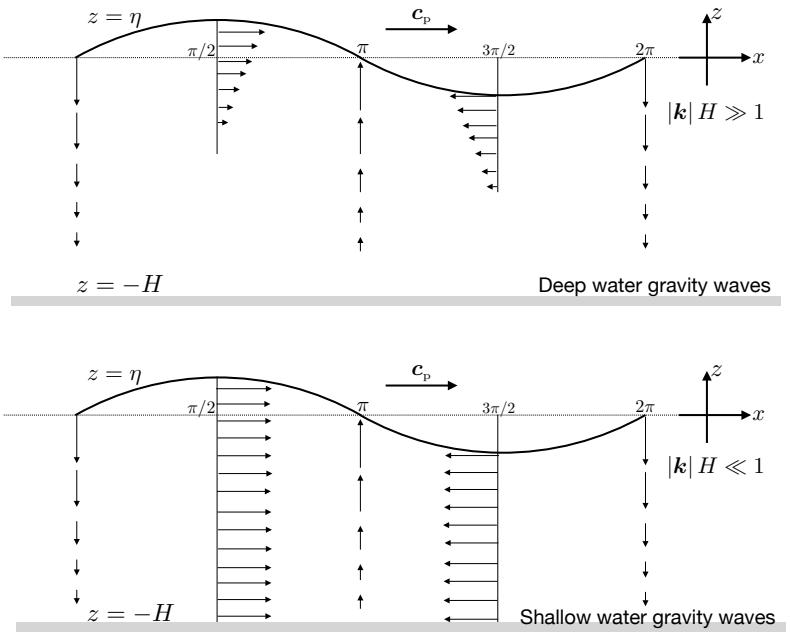

FIGURE 52.2: Snapshot of surface gravity waves over deep water ($|\boldsymbol{k}|\, H \gg 1$, top panel) and shallow water ($|\boldsymbol{k}|\, H \ll 1$, lower panel), with velocities computed according to equations (52.113a) and (52.113b). Shown here are the horizontal and vertical components to the velocity at a particular time instance, with the horizontal velocity in phase with the free surface undulations, and the vertical velocity $\pi/2$ out of phase. The horizontal axis along the top designates values for $\boldsymbol{k} \cdot \boldsymbol{x}$, with values of $0, \pi/2, \pi, 3\pi/2, 2\pi$ providing samples along the wave.

where the bottom boundary condition is required to satisfy the no-normal flow condition (52.93e). We write the solution in the form

$$\Psi = \Psi_0 \cosh[|\boldsymbol{k}|\,(z+H)] \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) \tag{52.111a}$$

$$\Psi_0 = \frac{g\, \eta_0/\omega}{\cosh(|\boldsymbol{k}|\, H)}, \tag{52.111b}$$

so that the dynamic boundary condition (52.93c) renders the free surface height

$$\eta(\boldsymbol{x}, t) = \eta_0 \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t). \tag{52.112}$$

The corresponding fluid velocity field, $\boldsymbol{v} = -\nabla\Psi$, is given by

$$\boldsymbol{u} = \frac{g\, \eta_0\, \hat{\boldsymbol{k}}}{C_\mathrm{p}} \frac{\cosh[|\boldsymbol{k}|\,(z+H)] \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}{\cosh(|\boldsymbol{k}|\, H)} \tag{52.113a}$$

$$w = -\frac{g\, \eta_0}{C_\mathrm{p}} \frac{\sinh[|\boldsymbol{k}|\,(z+H)] \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}{\cosh(|\boldsymbol{k}|\, H)}, \tag{52.113b}$$

where the wave phase speed is given by

$$C_\mathrm{p} = \omega/|\boldsymbol{k}| > 0. \tag{52.114}$$

Figure 52.2 depicts the horizontal and vertical velocity in a snapshot of a deep water wave ($|\boldsymbol{k}|\, H \gg 1$) and shallow water wave ($|\boldsymbol{k}|\, H \ll 1$). We emphasize the following properties of these waves.

- The horizontal fluid particle velocity, $\boldsymbol{u}$, is parallel to the horizontal wavevector, $\boldsymbol{k}$. Hence, the gravity waves are horizontally longitudinal.

- The horizontal velocity is in phase with the free surface, η, whereas they are both $\pi/2$ out of phase with the vertical velocity.
- The vertical velocity vanishes at the bottom, $z = -H$, as needed to satisfy the no-normal flow boundary condition.
- The horizontal wave number, $|\boldsymbol{k}|$, both determines the horizontal wavelength, $2\pi/|\boldsymbol{k}|$, as well as the vertical decay scale, $|\boldsymbol{k}|$. This coupling of the horizontal to the vertical is a notable property of surface gravity waves.
- Letting time progress at a fixed space position reveals a clockwise progression of a fluid particle, as can be imagined by letting Figure 52.2 evolve in time. Further details of fluid particle trajectories are developed in Section 52.11 when studying Stokes drift.
- In the shallow water limit, $|\boldsymbol{k}|\, H \ll 1$, the horizontal velocity is depth independent. The vertical velocity is a linear function of depth and it is a factor of $|\boldsymbol{k}|\, H$ times smaller in magnitude than the horizontal velocity. We provide a focused study of such shallow water gravity waves in Section 55.5.

52.5.2 Domain integrated mechanical energy of a traveling wave

The domain integrated kinetic energy (52.94) contained in a traveling surface gravity wave is

$$E_{\text{KE}} = -\frac{\rho}{2} \int_{z=0} \Psi\, \partial_t \eta \, \mathrm{d}A \tag{52.115a}$$

$$= (\rho/2)\, \Psi_0\, \eta_0\, \omega \cosh(|\boldsymbol{k}|\, H) \int \cos^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)\, \mathrm{d}A \tag{52.115b}$$

$$= (\rho/2)\, g\, \eta_0^2 \int \cos^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)\, \mathrm{d}A, \tag{52.115c}$$

and likewise the domain integrated available potential energy (52.96) is

$$E_{\text{APE}} = (\rho/2)\, g\, \eta_0^2 \int \sin^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)\, \mathrm{d}A, \tag{52.116}$$

so that their sum is a space and time constant

$$E_{\text{KE}} + E_{\text{APE}} = A_{\text{ocn}}\, \rho\, g\, \eta_0^2/2, \tag{52.117}$$

where A_{ocn} is the total ocean area.[12] We also see that the phase average of the domain integrated kinetic energy and available potential energy manifest the equipartition property (52.101)

$$\langle E_{\text{APE}} \rangle = \langle E_{\text{KE}} \rangle = A_{\text{ocn}}\, \rho\, g\, \eta_0^2/4. \tag{52.118}$$

52.5.3 Dispersion relation

Combining the two $z = 0$ boundary conditions (52.93c) and (52.93d) yields

$$(\partial_{tt} + g\, \partial_z)\Psi = 0 \qquad \text{at } z = 0. \tag{52.119}$$

Substituting the traveling plane wave (52.111a) into this relation leads to the *dispersion relation*

$$\omega^2 = g\, |\boldsymbol{k}| \tanh(|\boldsymbol{k}|\, H) \Longrightarrow \omega = \sqrt{g\, |\boldsymbol{k}| \tanh(|\boldsymbol{k}|\, H)}. \tag{52.120}$$

[12] For the single traveling surface gravity wave to be a valid wave solution requires no lateral boundaries, in which case the ocean area is formally infinite.

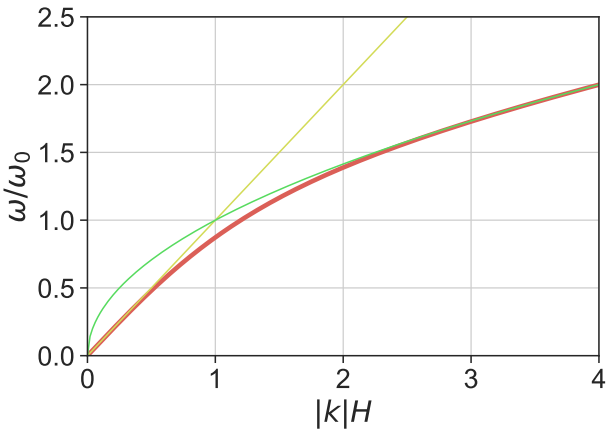

FIGURE 52.3: The dispersion relation (52.120) for surface gravity waves, plotted here as $\omega/\omega_0 = \sqrt{|\boldsymbol{k}|\,H\,\tanh(|\boldsymbol{k}|\,H)}$ (dark thick curved line), where $\omega_0^2 = g/H$ is the square of a fundamental frequency for surface gravity waves. We also show the dispersion relation for non-dispersive shallow water waves, $\omega/\omega_0 = |\boldsymbol{k}|\,H$ (straight line), which holds for $|\boldsymbol{k}|\,H \ll 1$, and the dispersive deep-water gravity waves, $\omega/\omega_0 = \sqrt{|\boldsymbol{k}|\,H}$, which holds for $|\boldsymbol{k}|\,H \gg 1$ (see Section 52.5.5).

The dispersion relation constrains those values available for the angular frequency, ω, and wavenumber, $|\boldsymbol{k}|$. That is, the surface gravity waves only exist if their frequency and wavenumber are related according to the dispersion relation (52.120). We depict the dispersion relation in Figure 52.3.

52.5.4 Alternative forms for the velocity potential and velocity

The dispersion relation (52.120) allows for a slight rewrite of the velocity potential (52.111a) and velocity field (52.113a) and (52.113b), with these variety of forms appearing in the literature

$$\eta = \eta_0 \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) \tag{52.121a}$$

$$\Psi_0 = \frac{g\,\eta_0}{\omega\cosh(|\boldsymbol{k}|\,H)} = \frac{\eta_0\,C_{\mathsf{p}}}{\sinh(|\boldsymbol{k}|\,H)} \tag{52.121b}$$

$$\Psi = \frac{g\,\eta_0\cosh[|\boldsymbol{k}|\,(z+H)]\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}{\omega\cosh(|\boldsymbol{k}|\,H)} = \frac{\eta_0\,C_{\mathsf{p}}\cosh[|\boldsymbol{k}|\,(z+H)]\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}{\sinh(|\boldsymbol{k}|\,H)} \tag{52.121c}$$

$$\boldsymbol{u} = \frac{g\,\eta_0\,\hat{\boldsymbol{k}}}{C_{\mathsf{p}}}\,\frac{\cosh[|\boldsymbol{k}|\,(z+H)]\sin(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}{\cosh(|\boldsymbol{k}|\,H)} = \frac{\eta_0\,\omega\,\hat{\boldsymbol{k}}\cosh[|\boldsymbol{k}|\,(z+H)]\sin(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}{\sinh(|\boldsymbol{k}|\,H)} \tag{52.121d}$$

$$w = -\frac{g\,\eta_0}{C_{\mathsf{p}}}\,\frac{\sinh[|\boldsymbol{k}|\,(z+H)]\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}{\cosh(|\boldsymbol{k}|\,H)} = -\frac{\eta_0\,\omega\sinh[|\boldsymbol{k}|\,(z+H)]\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}{\sinh(|\boldsymbol{k}|\,H)}. \tag{52.121e}$$

52.5.5 Phase speed, group velocity, and angular frequency

We here characterize the phase speed, group velocity, and angular frequency for the surface gravity waves, and introduce the limits for deep water and shallow water waves.

Phase speed

The phase speed for the surface gravity wave is given by

$$C_{\mathsf{p}} = \omega/|\boldsymbol{k}| = \sqrt{(g/|\boldsymbol{k}|)\,\tanh(|\boldsymbol{k}|\,H)}. \tag{52.122}$$

We consider the two limits: $|\boldsymbol{k}|\,H \gg 1$ are known as shortwaves or deep water waves, and $|\boldsymbol{k}|\,H \ll 1$ are known as longwaves or shallow water waves. In these two limits the phase speed is given by

$$\omega \approx \sqrt{g\,|\boldsymbol{k}|} \qquad C_{\text{p}} \approx \sqrt{g/|\boldsymbol{k}|} \qquad |\boldsymbol{k}|\,H \gg 1 \qquad \text{shortwave/deep water} \tag{52.123a}$$

$$\omega \approx |\boldsymbol{k}|\,\sqrt{g\,H} \qquad C_{\text{p}} \approx \sqrt{g\,H} \qquad |\boldsymbol{k}|\,H \ll 1 \qquad \text{longwave/shallow water.} \tag{52.123b}$$

Observe that the shallow water gravity waves are non-dispersive since the phase speed is the same for all wave numbers, $C_{\text{p}} \approx \sqrt{g\,H}$. In contrast, the deep water gravity waves are dispersive, with the shorter (and higher frequency) waves having a slower phase speed than longer waves. To further emphasize the point about deep water waves, write the squared phase speed for the deep water waves as

$$C_{\text{p}}^2 = \frac{g}{|\boldsymbol{k}|} = \frac{g^2}{\omega^2} \Longrightarrow C_{\text{p}} = g/\omega. \tag{52.124}$$

Hence, so long as the deep water limit is maintained, higher frequency and shorter waves have smaller phase speed than lower frequency and longer waves.

Group velocity

As shown in Section 49.6, the group velocity, $\boldsymbol{c}_{\text{g}} = \nabla_{\boldsymbol{k}}\omega$, measures the direction and speed of a group of waves (e.g., a wave train or wave packet), with the group velocity for surface gravity waves given by

$$\boldsymbol{c}_{\text{g}} = \frac{g\,\hat{\boldsymbol{k}}}{2\,\omega}\left[\frac{|\boldsymbol{k}|\,H + \cosh(|\boldsymbol{k}|\,H)\sinh(|\boldsymbol{k}|\,H)}{\cosh^2(|\boldsymbol{k}|\,H)}\right]. \tag{52.125}$$

The ratio of the group speed to the phase speed is given by

$$\frac{\hat{\boldsymbol{k}}\cdot\boldsymbol{c}_{\text{g}}}{C_{\text{p}}} = \frac{g\,|\boldsymbol{k}|^2\,[|\boldsymbol{k}|\,H + \cosh(|\boldsymbol{k}|\,H)\sinh(|\boldsymbol{k}|\,H)]}{2\,\omega^2\,\cosh^2(|\boldsymbol{k}|\,H)} = \frac{1}{2}\left[1 + \frac{2\,|\boldsymbol{k}|\,H}{\sinh(2\,|\boldsymbol{k}|\,H)}\right]. \tag{52.126}$$

The shallow water limit, with $|\boldsymbol{k}|\,H \ll 1$, has phase speed and group speed equal, whereas the deep water waves have group speed one-half the phase speed. More precisely, we find the following limiting behaviors.

$$\omega \approx \sqrt{g\,|\boldsymbol{k}|} \qquad C_{\text{p}} \approx \sqrt{g/|\boldsymbol{k}|} \qquad \boldsymbol{c}_{\text{g}} \approx \boldsymbol{c}_{\text{p}}/2 \qquad |\boldsymbol{k}|\,H \gg 1 \qquad \text{shortwave/deep water} \tag{52.127a}$$

$$\omega \approx |\boldsymbol{k}|\,\sqrt{g\,H} \qquad C_{\text{p}} \approx \sqrt{g\,H} \qquad \boldsymbol{c}_{\text{g}} \approx \boldsymbol{c}_{\text{p}} \qquad |\boldsymbol{k}|\,H \ll 1 \qquad \text{longwave/shallow water.} \tag{52.127b}$$

For shallow water gravity waves, the group velocity equals to the phase velocity. In contrast, for deep water gravity waves, the group velocity magnitude is one-half the phase speed. When watching a packet of deep water gravity waves, we see the phase of the carrier waves appear at the back of the packet and move forward at twice the speed of the packet, only to then disappear at the front of the packet.

Angular frequency

The deep water limit, $|\boldsymbol{k}|\,H \gg 1$, and shallow water limit, $|\boldsymbol{k}|\,H \ll 1$, are set according to the wavenumber. These limits lead to a distinct frequency for the two waves. To compute the ratio of the corresponding angular frequencies, introduce two non-dimensional numbers according to

$$\Gamma_{\text{sw}} \equiv H\,|\boldsymbol{k}|_{\text{sw}} \ll 1 \quad \text{and} \quad \Gamma_{\text{dw}} \equiv H\,|\boldsymbol{k}|_{\text{dw}} \gg 1, \tag{52.128}$$

in which case

$$\frac{\omega_{\rm dw}^2}{\omega_{\rm sw}^2} = \frac{g\,|\boldsymbol{k}|_{\rm dw}}{|\boldsymbol{k}|_{\rm sw}^2\, c_{\rm grav}^2} = \frac{g\,H^{-1}\,\Gamma_{\rm dw}}{\Gamma_{\rm sw}^2\,H^{-2}\,g\,H} = \frac{\Gamma_{\rm dw}}{\Gamma_{\rm sw}^2} \gg 1. \tag{52.129}$$

We conclude that frequency of those short gravity waves whose extent is largely confined to the upper ocean (deep water waves) is much higher than the long gravity waves that extend throughout the water column (shallow water gravity waves). So although the shallow water waves and deep water waves feel the same gravitational acceleration, the huge scale for the shallow water waves leads to far lower frequency than for the deep water gravity waves.

52.5.6 Particle trajectories ignoring Stokes drift

Following the discussion in Section 17.7.1 of fluid particles and the motion of points within a continuum, we here determine the trajectory of a fluid particle labeled by the material coordinate, $\boldsymbol{a}$, and do so by time integrating the ordinary differential equation (Section 17.3.1)

$$\frac{\partial \boldsymbol{X}(\boldsymbol{a},T)}{\partial T} = \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a},T),T], \tag{52.130}$$

where $T = t$ is the material time label. In Section 52.11 we study the fluid particle motion within a surface gravity wave, noting that there is a net motion in the direction of the phase. This *Stokes drift* arises from the distinction between averaging at a fixed point in space versus averaging that follows a fluid particle. Here, we provide a step towards the Stokes drift discussion by considering the leading order motion of fluid particles found by ignoring the distinction between Eulerian and Lagrangian averaging. In effect, we time integrate equation (52.130) by fixing the particle trajectory on the right hand side to the value it had at an arbitrary initial time, $T = t_0$. Using the horizontal velocity (52.121d) and vertical velocity (52.121e) we have (now dropping the $\boldsymbol{a}$ label for brevity)

$$\frac{{\rm d}\boldsymbol{X}_{\rm h}}{{\rm d}T} = \frac{\eta_0\,\omega\,\hat{\boldsymbol{k}}\cosh[|\boldsymbol{k}|\,(z_0+H)]\sin(\boldsymbol{k}\cdot\boldsymbol{x}_0 - \omega\,T)}{\sinh(|\boldsymbol{k}|\,H)} \tag{52.131a}$$

$$\frac{{\rm d}Z}{{\rm d}T} = -\frac{\eta_0\,\omega\sinh[|\boldsymbol{k}|\,(z_0+H)]\cos(\boldsymbol{k}\cdot\boldsymbol{x}_0 - \omega\,T)}{\sinh(|\boldsymbol{k}|\,H)}, \tag{52.131b}$$

which integrates to the horizontal and vertical trajectories

$$\boldsymbol{X}_{\rm h} = \boldsymbol{x}_0 + \frac{\eta_0\,\hat{\boldsymbol{k}}\cosh[|\boldsymbol{k}|\,(z_0+H)]\cos(\boldsymbol{k}\cdot\boldsymbol{x}_0 - \omega\,T)}{\sinh(|\boldsymbol{k}|\,H)} \tag{52.132a}$$

$$Z = z_0 + \frac{\eta_0\,\sinh[|\boldsymbol{k}|\,(z_0+H)]\sin(\boldsymbol{k}\cdot\boldsymbol{x}_0 - \omega\,T)}{\sinh(|\boldsymbol{k}|\,H)}. \tag{52.132b}$$

Eliminating the time dependence leads to the equation for an ellipse in the horizontal-vertical plane

$$\frac{(\boldsymbol{X}_{\rm h}-\boldsymbol{x}_0)^2}{\cosh^2[|\boldsymbol{k}|\,(z_0+H)]} + \frac{(Z-z_0)^2}{\sinh^2[|\boldsymbol{k}|\,(z_0+H)]} = \frac{\eta_0^2}{\sinh^2(|\boldsymbol{k}|\,H)}. \tag{52.133}$$

In the deep water limit, with $|\boldsymbol{k}|\,H \gg 1$, the ellipse becomes circular and the radius exponentially decreases with depth, with short waves (large $\boldsymbol{k}|$) decaying over a shorter depth range. As a result, deep water waves have nearly circular particle trajectories such as those shown in Figure 52.4. In the shallow water limit, with $|\boldsymbol{k}|\,H \ll 1$, the vertical motion reduces to zero so that particles move horizontally. Furthermore, their horizontal excursions are independent of z, so that particles throughout the full column move coherently by the same amount.

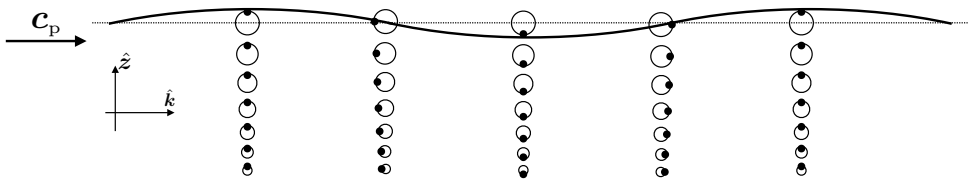

FIGURE 52.4: Motion of fluid particles in deep water waves. Shown here is a snapshot of the wave, with fluid particles denoted by black dots positioned at a point along their nearly circular orbits. The wavevector is directed to the right so that particles exhibit a clockwise orbital motion as the wave moves. Correspondingly, by moving ones eye to the left in this snapshot, then the series of fluid particles exhibit a clockwise rotation. As the horizontal motion is larger on the top of the orbit than the bottom, there is a net particle drift in the direction of the wave; this is *Stokes drift* discussed in Section 52.11. For these deep water waves, the particle motion becomes exponentially small when moving away from the interface. In contrast, for shallow water gravity waves, the particle orbits are elliptical and the horizontal major axis is depth independent whereas the vertical excursion vanishes at the bottom. This figure is taken after Figure 50 of *Lighthill* (1978).

52.5.7 Depth integrated mechanical energy of a traveling plane wave

In Section 52.4.4 we derived general expressions for the layer integrated mechanical energy budget. Here we specialize those results to the case of traveling plane surface gravity waves, and limit our focus to the phase averaged quantities.

Available potential energy

The layer integrated potential energy (per horizontal area) is given by

$$g\,\rho \int_{-H}^{\eta} z\,\mathrm{d}z = (\rho\, g\, \eta_0^2/2)\sin^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t) - \rho\, g\, H^2/2. \tag{52.134}$$

We are concerned with the potential energy relative to the constant term, $-\rho\, g\, H^2/2$. That is, we focus on the available potential energy of the waves rather than the potential energy (see Section 52.5.2), in which we compute

$$g\,\rho \int_{-H}^{\eta} z\,\mathrm{d}z - g\,\rho \int_{-H}^{0} z\,\mathrm{d}z = g\,\rho \int_{0}^{\eta} z\,\mathrm{d}z = (\rho\, g\, \eta_0^2/2)\sin^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t). \tag{52.135}$$

The phase average of the available potential energy (per horizontal area) is thus given by

$$\left\langle g\,\rho \int_{0}^{\eta} z\,\mathrm{d}z \right\rangle = \rho\, g\, \eta_0^2/4. \tag{52.136}$$

Evidently, the phase averaged and layer integrated available potential energy is proportional to the square of the amplitude of the free surface undulations, η_0^2.

Kinetic energy

Making use of the expression (52.113a) for the horizontal wave velocity leads to the layer integrated kinetic energy (per horizontal area) in the horizontal flow

$$\frac{\rho}{2}\int_{-H}^{0} \boldsymbol{u}^2\,\mathrm{d}z = \frac{\rho\,\Psi_0^2\,|\boldsymbol{k}|^2}{2}\int_{-H}^{0} \cosh^2[|\boldsymbol{k}|\,(z+H)]\sin^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)\,\mathrm{d}z, \tag{52.137}$$

which has the phase average

$$\left\langle \frac{\rho}{2}\int_{-H}^{0} \boldsymbol{u}^2\,\mathrm{d}z \right\rangle = \frac{\rho\,\Psi_0^2\,|\boldsymbol{k}|^2}{4}\int_{-H}^{0} \cosh^2[|\boldsymbol{k}|\,(z+H)]\,\mathrm{d}z. \tag{52.138}$$

Likewise, the phase averaged kinetic energy of the layer integrated vertical wave motion (52.113b) is given by

$$\left\langle \frac{\rho}{2} \int_{-H}^{0} w^2 \, \mathrm{d}z \right\rangle = \frac{\rho \, \Psi_0^2 \, |\boldsymbol{k}|^2}{4} \int_{-H}^{0} \sinh^2[|\boldsymbol{k}| \, (z+H)] \, \mathrm{d}z. \tag{52.139}$$

With $\cosh^2 y + \sinh^2 y = \cosh(2y)$, the phase average of the layer integrated kinetic energy per area of the wave is

$$\left\langle \frac{\rho}{2} \int_{-H}^{0} \boldsymbol{v}^2 \, \mathrm{d}z \right\rangle = \frac{\rho \, \Psi_0^2 \, |\boldsymbol{k}|^2}{4} \int_{-H}^{0} \cosh[2 \, |\boldsymbol{k}| \, (z+H)] \, \mathrm{d}z = (\Psi_0^2 \, |\boldsymbol{k}|/8) \sinh(2 \, |\boldsymbol{k}| \, H). \tag{52.140}$$

Making use of the expression (52.111b) for Ψ_0, as well as the dispersion relation (52.120) yields

$$\left\langle \frac{\rho}{2} \int_{-H}^{0} \boldsymbol{v}^2 \, \mathrm{d}z \right\rangle = \frac{\rho \, g^2 \, \eta_0^2 \, |\boldsymbol{k}|}{8 \, \omega^2} \frac{\sinh(2 \, |\boldsymbol{k}| \, H)}{\cosh^2(|\boldsymbol{k}| \, H)} = \rho \, g \, \eta_0^2/4, \tag{52.141}$$

which is identical to the phase averaged layer integrated available potential energy (52.136). We thus find, again, the equipartition of the phase averaged kinetic and available potential energies, here computed per horizontal area.

Energy flux vector

Now we determine the phase averaged horizontal flux of layer integrated mechanical energy. The general expression is given by equations (52.106) and (52.107), and is here specialized to the plane wave

$$\int_{-H}^{0} p_{\mathrm{d}} \, \boldsymbol{u} \, \mathrm{d}z = -\rho \int_{-H}^{0} \partial_t \Psi \, \nabla_{\!\mathrm{h}} \Psi \, \mathrm{d}z \tag{52.142a}$$

$$= (\rho \, \Psi_0^2 \, \boldsymbol{k} \, \omega) \sin^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t) \int_{-H}^{0} \cosh^2[|\boldsymbol{k}| \, (z+H)] \, \mathrm{d}z, \tag{52.142b}$$

which has a phase average

$$\left\langle \int_{-H}^{0} p_{\mathrm{d}} \, \boldsymbol{u} \, \mathrm{d}z \right\rangle = \frac{\rho \, \Psi_0^2 \, \boldsymbol{k} \, \omega}{2} \int_{-H}^{0} \cosh^2[k \, (z+H)] \, \mathrm{d}z \tag{52.143a}$$

$$= \frac{\rho \, \Psi_0^2 \, \omega \, \hat{\boldsymbol{k}}}{4} \left[|\boldsymbol{k}| \, H + \sinh(|\boldsymbol{k}| \, H) \cosh(|\boldsymbol{k}| \, H) \right] \tag{52.143b}$$

$$= (\rho \, g \, \eta_0^2/2) \, \boldsymbol{c}_{\mathrm{g}}, \tag{52.143c}$$

where we used equation (52.125) for the group velocity and equation (52.111b) for Ψ_0. We thus see that the mechanical energy fluxed by the waves is, in the phase average and depth integral, equal to the mechanical energy times the group velocity

$$\left\langle \int_{-H}^{0} p_{\mathrm{d}} \, \boldsymbol{u} \, \mathrm{d}z \right\rangle = \rho \, \boldsymbol{c}_{\mathrm{g}} \left\langle \int_{-H}^{0} \mathcal{K} \, \mathrm{d}z + \int_{0}^{\eta} \Phi \, \mathrm{d}z \right\rangle. \tag{52.144}$$

This connection between wave energy flux and the group velocity provides yet another reason why the group velocity is more relevant to wave mechanics than the phase velocity.

Comments on group velocity and a single wave

The analysis in this subsection focused on energetics for a single wave with wavevector, $\boldsymbol{k}$. However, the group velocity is the wavevector space gradient of the dispersion relation, $c_{\mathrm{g}} = \nabla_{\boldsymbol{k}} \varpi$,

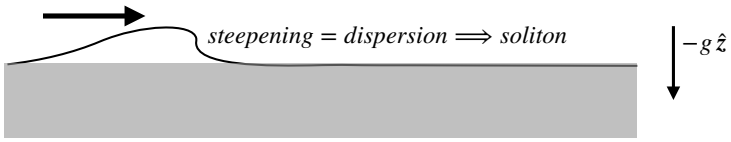

FIGURE 52.5: A soliton in the deep water limit results when the wave dispersion (long waves travel faster than short waves) balances the nonlinear steepening. The result is a soliton, which has an exact analytic expression following from the KdV equation (see *Drazin and Johnson* (1989)).

which tacitly considers more than a single wavevector. From our study of wavepackets in Section 49.6, we consider the packet to be localized in $\boldsymbol{k}$-space around a single wavevector, so that we can develop wave energetics by focusing on that single wave. When this wave forms the central carrier wave for a packet, then the group velocity serves as the velocity of the packet and it appears in the energy flux.

52.5.8 Further study

Further discussions of surface gravity waves, following that provided here, can be found in Section 54 of *Fetter and Walecka* (2003), Lectures 3 and 4 of *Pedlosky* (2003), and Section 7.1 of *Vallis* (2017).

52.6 Qualitative features of deep water waves

The shortwave/deep water waves are notable for having shorter waves travel slower than longer waves. In the event of a perturbation to the fluid, such as from a stone dropped into a pond or a storm on a lake or the ocean, deep water waves are energized. The dispersion relation (52.123a) means that longer waves spread away from the source faster than the shorter waves, leading to a self-organization of the wavelengths and corresponding wave packets.

Now imagine a deep water wave packet that somehow steepens and takes on a nonlinear form. Fourier decomposing this nonlinear wave into linear deep water modes requires more shortwave modes in the steep region, whereas the less steep portion of the wave requires longer deep water modes, which travel faster. If the nonlinear steepening on the wave face is exactly balanced by the faster dispersion of the long waves near the wave base and backside, then the wave pattern remains stable; it does not break. This balance of steepening and dispersion describes the fundamental features of a *soliton* as depicted in Figure 52.5, with a soliton a *nonlinear wave*.

52.7 Shallow water waves approaching a shore

The shallow water limit is notable for the absence of wave dispersion; i.e., shallow water gravity waves of all wavelengths travel at speed $\sqrt{g\,H}$. Tsunamis are the prototypical shallow water waves. The shallow water dispersion relation also means that shallow water gravity waves slow down when the ocean depth shoals, as when approaching a shoreline. Consequently, as waves reach the shoreline there is a tendency to accumulate wave energy as the deeper waves pile up behind the shallower waves. Furthermore, the steeper part of the wave, being part of a thicker region of the fluid and thus a larger effective H, travels slightly faster than the wave trough. As such, the steeper part of the wave overtakes the trough and, at some point, the assumptions of linearity breakdown and the shallow water waves break on the beach as depicted in Figure 52.6. In the remainder of this section, we provide some quantitative context for these remarks.

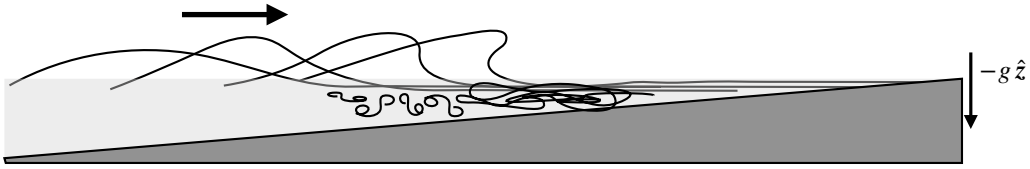

FIGURE 52.6: Shallow water waves approaching a shoreline steepen and eventually break. We can infer this behavior from the phase speed, $C_{\text{p}} = \sqrt{g\,H}$, whereby waves in deeper water move slightly faster than those in shallower water, so that the wave energy accumulates near the shore. Furthermore, water on the steeper part of the wave moves slightly faster than water in the trough, due to the difference in thickness of the water. This process causes water on the steeper portion of the wave to travel slightly faster than in the trough, leading to steepening of the waves. Nonlinearities eventually invalidate the assumptions made in deriving the linear waves. Even so, the qualitative characterization based on the linear analysis allows for a useful heuristic understanding of shallow water wave breaking on the beach. This video offers a pedagogical introduction to shallow water waves, with the 12-minute mark describing "compression" waves, in which waves steepen due to differences in the layer thickness, much like shallow water waves approaching a beach

52.7.1 Wavenumber changes

Consider the ray equations from Section 50.3 for a one-dimensional shallow water gravity wave approaching a beach with $\boldsymbol{k} = k\,\hat{\boldsymbol{x}}$ where $k > 0$. Let the resting depth be a function, $H(x)$, that decreases in the $+\hat{\boldsymbol{x}}$ direction, $\partial_x H < 0$. Since the background state is time-independent (i.e., the resting depth is static), the angular frequency remains fixed while following along a ray, so that[13]

$$\frac{\mathrm{D}_{\mathrm{r}}\varpi}{\mathrm{D}t} = 0. \tag{52.145}$$

With the local shallow water dispersion relation given by

$$\varpi(x) = k(x)\,\sqrt{g\,H(x)}, \tag{52.146}$$

we have

$$\frac{\mathrm{D}_{\mathrm{r}}\varpi}{\mathrm{D}t} = 0 \Longrightarrow \frac{1}{k}\,\frac{\mathrm{D}_{\mathrm{r}}k}{\mathrm{D}t} = -\frac{1}{2\,H}\,\frac{\mathrm{D}_{\mathrm{r}}H}{\mathrm{D}t} > 0. \tag{52.147}$$

The inequality holds since the shoreline gets shallower as the ray approaches the beach. Consequently, the wavenumber increases and the wavelength decreases for waves approaching the shore.

52.7.2 Wave energy and wave action

What happens to the wave energy as a wave approaches the shore? Common experience suggests that the wave energy increases since the amplitude increases when the wave moves into shallower water. To see this effect analytically, consider the wave action equation introduced in Section 50.5. Recall that the wave action, $\mathcal{A}$, equals to the phase averaged wave energy, $\langle \mathcal{H} \rangle$, divided by the angular frequency, ω. When following a ray, the wave action satisfies equation (50.88), which here takes the form

$$\frac{1}{\mathcal{A}}\,\frac{\mathrm{D}_{\mathrm{r}}\mathcal{A}}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{c}_{\mathrm{g}}. \tag{52.148}$$

For the one-dimensional shallow water example considered here, the convergence of the group velocity is

$$-\nabla \cdot \boldsymbol{c}_{\mathrm{g}} = -\partial_x c_{\mathrm{g}} = -\partial_x (g\,H)^{1/2} = -(g\,H)^{1/2}\,\partial_x H/(2\,H) > 0. \tag{52.149}$$

Hence, the wave action increases along a ray moving towards a beach. Furthermore, as noted earlier, a static background environment means that the angular frequency remains constant

[13] Standing on a pier looking at a periodic wave field approaching the beach should reveal that the angular frequency is a constant even as the waves move into shallower water.

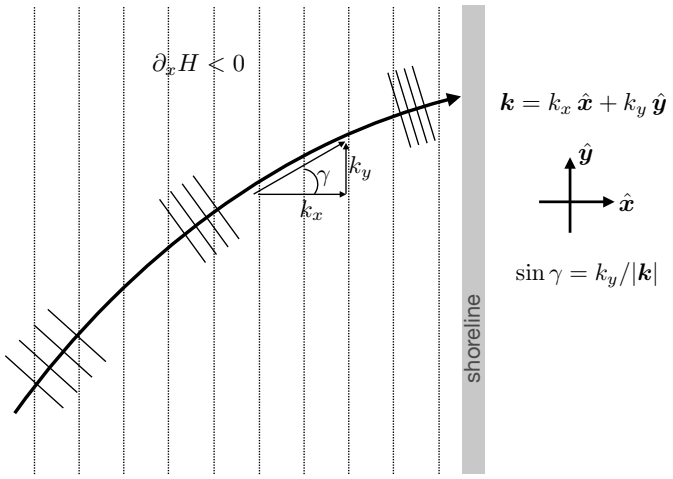

FIGURE 52.7: Depicting the refraction of shallow water gravity waves as a packet approaches the shoreline, thus causing the phase velocity to bend more directly into the shore and lines of constant phase to become more parallel to the shore. Refraction with the bottom shoaling ($\partial_x H > 0$) occurs by increasing k_x (wave length on a ray gets smaller approaching the shore) while keeping the angular frequency and k_y constant along a ray. In this manner, the angle, γ, reduces toward zero as the bottom shoals, simply through increasing k_x as a wave packet moves toward the shoreline. The dotted straight lines are lines of constant bottom depth, $H(x) =$ constant.

along a ray. Consequently, the increase in wave action following a ray onto the beach occurs since the phase averaged wave energy increases, which means that the wave amplitude is increasing. Eventually the linear analysis fails when the nonlinear effects amplify with increasing wave amplitude, as illustrated in Figure 52.6 where the waves eventually break. Even so, it is satisfying that the linear theory provides a clear picture of its ultimate demise as nonlinear effects take over.

52.7.3 Wave refraction

When distant from the shore, waves typically approach at an oblique angle, but, observations readily verify, waves bend as they start to feel the bottom, so that their phase velocity is nearly straight onto the shoreline upon reaching the beach. This bending of the wave phase lines is known as *refraction*, and the amount of refraction is a function of the bottom slope and rules for refraction are embodied in *Snell's law* from optics.

To introduce the notion of shallow water gravity wave refraction, return to the ray equation (50.37c), now with the wavevector two-dimensional,

$$\boldsymbol{k} = \hat{\boldsymbol{x}}\,k_x + \hat{\boldsymbol{y}}\,k_y. \tag{52.150}$$

If the bottom remains a function just of x, then the angular frequency remains constant along a ray, as does k_y. So writing the squared angular frequency as

$$\omega^2 = g\,H\,(k_x^2 + k_y^2), \tag{52.151}$$

it is only H and k_x that change when following along a ray. As the ray approaches the shore, $H(x)$ gets smaller. So to keep the angular frequency constant along the ray requires k_x to increase, which is the same result as in Section 52.7.1. However, now the increase in k_x means that the wave phase velocity turns into the coast so that phase lines become more parallel as the wave approaches the shore. Figure 52.7 illustrates the basic physics.

52.7.4 Further study

This video from Prof. A. Hogg provides a pedagogical introduction to shallow water wave breaking along with deep water solitons, both as realized in a laboratory. Also, section 2.2 of *Johnson* (1997) provides a thorough mathematical analysis of shallow water waves approaching a shoreline.

52.8 Standing gravity waves in a closed basin

We now consider the surface gravity wave equations (52.93a)-(52.93e) for a closed rectangular basin of constant depth and with horizontal dimensions $x \in [0, L_x]$ and $y \in [0, L_y]$. As we show, waves in a bounded domain are no longer traveling, but instead they are standing waves that oscillate in place rather than travel. We can think of such standing wave modes as a superposition of two oppositely traveling waves with the same frequency and wavenumber that are locked in-phase in a manner that satisfies the boundary conditions. For example, the sum of a right and left moving wave with equal amplitude, wavenumber, and frequency is given by the standing pattern

$$A\cos(k\,x - \omega\,t) + A\cos(-k\,x - \omega\,t) = 2\,A\cos(\omega\,t)\cos(k\,x). \tag{52.152}$$

We encountered a similar situation in Exercise 51.1 when considering acoustic waves in a closed rectangular cavity.

52.8.1 Solution for the standing waves

To satisfy the no-normal flow conditions at the four walls (equation (52.93e)) requires the horizontal wave numbers to be quantized. Correspondingly, the waves are not traveling plane waves since the flow is confined in a box. Rather, the solution is in the form of spatially standing wave that oscillates in time

$$\Psi(x, y, z, t) = \Psi_0\,\Gamma(z)\cos(k_m\,x)\cos(l_n\,y)\cos(\omega\,t), \tag{52.153}$$

where the quantized wave numbers are

$$k_m = m\,\pi/L_x \quad \text{and} \quad l_n = n\,\pi/L_y \quad \text{with} \quad m, n \text{ integers}. \tag{52.154}$$

The vertical structure function satisfies same differential equation as for the traveling waves in a channel from Section 52.5,

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}z^2} = (k_m^2 + l_n^2)\,\Gamma \qquad -H \le z \le 0 \tag{52.155a}$$

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}z} = 0 \qquad \text{at } z = -H, \tag{52.155b}$$

thus leading to the standing gravity wave solution

$$\Psi = \Psi_0\cosh[K_{m,n}\,(z + H)]\cos(k_m\,x)\cos(l_n\,y)\sin(\omega\,t) \tag{52.156a}$$

$$\Psi_0 = \frac{g\,\eta_0/\omega_{m,n}}{\cosh(K_{m,n}\,H)} \tag{52.156b}$$

$$\eta = \eta_0\cos(k_m\,x)\cos(l_n\,y)\cos(\omega_{m,n}\,t) \tag{52.156c}$$

$$u = \frac{g\,\eta_0\,k_m}{\omega_{m,n}}\,\frac{\cosh[K_{m,n}\,(z + H)]}{\cosh(K_{m,n}\,H)}\sin(k_m\,x)\cos(l_n\,y)\sin(\omega_{m,n}\,t) \tag{52.156d}$$

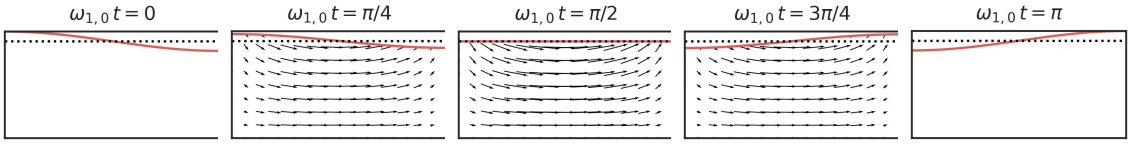

FIGURE 52.8: Flow in the $(m, n) = (1, 0)$ seiche mode, with panels corresponding to an increment of $\omega_{1,0}\, t = \pi/4$. Note that there is no flow at times $\omega_{1,0}\, t = 0$ and $\omega_{1,0}\, t = \pi$. Units are arbitrary.

$$v = \frac{g\,\eta_0\,l_n}{\omega_{m,n}}\,\frac{\cosh[K_{m,n}\,(z+H)]}{\cosh(K_{m,n}\,H)}\,\cos(k_m\,x)\,\sin(l_n\,y)\,\sin(\omega_{m,n}\,t) \tag{52.156e}$$

$$w = -\frac{g\,\eta_0\,K_{m,n}}{\omega_{m,n}}\,\frac{\sinh[K_{m,n}\,(z+H)]}{\cosh(K_{m,n}\,H)}\,\cos(k_m\,x)\,\cos(l_n\,y)\,\sin(\omega_{m,n}\,t) \tag{52.156f}$$

$$K_{m,n}^2 = k_n^2 + l_m^2. \tag{52.156g}$$

As for the channel, we find the dispersion relation by substituting the standing wave solution into the boundary condition equation (52.119), thus leading to the quantized angular frequencies

$$\omega_{m,n}^2 = g\,K_{m,n}\tanh(K_{m,n}\,H). \tag{52.157}$$

52.8.2 Gravest seiche mode as an example

The standing wave solutions are commonly referred to as *seiches*, and they can be found in enclosed lakes and ocean basins after strong and persistent winds. Winds, generally with large scale variations, tend to force the lowest or *gravest* seiche mode. For example, assume the wind blows in the zonal direction so that it excites the lowest zonal standing wave with frequency

$$\omega_{1,0}^2 = g\,K_{1,0}\tanh(K_{1,0}\,H) = (g\,\pi/L_x)\tanh(\pi\,H/L_x), \tag{52.158}$$

which has the shallow water limit $(H/L_x \to 0)$

$$\omega_{1,0}^2 \approx g\,H\,(\pi/L_x)^2. \tag{52.159}$$

As the winds relax, the seiche mode oscillates according to the angular frequency $\omega_{1,0}^2$. We depict such oscillations in Figure 52.8 over one-half a period.

52.8.3 Further study

More discussion of seiche modes can be found in Section 12.5 of *Cushman-Roisin and Beckers* (2011), Section 1.6.4 of *Brown* (1999), and Chapter 10 of *Neumann and Pierson* (1966).

52.9 Wave packets of surface gravity waves

In this section we derive expressions for surface gravity wave packets moving over a flat bottom domain, specializing the general approach considered in Section 49.6. It is sufficient to focus on the free surface, though note that the free surface packets are associated with packets of the velocity potential and velocity field, with amplitudes related by equations (52.121b)-(52.121e). We apply the wave packet technology from Sections 49.6 and 49.7 to write a free surface wave packet as

$$\eta(\boldsymbol{x}, t) = \frac{1}{(2\pi)^2}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t]}\,\mathrm{d}\boldsymbol{k}. \tag{52.160}$$

In this equation, $\boldsymbol{k}$ is the horizontal wavevector, the wavevector integral extends over all of the horizontal wavevector space, and the amplitude function, $\mathcal{A}(\boldsymbol{k})$, is generally complex and peaked around a wavevector, $\boldsymbol{k}_0$. The surface gravity wave dispersion relation (52.120) specifies the angular frequency, $\omega = \varpi(\boldsymbol{k})$, as a function of the wavevector. Since the surface gravity wave dispersion relation is a function only of the wavevector magnitude, it satisfies

$$\varpi(\boldsymbol{k}) = \varpi(-\boldsymbol{k}) = \varpi(|\boldsymbol{k}|). \tag{52.161}$$

This property affects some simplification relative to the general discussion of wave packets in Section 49.6.

52.9.1 Initializing the packet and dispensing with conjugate symmetry

To initialize the packet we consider the possiblity of initializing the free surface, $\eta(\boldsymbol{x}, t = 0)$, and/or its time derivative, $\partial_t \eta(\boldsymbol{x}, t = 0)$. As shown here, by allowing for either possibility we must dispense with the conjugate symmetry property (8.67) otherwise assumed for the amplitudes of wave packets in Sections 49.6 and 49.7.

Given that the free surface height, η, is a real field, we can write its packet as one-half the sum of the real and imaginary parts of the integral (52.160) so that

$$\eta(\boldsymbol{x}, t) = \frac{1}{2\,(2\pi)^2} \int \left[\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t]} + \left(\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t]}\right)^*\right] \mathrm{d}\boldsymbol{k} \tag{52.162a}$$

$$= \frac{1}{2\,(2\pi)^2} \int \left[\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t]} + \mathcal{A}^*(\boldsymbol{k})\, \mathrm{e}^{-\mathrm{i}\,[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t]}\right] \mathrm{d}\boldsymbol{k} \tag{52.162b}$$

$$= \frac{1}{2\,(2\pi)^2} \int \left[\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,[\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t]} + \mathcal{A}^*(-\boldsymbol{k})\, \mathrm{e}^{-\mathrm{i}\,[-\boldsymbol{k}\cdot\boldsymbol{x} - \varpi(-\boldsymbol{k})\,t]}\right] \mathrm{d}\boldsymbol{k} \tag{52.162c}$$

$$= \frac{1}{2\,(2\pi)^2} \int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}} \left[\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} + \mathcal{A}^*(-\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,\varpi(\boldsymbol{k})\,t}\right] \mathrm{d}\boldsymbol{k}, \tag{52.162d}$$

where the second equality made use of the associative property (8.6b) of the complex conjugate operation, and the final equality used the property (52.161) of the surface gravity wave dispersion relation. We can compute the time derivative of the wave packet by differentiating equation (52.162d) to have

$$\partial_t \eta(\boldsymbol{x}, t) = \frac{\mathrm{i}}{2\,(2\pi)^2} \int \varpi(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}} \left[-\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} + \mathcal{A}^*(-\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,\varpi(\boldsymbol{k})\,t}\right] \mathrm{d}\boldsymbol{k}. \tag{52.163}$$

It is now clear why we must dispense with the conjugate symmetry property (8.67), which says that $\mathcal{A}^*(-\boldsymbol{k}) = \mathcal{A}(\boldsymbol{k})$. Namely, if conjugate symmetry holds, then $\partial_t \eta(\boldsymbol{x}, t = 0) = 0$. If we instead choose conjugate anti-symmetry, whereby $\mathcal{A}^*(-\boldsymbol{k}) = -\mathcal{A}(\boldsymbol{k})$, then $\eta(\boldsymbol{x}, t = 0) = 0$. So to enable a nonzero initial free surface and/or a nonzero free surface time derivative requires an amplitude function that does not satisfy conjugate symmetry. If one is physically motivated to choose just one of these initial conditions, then either conjugate symmetry or conjugate anti-symmetry is available. For the current analysis, we do not constrain the amplitudes. Even so, η remains a real function given that it is written in equation (52.162a) as the sum of a complex number plus its complex conjugate.

52.9.2 Expressions for the amplitude function

Setting $t = 0$ in equation (52.160) for the free surface and equation (52.163) for its time derivative leads to

$$\eta(\boldsymbol{x}, 0) = \frac{1}{2\,(2\pi)^2} \int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,[\mathcal{A}(\boldsymbol{k}) + \mathcal{A}^*(-\boldsymbol{k})]\;\mathrm{d}\boldsymbol{k} \tag{52.164a}$$

$$\partial_t\eta(\boldsymbol{x}, 0) = \frac{\mathrm{i}}{2\,(2\pi)^2} \int \varpi(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,[-\mathcal{A}(\boldsymbol{k}) + \mathcal{A}^*(-\boldsymbol{k})]\;\mathrm{d}\boldsymbol{k}. \tag{52.164b}$$

Inverting these Fourier integral yields

$$[\mathcal{A}(\boldsymbol{k}) + \mathcal{A}^*(-\boldsymbol{k})]/2 = \int \eta(\boldsymbol{x}, 0)\,\mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{x} \tag{52.165a}$$

$$\mathrm{i}\,\varpi(\boldsymbol{k})\,[-\mathcal{A}(\boldsymbol{k}) + \mathcal{A}^*(-\boldsymbol{k})]/2 = \int \partial_t\eta(\boldsymbol{x}, 0)\,\mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{x}, \tag{52.165b}$$

which then provide expressions for the amplitude functions in terms of the prescribed initial conditions

$$\mathcal{A}(\boldsymbol{k}) = \int [\eta(\boldsymbol{x}, 0) + (\mathrm{i}/\varpi)\,\partial_t\eta(\boldsymbol{x}, 0)]\,\mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{x} \tag{52.166a}$$

$$\mathcal{A}^*(-\boldsymbol{k}) = \int [\eta(\boldsymbol{x}, 0) - (\mathrm{i}/\varpi)\,\partial_t\eta(\boldsymbol{x}, 0)]\,\mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{x}. \tag{52.166b}$$

Note that the $\boldsymbol{x}$-integral extends over all of the horizontal $\boldsymbol{x}$-space. As discussed in Section 52.9.1, we find that the amplitude function indeed does not satisfy conjugate symmetry

$$\mathcal{A}(\boldsymbol{k}) \neq \mathcal{A}^*(-\boldsymbol{k}). \tag{52.167}$$

52.9.3 Wave packet in terms of a propagator function

Making use of the amplitude functions (52.166a) and (52.166b) in the integral expansion (52.162d) leads to the expression for the free surface height

$$\eta(\boldsymbol{x}, t) = \frac{1}{2\,(2\pi)^2} \int\int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{\xi})-\mathrm{i}\,\varpi\,t}[\eta(\boldsymbol{\xi}, 0) + (\mathrm{i}/\varpi)\,\partial_t\eta(\boldsymbol{\xi}, 0)]\;\mathrm{d}\boldsymbol{k}\,\mathrm{d}\boldsymbol{\xi} \tag{52.168}$$

$$+ \frac{1}{2\,(2\pi)^2} \int\int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{\xi})+\mathrm{i}\,\varpi\,t}[\eta(\boldsymbol{\xi}, 0) - (\mathrm{i}/\varpi)\,\partial_t\eta(\boldsymbol{\xi}, 0)]\;\mathrm{d}\boldsymbol{k}\,\mathrm{d}\boldsymbol{\xi}. \tag{52.169}$$

Rearrangement then renders the tidy expression

$$\eta(\boldsymbol{x}, t) = \int [\partial_t G(\boldsymbol{x} - \boldsymbol{\xi}, t)\,\eta(\boldsymbol{\xi}, 0) + G(\boldsymbol{x} - \boldsymbol{\xi}, t)\,\partial_t\eta(\boldsymbol{\xi}, 0)]\mathrm{d}\boldsymbol{\xi}, \tag{52.170}$$

where we introduced the propagator function and its time derivative

$$G(\boldsymbol{x}, t) = \frac{1}{(2\pi)^2} \int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,\frac{\sin((\varpi(|\boldsymbol{k}|)\,t)}{(\varpi(|\boldsymbol{k}|)}\,\mathrm{d}\boldsymbol{k} \quad \text{and} \quad \partial_t G(\boldsymbol{x}, t) = \frac{1}{(2\pi)^2} \int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}} cos(\varpi(|\boldsymbol{k}|)\,t)\,\mathrm{d}\boldsymbol{k}. \tag{52.171}$$

As written, the function, $G(\boldsymbol{x}, t)$, and its time derivative encapsulate all the temporal behavior of the wave packet, acting to propagate the initial conditions, $\eta(\boldsymbol{\xi}, 0)$ and $\partial_t\eta(\boldsymbol{\xi}, 0)$, forward in time. As noted in Section 49.6. equation (52.170) is quite elegant since $G(\boldsymbol{x}, t)$ is independent of details of the initial conditions. In this manner it acts like a Green's function (Chapter 9).

52.9.4 Further study

Elements of this section follow from Section 55 of *Fetter and Walecka* (2003).

52.10 Capillary-gravity waves

As studied in Section 25.11, surface tension exists at the interface between two media, such as a liquid and solid or liquid and gas. In this section we consider the effects from surface tension on surface waves, with surface tension providing the means to realize *capillary waves*.

52.10.1 Pressure jump across the air-sea surface

As studied in Section 25.11, surface tension on an interface between two fluids leads to a pressure jump across the interface. That is, the pressure on one side of the interface is different from the pressure on the other side. The pressure jump is given by the Young-Laplace formula (25.149), which when applied to the ocean free surface renders

$$p_{\text{a}} - p_{\text{ocn}} = \gamma \nabla^2 \eta \implies p_{\text{ocn}} = p_{\text{a}} - \gamma \nabla^2 \eta. \tag{52.172}$$

In this equation, $\gamma > 0$ is the surface tension (dimensions of force per length = M T^{-2}), p_{a} is the pressure on the atmospheric side of the free surface, and p_{ocn} is the pressure on the ocean side of the free surface. To help remember signs for the pressure jump, note that the Young-Laplace formula (52.172) says that pressure on the concave side of the interface is higher than on the convex side. For example, if the free surface extends upward then $p_{\text{ocn}} - p_{\text{a}} > 0$ since the ocean is on the concave side and so it has the higher pressure. This result also follows since $\nabla^2 \eta < 0$ for an upward extension, which leads to a local free surface maximum.[14]

52.10.2 Dynamic boundary condition with surface tension

We can continue to apply Bernoulli's theorem even in the presence of surface tension to determine the dynamic boundary condition. Hence, we proceed as in Section 52.3.2 to evaluate the Bernoulli potential at the free surface. Now, however, it is important to specify which side of the free surface we evaluate the Bernoulli potential. Being interested in ocean waves, we evaluate the Bernoulli potential on the ocean side, in which case equation (52.84) takes on the form

$$g\,\eta + \mathcal{K} - \partial_t \Psi = -p_{\text{ocn}}/\rho = -(p_{\text{a}} - \gamma \nabla^2 \eta)/\rho, \tag{52.173}$$

where the second equality follows from the Young-Laplace formula (52.172). We again assume the atmospheric pressure is a given constant that can be trivially absorbed by a gauge transformation (just like we did in Section 52.2.3 for surface gravity waves). We thus have the equation of motion

$$\partial_t \Psi = \rho^{-1} \left[g\,\rho - \gamma\,\nabla^2 \right] \eta + \mathcal{K}. \tag{52.174}$$

The surface tension term, $-(\gamma/\rho)\,\nabla^2 \eta$, is new relative to equation (52.84) holding for gravity waves.

52.10.3 Dispersion relation for capillary-gravity waves

In Section 52.3.4 we detailed the steps needed to derive the linear equations (52.93b)-(52.93e) for surface gravity waves. Those steps also hold for capillary-gravity waves, with the only difference

[14] The discussion in Section 25.11.4 considered bubbles, where the Young-Laplace formula shows that surface tension causes pressure inside of a bubble (concave side) to be larger than outside the bubble.

being a modification to the dynamic boundary condition arising from surface tension

$$\nabla^2 \Psi = 0 \qquad \text{irrotational and non-divergent velocity} \tag{52.175a}$$

$$\partial_t \Psi = \rho^{-1} \left[g\,\rho - \gamma\,\nabla^2 \right] \eta \qquad \text{linearized dynamic b.c. at } z = 0 \tag{52.175b}$$

$$\partial_z \Psi = -\partial_t \eta \qquad \text{linearized kinematic b.c. at } z = 0 \tag{52.175c}$$

$$\hat{\boldsymbol{n}} \cdot \nabla \Psi = 0 \qquad \text{no-normal flow kinematic b.c. on rigid boundaries.} \tag{52.175d}$$

The analysis in Section 52.5.1 concerns the interior harmonic scalar potential as well as the kinematic boundary condition. Both of these properties hold equivalently for surface gravity waves and for capillary-gravity waves. Hence, we can write the scalar potential for capillary-gravity waves as in equations (52.111a) and (52.111b), and the corresponding free surface as equation (52.112). The dispersion relation is derived by using these expressions for Ψ and η in the dynamic boundary condition (52.175b), with a few lines of algebra rendering

$$\omega^2 = g\,|\boldsymbol{k}|\,(1 + \Upsilon)\tanh(|\boldsymbol{k}|\,H) \quad \text{capillary-gravity waves,} \tag{52.176}$$

where we introduced the non-dimensional parameter

$$\Upsilon = |\boldsymbol{k}|^2\,\gamma/(g\,\rho). \tag{52.177}$$

The capillary-gravity wave dispersion relation (52.176) generalizes the gravity wave dispersion (52.120). The Υ parameter provides a regime boundary where capillary waves dominate ($\Upsilon \gg 1$) versus where gravity waves dominate ($\Upsilon \ll 1$).

52.10.4 Deep water capillary-gravity waves

The hydrostatic limit is not relevant for capillary waves since capillary waves are generally very small (as seen below) and thus do not satisfy hydrostatic scaling. Hence, we find it physically most interesting to examine the limit of deep water capillary-gravity waves, in which case $|\boldsymbol{k}|\,H \to \infty$ so that the dispersion relation (52.176) simplifies to

$$\omega^2 = g\,|\boldsymbol{k}|\,(1 + \Upsilon) \quad \text{deep water capillary-gravity waves.} \tag{52.178}$$

Phase speed

The phase speed for deep water capillary-gravity waves is given by

$$C_{\mathsf{p}} = \omega/|\boldsymbol{k}| = \sqrt{(g/|\boldsymbol{k}|)\,(1 + \Upsilon)} = \sqrt{g/|\boldsymbol{k}| + \gamma\,|\boldsymbol{k}|/\rho}, \tag{52.179}$$

which has the longwave and shortwave limits

$$C_{\mathsf{p}} \approx C_{\mathsf{p}}^{\text{dwg}} \quad \text{for } \Upsilon \ll 1 \quad \text{and} \quad C_{\mathsf{p}} \approx \sqrt{\gamma\,|\boldsymbol{k}|/\rho} \quad \text{for } \Upsilon \gg 1, \tag{52.180}$$

where we introduced the deep water gravity wave phase speed from equation (52.123a)

$$C_{\mathsf{p}}^{\text{dwg}} = \sqrt{g/|\boldsymbol{k}|}. \tag{52.181}$$

At both extremes the phase speed is unbounded, with gravity waves dominant for longwaves and capillary waves dominant for shortwaves.

Group velocity

The transport of energy within a packet of capillary-gravity waves is determined by the group velocity, $\boldsymbol{c}_{\mathrm{g}} = \nabla_{\boldsymbol{k}}\omega$, which takes the form

$$\boldsymbol{c}_{\mathrm{g}} = \frac{\hat{\boldsymbol{k}}\, C_{\mathrm{p}}^{\mathrm{dwg}}}{2}\, \frac{1+3\,\Upsilon}{(1+\Upsilon)^{1/2}} = \frac{\hat{\boldsymbol{k}}}{2}\left[\frac{g\,\gamma}{\rho}\right]^{1/4} \frac{1+3\,\Upsilon}{\sqrt{\Upsilon^{1/2}+\Upsilon^{3/2}}}. \tag{52.182}$$

The group velocity has the following shortwave and longwave limits

$$\boldsymbol{c}_{\mathrm{g}} \approx \hat{\boldsymbol{k}}\, C_{\mathrm{p}}^{\mathrm{dwg}}/2 \quad \text{for } \Upsilon \ll 1 \quad \text{and} \quad \boldsymbol{c}_{\mathrm{g}} \approx \frac{3}{2}\hat{\boldsymbol{k}}\left[\frac{|\boldsymbol{k}|\,\gamma}{\rho}\right]^{1/2} \quad \text{for } \Upsilon \gg 1. \tag{52.183}$$

As for the phase speed, we find that the group velocity is unbounded at both extremes, with gravity waves dominant for longwaves and capillary waves dominant at shortwaves.

Wavelength of the minimum group velocity

As seen above, there is a continuum of wavelengths for capillary-gravity waves, with gravity waves dominating for longwaves and capillary waves dominating for shortwaves. To delineate between shortwaves and longwaves, we seek the wavenumber where the group velocity is a minimum. To simplify the algebra, assume $\boldsymbol{k} = k\,\hat{\boldsymbol{x}}$ so that we reach an extrema of the group velocity when

$$\frac{\mathrm{d}c_{\mathrm{g}}}{\mathrm{d}k} = 0 \Longrightarrow 3\,\Upsilon_{\mathrm{min}}^2 + 6\,\Upsilon_{\mathrm{min}} - 1 = 0, \tag{52.184}$$

in which case

$$\Upsilon_{\mathrm{min}} = 2/\sqrt{3} - 1 \approx 0.1547 \tag{52.185a}$$

$$k_{\mathrm{min}} = (\Upsilon_{\mathrm{min}}\, g\,\rho/\gamma)^{1/2} \approx 0.393\,(g\,\rho/\gamma)^{1/2} \tag{52.185b}$$

$$(c_{\mathrm{g}})_{\mathrm{min}} \approx 1.086\,(g\,\gamma/\rho)^{1/4}. \tag{52.185c}$$

For an air-water interface we take $\gamma = 0.072$ N m^{-1} $= 0.072$ kg s^{-2}, along with the water density of $\rho = 10^3$ kg m^{-3} and gravitational acceleration $g = 9.8$ m s^{-2}, thus leading to

$$k_{\mathrm{min}} \approx 145 \text{ m}^{-1} \tag{52.186a}$$

$$\Lambda_{\mathrm{min}} \approx 4.3 \times 10^{-2} \text{ m} \tag{52.186b}$$

$$(c_{\mathrm{g}})_{\mathrm{min}} \approx 1.7 \times 10^{-1} \text{ m s}^{-1}. \tag{52.186c}$$

Evidently, for wavelengths smaller than roughly 4 cm the surface tension effects are important in their support of capillary waves. In contrast, larger wavelengths are dominated by gravity waves.

52.10.5 Comments and further study

As noted in Section 25.11.5, we can ignore the pressure jump induced by surface tension across the air-sea interface if the radius of curvature of the air-sea interface is larger than a few centimeters. Here, we also see that the boundary between gravity waves and capillary waves occurs for wavelengths of a few centimeters. It is for these reasons that capillary waves, and surface tension more generally, can be ignored when considering geophysical fluid motions with scales larger than a few centimeters. Even so, we highlight the importance of surface tension and capillary waves for the study of fundamental processes affecting air-sea exchanges of matter, energy, and momentum.

Much of the discussion in this section follows that in Section 54 of *Fetter and Walecka* (2003). We again encounter surface tension effects in Section 60.2 when studying the Rayleigh-Taylor instability in the presence of gravity and surface tension.

52.11 Particle trajectories and Stokes drift

We here consider the trajectories of fluid particles moving as part of a wave field, going to the next order in asymptotics beyond the leading order results from Section 52.5.6. With a spatially constant wave amplitude, a fluid particle periodically returns to its original position. However, in the presence of wave inhomogeneities, such as the surface gravity waves considered in Sections 52.3 and 52.5, fluid particles oscillate between regions where the undulation in one direction does not match that in the other direction. In effect, a fluid particle spends a bit more time in the forward moving part of the wave crest than the backward moving part of the wave trough. This asymmetry leads to a net drift of fluid particles in the direction of the wave. Figure 52.4 illustrates particle trajectories in a deep water wave for the case where the Stokes drift is ignored, in which case the particles exhibit periodic orbits. In this section we focus on the Stokes drift, in which case the particle orbits are nearly periodic, but not exactly, so that they do not return to their initial point.

To describe fluid particle drift induced by waves requires us to distinguish between an average computed at a fixed point in space (Eulerian mean), versus along a fixed fluid particle (Lagrangian mean). Their difference defines the *Stokes correction*

$$\text{Lagrangian mean} = \text{Eulerian mean} + \text{Stokes correction}. \tag{52.187}$$

When applied to the trajectory of fluid particles, the Stokes correction is referred to as the *Stokes drift*. In linear waves, Stokes drift arises when the wave field has spatial inhomogeneities that cause a particle to sample distinct portions of the wave that lead to a net, or rectified, transport. For the examples considered in this section, where there are no boundaries, then the Eulerian mean vanishes so that the Lagrangian mean particle position equals to the Stokes drift.

In this section we introduce the basic mathematics to support equation (52.187) when applied to the fluid particle position within a plane wave. These ideas form part of the rudiments for wave-mean flow interaction theory further studied in Chapter 70 and pursued in far more detail by *Bühler* (2014a).

52.11.1 Formulation of Stokes drift

Consider a three-dimensional particle trajectory written in Cartesian coordinates,

$$\boldsymbol{X}(\boldsymbol{a}, t) = X(\boldsymbol{a}, t)\, \hat{\boldsymbol{x}} + Y(\boldsymbol{a}, t)\, \hat{\boldsymbol{y}} + Z(\boldsymbol{a}, t)\, \hat{\boldsymbol{z}}. \tag{52.188}$$

In the analysis of waves, it is common to assume the material coordinate, $\boldsymbol{a}$, is the initial position of a fluid particle, which we here assume. As discussed in Section 17.7.1, the particle trajectory is determined by time integrating the particle velocity

$$\frac{\partial \boldsymbol{X}(\boldsymbol{a}, t)}{\partial t} = \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a}, t), t] \tag{52.189}$$

so that

$$\boldsymbol{X}(\boldsymbol{a}, t) = \boldsymbol{X}(\boldsymbol{a}, 0) + \int_0^t \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a}, t'), t']\, \mathrm{d}t'. \tag{52.190}$$

This equation is a trivial result of time integrating the particle velocity. Nonetheless, it is useful to express the content of this equation in words. It says that the position at time, t, of a fluid

particle labelled by the material coordinate, $\boldsymbol{a}$, is given by the initial position of the particle, $\boldsymbol{X}(\boldsymbol{a}, 0)$, plus the time integrated movement of the particle following the fluid flow.

Equation (52.190) provides the trajectory, but only by knowing the velocity following the trajectory. To produce a result that is more readily computed analytically, we develop a Taylor series computed relative to the initial position of the fluid particle. In this manner we make use of the approximate expression for the particle velocity at time t

$$v^n[\boldsymbol{X}(\boldsymbol{a}, t), t] \approx v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] + \nabla v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] \cdot [\boldsymbol{X}(\boldsymbol{a}, t) - \boldsymbol{X}(\boldsymbol{a}, 0)] \tag{52.191a}$$

$$= v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] + \nabla v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] \cdot \int_0^t \frac{\mathrm{d}\boldsymbol{X}(\boldsymbol{a}, t')}{\mathrm{d}t'} \, \mathrm{d}t' \tag{52.191b}$$

$$= v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] + \nabla v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] \cdot \int_0^t \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a}, t'), t'] \, \mathrm{d}t', \tag{52.191c}$$

where the Taylor series was truncated after terms linear in the particle displacement $\boldsymbol{X}(\boldsymbol{a}, t) - \boldsymbol{X}(\boldsymbol{a}, 0)$. We emphasize two points regarding equation (52.191c).

- The velocity, $v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t]$, is the n'th component of the fluid velocity field evaluated at the initial point of the fluid particle trajectory, $\boldsymbol{X}(\boldsymbol{a}, 0)$, and at the time t. That is, $v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t]$ is the Eulerian velocity evaluated at the fixed Eulerian point, $\boldsymbol{X}(\boldsymbol{a}, 0)$.

- What determines the accuracty of the Taylor series? A suitable non-dimensional expansion coefficient for the Taylor expansion is the ratio of the particle displacement to the wave length, L,

  $$\epsilon = \frac{|\boldsymbol{X}(\boldsymbol{a}, t) - \boldsymbol{X}(\boldsymbol{a}, 0)|}{L}. \tag{52.192}$$

  This ratio is small for the small amplitude waves considered here, whereby the particle displacements are far smaller than the wavelength.

The integrand on the right hand side of equation (52.191c) is the Lagrangian velocity integrated over the time interval. To within the same order of accuracy as maintained for writing equation (52.191c), we can use the Eulerian velocity evaluated at the initial position, thus rendering

$$v^n[\boldsymbol{X}(\boldsymbol{a}, t), t] \approx v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] + \nabla v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] \cdot \int_0^t \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a}, 0), t'] \, \mathrm{d}t', \tag{52.193}$$

with rearrangement leading to

$$v^n[\boldsymbol{X}(\boldsymbol{a}, t), t] - v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] \approx \nabla v^n[\boldsymbol{X}(\boldsymbol{a}, 0), t] \cdot \int_0^t \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a}, 0), t'] \, \mathrm{d}t'. \tag{52.194}$$

The left hand side is the difference between the velocity following a fluid particle (the Lagrangian velocity for the moving fluid particle) from the velocity at the initial particle point (the Eulerian velocity at the initial point of the trajectory). The right hand side terms are all evaluated at the initial position, $\boldsymbol{X}(\boldsymbol{a}, 0)$. Furthermore, the right hand side is non-zero where the velocity at the initial position has a nonzero gradient (i.e., it is spatially inhomogeneous), with its inhomogeneity projecting onto the time integrated velocity at that point. Equation (52.194) says that the velocity following a fluid particle is modified from the velocity at its initial position if the particle moves through an inhomogeneous velocity field.

Stokes drift of fluid particles is defined as the difference of the velocities in equation (52.194)

when phased averaged, which we write as[15]

$$(v^{(\mathsf{S})})^n[\boldsymbol{X}(\boldsymbol{a},0),t] = \langle v^n[\boldsymbol{X}(\boldsymbol{a},t),t] - v^n[\boldsymbol{X}(\boldsymbol{a},0),t]\rangle \tag{52.195a}$$

$$\approx \left\langle \nabla v^n[\boldsymbol{X}(\boldsymbol{a},0),t] \cdot \int_0^t \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a},0),t']\,\mathrm{d}t' \right\rangle. \tag{52.195b}$$

This expression holds for any arbitrary initial point in the fluid, so that we can write it in a concise Eulerian form that dispenses with trajectories

$$(v^{(\mathsf{S})})^n(\boldsymbol{x},t) \approx \left\langle \nabla v^n(\boldsymbol{x},t) \cdot \int_0^t \boldsymbol{v}(\boldsymbol{x},t')\,\mathrm{d}t' \right\rangle. \tag{52.196}$$

We can draw an analogy between Stokes drift and surfing. Namely, the more a fluid particle samples larger amplitude variations in the velocity field (the gradient term), the further it drifts (the integral term).

52.11.2 Particle trajectories in a homogeneous wave

The expression (52.196) for the Stokes drift is general and will be specialized in Section 52.11.4 for the case of surface gravity waves. Before doing so, in this section and in Section 52.11.3 we determine particle trajectories for the traveling plane wave

$$\frac{\mathrm{d}X}{\mathrm{d}t} = U\sin(k\,x - \omega\,t) \tag{52.197a}$$

$$\frac{\mathrm{d}Z}{\mathrm{d}t} = -U\cos(k\,x - \omega\,t). \tag{52.197b}$$

We here set the wavevector to $\boldsymbol{k} = k\,\hat{\boldsymbol{x}}$, so that it is purely zonal, let $U > 0$ be the speed of the particle motion, and wrote X and Z for the Cartesian components of the particle trajectory. To simplify the mathematics we perform the analysis in a frame moving with the waves so that the phase $k\,x - \omega\,t$ can be replaced by $-\omega\,t$, so that the particle trajectories satisfy

$$\frac{\mathrm{d}X}{\mathrm{d}t} = -U\sin(\omega\,t) \tag{52.198a}$$

$$\frac{\mathrm{d}Z}{\mathrm{d}t} = -U\cos(\omega\,t). \tag{52.198b}$$

Figure 52.4 shows a schematic of the particle trajectories appropriate for a deep water gravity wave, with the trajectories resulting from equations (52.198a) and (52.198b) directly analogous.

We start by examining particle motion in the case with a constant wave amplitude, $U = U_0$. Particle trajectories in this case are clockwise in the x-z plane around a circle with radius U_0/ω

$$X(t) - X_0 = (U_0/\omega)\,[\cos(\omega t) - 1] \tag{52.199a}$$

$$Z(t) - Z_0 = -(U_0/\omega)\sin(\omega t), \tag{52.199b}$$

where the initial position at time $t = 0$ is

$$\boldsymbol{X}(t = t_0) = \hat{\boldsymbol{x}}\,X_0 + \hat{\boldsymbol{z}}\,Z_0, \tag{52.200}$$

and the center of the circle is

$$\boldsymbol{X}_{\text{center}} = [X_0 - U_0/\omega]\,\hat{\boldsymbol{x}} + Z_0\,\hat{\boldsymbol{z}}. \tag{52.201}$$

[15] We introduced the phase average in Section 8.1.2. It is realized by averaging over a 2π extent of the wave phase. It can be performed via a time average over a period, a space average over a wavelength, or a combination.

There is no Stokes drift since the particles return to their initial position each wave period.

52.11.3 Stokes drift from an inhomogeneous wave

Now consider the case of a vertically dependent wave amplitude, $U = U(z)$. The canonical example is where the wave amplitude decreases with depth, as for the surface gravity waves from Section 52.5. In turn, we expect there to be a fluid particle drift in the zonal direction introduced by the vertical wave inhomogeneity. This drift is a particular realization of Stokes drift.

To compute the leading order expression for the Stokes drift, expand U in a Taylor series about the initial position

$$U \approx U_0 + \sigma\,(Z - Z_0) \tag{52.202}$$

where the vertical shear, σ, has units of inverse time and is given by

$$\sigma = \left[\frac{\mathrm{d}U}{\mathrm{d}Z}\right]_{Z=Z_0}. \tag{52.203}$$

The Taylor series (52.202) is valid so long as the vertical trajectories maintain the inequality

$$|\sigma|\,|Z - Z_0| \ll U_0, \tag{52.204}$$

which says that the vertical shear is small

$$|\sigma| \ll \frac{U_0}{|Z - Z_0|}. \tag{52.205}$$

We use the Taylor series expansion (52.202) to solve for the vertical trajectory as determined by

$$\frac{\mathrm{d}(Z - Z_0)}{\mathrm{d}t} = -[U_0 + \sigma\,(Z - Z_0)]\cos(\omega t). \tag{52.206}$$

Rearrangement leads to

$$\int_{Z_0}^{Z} \frac{\mathrm{d}(Z - Z_0)}{U_0 + \sigma\,(Z - Z_0)} = -\int_0^t \cos(\omega t)\,\mathrm{d}t. \tag{52.207}$$

The left hand side integral can be computed by changing variables

$$\Sigma = U_0 + \sigma\,(Z - Z_0) \Longrightarrow \mathrm{d}\Sigma = \sigma\,\mathrm{d}(Z - Z_0), \tag{52.208}$$

so that equation (52.207) becomes

$$\int_{U_0}^{\Sigma} \frac{\mathrm{d}\Sigma}{\Sigma} = -\sigma \int_0^t \cos(\omega t)\,\mathrm{d}t. \tag{52.209}$$

Performing the integrals and evaluating the end points renders

$$\ln\left[1 + \frac{\sigma}{U_0}(Z - Z_0)\right] = -\frac{\sigma \sin(\omega t)}{\omega}, \tag{52.210}$$

which yields the exponential solution

$$1 + \frac{\sigma}{U_0}(Z - Z_0) = \mathrm{e}^{-(\sigma/\omega)\sin(\omega t)} \Longrightarrow Z - Z_0 = \frac{U_0}{\sigma}\left[-1 + \mathrm{e}^{-(\sigma/\omega)\sin(\omega t)}\right]. \tag{52.211}$$

The vertical particle position is seen to oscillate around its initial position Z_0.

We next consider the zonal particle position, in which case

$$\frac{\mathrm{d}(X - X_0)}{\mathrm{d}t} = -U_0 \left[1 + \frac{\sigma}{U_0}(Z - Z_0)\right] \sin(\omega t) = -U_0 \, \mathrm{e}^{-(\sigma/\omega)\sin(\omega t)} \sin(\omega t), \tag{52.212}$$

where we used equation (52.211) for the vertical trajectory. To make progress, we expand the exponential assuming the ratio of inverse time scales, σ/ω, is small

$$|\sigma/\omega| \ll 1. \tag{52.213}$$

In this limit, the vertical trajectory retains its unperturbed form (52.199b), and the zonal trajectory satisfies

$$\frac{\mathrm{d}(X - X_0)}{\mathrm{d}t} \approx -U_0 \sin(\omega t) \left[1 - \frac{\sigma}{\omega} \sin(\omega t)\right], \tag{52.214}$$

where we dropped terms of order $(\sigma/\omega)^2$. We can understand the scaling in equation (52.213) by noting that the period for the circular motion is given by

$$\tau_{\text{circle}} = 2\,\pi/\omega. \tag{52.215}$$

The inverse time, σ, introduces a time scale for the drift, defined according to

$$\tau_{\text{drift}} = 2\,\pi/|\sigma|. \tag{52.216}$$

A small ratio $|\sigma/\omega|$ thus implies

$$|\sigma/\omega| = \tau_{\text{circle}}/\tau_{\text{drift}} \ll 1. \tag{52.217}$$

Hence, we are solving for the zonal trajectory in the limit where the time scale for the circular motion is small (i.e., fast oscillations around the circle) relative to the time scale for the drift (i.e., slow drift).

Returning now to the approximate zonal trajectory equation (52.214) yields

$$\frac{\mathrm{d}(X - X_0)}{\mathrm{d}t} = -U_0 \sin(\omega t) \left[1 - \frac{\sigma}{\omega} \sin(\omega t)\right] \tag{52.218a}$$

$$= -U_0 \sin(\omega t) + \frac{U_0\,\sigma}{2\,\omega}\,[1 - \cos(2\,\omega t)], \tag{52.218b}$$

which integrates to

$$X - X_0 = \left(\frac{U_0}{\omega}\right)\left[\cos(\omega\,t) - 1 - \frac{\sigma \sin(2\,\omega\,t)}{4\,\omega} + \frac{\sigma\,t}{2}\right] \tag{52.219a}$$

$$= \underbrace{\left(\frac{U_0}{\omega}\right)[\cos(\omega\,t) - 1]}_{\text{homogeneous}} + \underbrace{\frac{U_0\,\sigma\,t}{2\,\omega}}_{\text{Stokes drift}} - \underbrace{\frac{U_0\,\sigma \sin(2\,\omega\,t)}{4\,\omega^2}}_{\text{higher harmonic}} + \mathcal{O}(\sigma/\omega)^2. \tag{52.219b}$$

The leading order term is the homogeneous motion given by equation (52.199a). The next term is the Stokes drift, followed by a higher order harmonic and then further terms on the order of $(\sigma/\omega)^2$. There is no vertical Stokes drift to this order in (σ/ω), so that the Stokes drift velocity is given by

$$\left[\frac{\boldsymbol{X} - \boldsymbol{X}_0}{t}\right]^{\text{drift}} = \frac{\sigma\,U_0}{2\omega}\,\hat{\boldsymbol{x}}. \tag{52.220}$$

The circular motion of the parcels is therefore deformed by the zonal Stokes drift. The drift

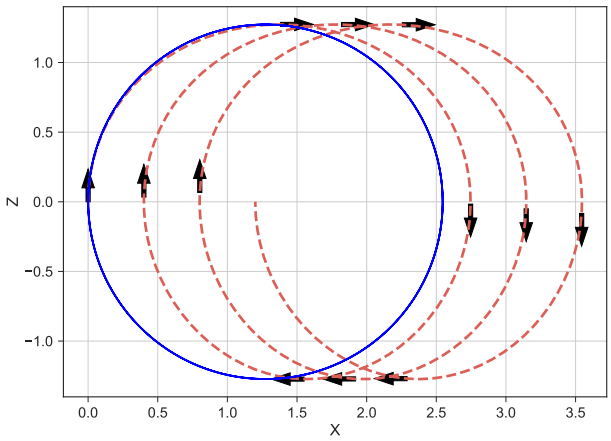

FIGURE 52.9: Example trajectories of fluid particles undergoing Stokes drift. Particle motion is clockwise in the x-z plane. For homogeneous waves, there is zero Stokes drift with circular trajectories given by equations (52.199a) and (52.199b), as depicted here by the blue trajectory. There is a Stokes drift in the presence of vertical derivative in the wave amplitude and thus in the particle velocity, with trajectories for this example given by equation (52.211) for the vertical component and equation (52.219b) for the horizontal component. We set the parameters as follows: $T = 2\pi/\omega = 60$ s, $U_0 = 0.1$ m s^{-1}, and $\sigma = \omega/10$ and exhibit trajectories over four minutes.

increases with larger wave amplitude (U_0 large); with larger vertical shear (σ large); and with longer period waves (ω small). Each of these wave properties affects the time that a fluid particle samples the wave as it moves forward versus backward, thus determining the magnitude of the Stokes drift. See Figure 52.9 for an illustration based on a particular choice for the dimensional parameters.

52.11.4 Stokes drift for surface gravity waves

The velocity field for surface gravity waves, given by equations (52.113a) and (52.113b), is far more complicated than the prototypical wave considered in Sections 52.11.2 and 52.11.3. For that reason we make use of the general expression (52.196) to determine the Stokes drift velocity for surface gravity waves in a flat channel, rather than directly integrate to determine the trajectories. Hence, we need to compute terms in the following equations for surface gravity waves

$$u^{(\mathsf{S})}(\boldsymbol{x}) \approx \left\langle \nabla u(\boldsymbol{x},t) \cdot \int_0^t \boldsymbol{v}(\boldsymbol{x},t')\,\mathrm{d}t' \right\rangle \tag{52.221a}$$

$$v^{(\mathsf{S})}(\boldsymbol{x}) \approx \left\langle \nabla v(\boldsymbol{x},t) \cdot \int_0^t \boldsymbol{v}(\boldsymbol{x},t')\,\mathrm{d}t' \right\rangle \tag{52.221b}$$

$$w^{(\mathsf{S})}(\boldsymbol{x}) \approx \left\langle \nabla w(\boldsymbol{x},t) \cdot \int_0^t \boldsymbol{v}(\boldsymbol{x},t')\,\mathrm{d}t' \right\rangle . \tag{52.221c}$$

The components to the velocity field for surface gravity waves are given by equations (52.113a) and (52.113b), repeated here to be self-contained

$$\boldsymbol{u} = \frac{g\,\eta_0\,\hat{\boldsymbol{k}}}{C_{\mathsf{p}}} \frac{\cosh[|\boldsymbol{k}|\,(z+H)]\sin(\mathcal{P})}{\cosh(|\boldsymbol{k}|\,H)} \tag{52.222a}$$

$$w = -\frac{g\,\eta_0}{C_{\mathsf{p}}} \frac{\sinh[|\boldsymbol{k}|\,(z+H)]\cos(\mathcal{P})}{\cosh(|\boldsymbol{k}|\,H)}, \tag{52.222b}$$

and their spatial gradients are given by

$$\nabla u = \frac{g\,\eta_0\,k_x\left[\hat{\boldsymbol{k}}\cos(\mathcal{P})\cosh[|\boldsymbol{k}|\,(z+H)] + \hat{\boldsymbol{z}}\sin(\mathcal{P})\sinh[|\boldsymbol{k}|\,(z+H)]\right]}{C_{\mathsf{p}}\cosh(|\boldsymbol{k}|\,H)} \tag{52.223a}$$

$$\nabla v = \frac{g\,\eta_0\,k_y\left[\hat{\boldsymbol{k}}\cos(\mathcal{P})\cosh[|\boldsymbol{k}|\,(z+H)] + \hat{\boldsymbol{z}}\sin(\mathcal{P})\sinh[|\boldsymbol{k}|\,(z+H)]\right]}{C_{\mathsf{p}}\cosh(|\boldsymbol{k}|\,H)} \tag{52.223b}$$

$$\nabla w = \frac{g\,\eta_0\,|\boldsymbol{k}|\left[\hat{\boldsymbol{k}}\sin(\mathcal{P})\sinh[|\boldsymbol{k}|\,(z+H)] - \hat{\boldsymbol{z}}\cos(\mathcal{P})\cosh[|\boldsymbol{k}|\,(z+H)]\right]}{C_{\mathsf{p}}\cosh(|\boldsymbol{k}|\,H)}, \tag{52.223c}$$

where we introduced the phase

$$\mathcal{P} = \boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t \tag{52.224}$$

to produce more tidy expressions, and recall that

$$\hat{\boldsymbol{k}} = \boldsymbol{k}/|\boldsymbol{k}| = (\hat{\boldsymbol{x}}\,k_x + \hat{\boldsymbol{y}}\,k_y)/|\boldsymbol{k}| \tag{52.225}$$

is the wave direction in the horizontal plane. We also require the following time integrals

$$\int_0^t \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t')\,\mathrm{d}t' = \omega^{-1}\left[\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) - \cos(\boldsymbol{k}\cdot\boldsymbol{x})\right] \tag{52.226a}$$

$$\int_0^t \cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t')\,\mathrm{d}t' = -\omega^{-1}\left[\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) - \sin(\boldsymbol{k}\cdot\boldsymbol{x})\right]. \tag{52.226b}$$

Use of these results in equations (52.221a)-(52.221c) leads to the horizontal Stokes drift velocity for surface gravity waves in a flat bottom domain, here written in three equivalent manners through use of the dispersion relation and the phase speed

$$\boldsymbol{v}^{(\mathsf{S})} = \frac{\boldsymbol{k}\,(g\,\eta_0)^2\cosh[2|\boldsymbol{k}|\,(z+H)]}{2\,\omega\,C_{\mathsf{p}}^2\cosh^2(|\boldsymbol{k}|\,H)} \tag{52.227a}$$

$$= \frac{\boldsymbol{k}\,\omega\,\eta_0^2\cosh[2\,|\boldsymbol{k}|\,(z+H)]}{2\sinh^2(|\boldsymbol{k}|\,H)} \tag{52.227b}$$

$$= \frac{\hat{\boldsymbol{k}}\,C_{\mathsf{p}}\,(|\boldsymbol{k}|\,\eta_0)^2\cosh[2\,|\boldsymbol{k}|\,(z+H)]}{2\sinh^2(|\boldsymbol{k}|\,H)}. \tag{52.227c}$$

The purely horizontal nature of the Stokes drift agrees with that found for the prototypical wave in Section 52.11.3.

The ratio of the Stokes speed at $z=0$ to that at $z=-H$ is given by

$$\frac{\hat{\boldsymbol{k}}\cdot\boldsymbol{v}^{(\mathsf{S})}(z=0)}{\hat{\boldsymbol{k}}\cdot\boldsymbol{v}^{(\mathsf{S})}(z=-H)} = \cosh(2\,|\boldsymbol{k}|\,H). \tag{52.228}$$

In the deep water limit, $k\,H \gg 1$, this ratio is much greater than unity, indicating a nontrivial vertical shear in the zonal Stokes velocity. In contrast, the ratio becomes unity in the shallow water limit, $|\boldsymbol{k}|\,H \ll 1$, so that there is no vertical shear to the Stokes velocity. In this case the Stokes speed takes on the depth-independent shallow water form

$$\boldsymbol{v}^{(\mathsf{S})}\cdot\hat{\boldsymbol{k}} \approx (C_{\mathsf{p}}/2)\,(\eta_0/H)^2 \quad \text{for } |\boldsymbol{k}|\,H \ll 1, \tag{52.229}$$

which has no dependence on the wavelength (other than $|\boldsymbol{k}|\,H \ll 1$). This speed is much smaller

than the deep water Stokes speed at $z = 0$, which we can see by computing

$$\hat{\boldsymbol{k}} \cdot \boldsymbol{v}^{(\mathsf{S})}(z=0) \approx \eta_0^2 \, g^{1/2} \, |\boldsymbol{k}|^{3/2}/4 \quad \text{for } |\boldsymbol{k}| \, H \gg 1 \tag{52.230a}$$

$$\hat{\boldsymbol{k}} \cdot \boldsymbol{v}^{(\mathsf{S})}(z=0) \approx (\eta_0/H)^2 \, \sqrt{g \, H} \quad \text{for } |\boldsymbol{k}| \, H \ll 1, \tag{52.230b}$$

so that the ratio of the deep water to shallow water Stokes speed at $z = 0$ is

$$\frac{\hat{\boldsymbol{k}} \cdot \boldsymbol{v}^{(\mathsf{S})\mathsf{dw}}(z=0)}{\hat{\boldsymbol{k}} \cdot \boldsymbol{v}^{(\mathsf{S})\mathsf{sw}}(z=0)} \approx |\boldsymbol{k} \, H|^{3/2}/4 \gg 1. \tag{52.231}$$

Since the phase average vanishes at a fixed point in space, the Eulerian mean vanishes so that the Lagrangian mean in equation (52.187) is given by the Stokes drift. Hence, the presence of Stokes drift indicates that there is a net movement of matter in the direction of the wave. In particular, for the shallow water case there is a steady column of fluid moving in the direction of the wave according to the Stokes drift expression (52.229). It is important to appreciate that this example is on an unbounded domain. If the domain is bounded so that the phase averaged center of mass for the fluid is fixed in space, then the Eulerian mean exactly compensates the Stokes drift to render a zero Lagrangian mean motion.

52.11.5 Comments and further study

Is Stokes drift a nonlinear phenomena? In answering this question we note that Stokes drift occurs with particle motion in linear waves, but the waves must be inhomogeneous such as the surface gravity waves studied in this chapter. Nonlinearity appears in the form of the particle-following (Lagrangian) average, as can be seen by the expression of Stokes drift given by equation (52.196)

$$(v^{(\mathsf{S})})^n(\boldsymbol{x}, t) \approx \left\langle \nabla v^n(\boldsymbol{x}, t) \cdot \int_0^t \boldsymbol{v}(\boldsymbol{x}, t') \, \mathrm{d}t' \right\rangle . \tag{52.232}$$

The dot product of the velocity gradient with the time integrated velocity (to give the time integrated position) is nonlinear. So although the waves are linear, the Lagrangian kinematics of particle trajectories introduces nonlinearites.

Stokes drift occurs in many guises when studying the motion of fluid particles within wave fields. We revisit elements of Stokes drift in Chapter 70 when studying the rudiments of eddy-induced tracer transport. This video from Prof. Hogg at Australian National University provides an overview of the discussion in this section along with some laboratory experiments to illustrate Stokes drift. Section 10.1.1 of *Bühler* (2014a) discusses Stokes corrections in the context of generalized Lagrangian mean.

52.12 Exercises

EXERCISE 52.1: UNIQUENESS THEOREM FOR POTENTIAL FLOW
Here we show that there is a unique potential flow that satisfies any given boundary condition. For that purpose, assume there are two potential flows, $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$, that satisfy the same boundary conditions on $\partial\mathcal{R}$. Show that $\boldsymbol{v}_1 = \boldsymbol{v}_2$ throughout the domain. Hint: consider the domain integrated kinetic energy contained in the difference field, $\boldsymbol{V} = \boldsymbol{v}_1 - \boldsymbol{v}_2$, and make use of the results from Section 52.2.7.

EXERCISE 52.2: SURFACE GRAVITY WAVES ON THE VIDEO CHANNEL *Veritasium*
Veritasium is a science channel that has the following educational video on surface ocean waves.

However, the host makes a few minor errors in this video. Discuss the errors.

EXERCISE 52.3: SURFACE KINEMATIC BOUNDARY CONDITION
Show that for an irrotational and non-divergent flow, the surface kinematic boundary condition (52.25) can be written

$$\partial_t \eta = -\nabla \cdot [(z-\eta)\, \nabla \Psi] \quad \text{at } z = \eta. \tag{52.233}$$

Hint: read Section 21.3.

EXERCISE 52.4: GAUGE INVARIANCE OF KINETIC ENERGY
In Section 52.2.6 we argued that the gauge invariance of the globally integrated kinetic energy follows from equation (52.49): $\int \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = 0$, which follows for the case where the free surface is a material interface so that $\partial_t \eta = -\nabla \cdot \boldsymbol{U}$. Discuss whether the kinetic energy remains gauge invariant if the upper free surface is not material, so that $\partial_t \eta = -\nabla \cdot \boldsymbol{U} + Q_{\mathsf{m}}/\rho$, where $Q_{\mathsf{m}} \neq 0$ is a mass flux crossing the free surface and with this mass flux having density equal to the constant layer density, ρ.

Hint: to write $\boldsymbol{v} = -\nabla \Psi$ requires $\nabla \times \boldsymbol{v} = 0$. Do we expect the flow to remain irrotational in the presence of nonzero Q_{m} when the density of Q_{m} equals to that of the homogeneous domain?

EXERCISE 52.5: ENERGETICS OF DEPTH INTEGRATED FLOW IN FULL NONLINEAR THEORY
In Section 52.4.4 we computed the energy budget for the depth integrated flow within the linearized theory. Derive the mechanical energy equation for the full nonlinear theory integrated over $-H \leq z \leq \eta$, thus providing the nonlinear analog to the energy equation (52.107) derived for the linear theory. Do not assume the bottom is flat for the nonlinear theory. Confirm that all terms missing from the energy budget (52.107) are third order or higher. Hint: make use of results from Section 52.2.6.

EXERCISE 52.6: ENERGETICS OF CAPILLARY-GRAVITY WAVES
In Section 52.4.4 we derived equations for the energetics of depth integrated linearized flow in absence of surface tension. Extend that discussion to include surface tension as discussed in Section 52.10. Specifically, derive the equation for the time tendency of the depth integrated sum of the kinetic plus gravitational potential energy. Interpret the extra term arising from surface tension. Hint: start at a point in the derivation from Section 52.4.4 that is valid whether surface tension is present or not. Thereafter, make use of the dynamic boundary condition that includes surface tension.

EXERCISE 52.7: STOKES DRIFT FOR ONE-DIMENSIONAL MONOCHROMATIC WAVE
Consider a one-dimensional monochromatic longitudinal wave with velocity

$$u = u_0 \sin(k\, x - \omega\, t), \tag{52.234}$$

where u_0 is the wave amplitude, $k = 2\pi/\Lambda > 0$ the wave number, Λ the wavelength, $\omega = 2\pi/T > 0$ the angular frequency, T the wave period, and $C_{\mathsf{p}} = \omega/k = \Lambda/T$ is the phase speed. A longitudinal wave is one whose particle motions are parallel to the wave vector, which in this exercise are both in the $\hat{\boldsymbol{x}}$ direction. Determine the wave period averaged Stokes velocity to first order accuracy in the small parameter

$$\epsilon = u_0/C_{\mathsf{p}} = u_0\, k/\omega = u_0\, T/\Lambda, \tag{52.235}$$

with this parameter the ratio of the wave amplitude to wave speed, or equivalently the ratio of the length scale of particle displacements to the wavelength. Hint: make use of the general result given by equation (52.196).

Chapter 53

INERTIAL WAVES ON THE f-PLANE

Inertial waves are dispersive waves that arise from the Coriolis acceleration. Fluid particles within inertial waves exhibit the anti-cyclonic *inertial oscillations* studied in Section 14.4. We study inertial waves in an inviscid, homogeneous (constant density), f-plane fluid, and examine traveling plane inertial waves in an unbounded domain as well as forced inertial waves in both unbounded domains and vertically bounded domains. Inertial waves provide the mechanism for vertical stiffness exhibited by the *Taylor-Proudman effect* (Section 31.5.3), and we discuss that role in this chapter.

READER'S GUIDE TO THIS CHAPTER

We assume a working knowledge of fluid mechanics in a rotational reference frame as studied in Chapter 31. Our study of inertial waves was inspired by Section 9.2 of *Davidson* (2015), who emphasizes the role of inertial waves in forming vertically stiff structures in rapidly rotating turbulent flows, as well as Section 2.2 of *Stern* (1975), the Epilogue of *Lighthill* (1978), and the concise review by *Mory* (1992). For a visualization of inertial waves, refer to the 18 minute mark from the rotating tank experiments of Prof. Fultz, which illustrates inertial oscillations within a bounded rotating homogeneous fluid. We again encounter inertial waves in Section 57.9 when studying free inertia-gravity waves, in which case the limit of zero buoyancy frequency reduces to the inertial waves of this chapter.[a]

[a] Some authors refer to Rossby waves as a type of inertial wave, since Rossby waves also owe their existence to the Coriolis acceleration. However, we consider *inertial waves* to be those waves occuring on an f-plane, where Rossby waves do not occur. We study Rossby waves in Chapters 54, 55, and 62.

53.1 Equations for a uniformly rotating homogeneous fluid

We study inertial motions in a homogeneous and unbounded inviscid fluid on an f-plane. To start that study, we here formulate the nonlinear equations for the fluid motion and follow up in Section 53.2 with the linearized equations. Recall that we also studied motion of surface waves in a homogeneous fluid in Chapter 52. One key distinction is that here we are concerned with motion away from any boundary, including a free surface. Additionally, we now work on the f-plane.

53.1.1 Velocity equation

A homogeneous inviscid fluid on the f-plane is governed by the momentum equation

$$[\partial_t + (\boldsymbol{v} \cdot \nabla)]\, \boldsymbol{v} + 2\, \boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla p/\rho - g\, \hat{\boldsymbol{z}}, \tag{53.1}$$

where g is the effective gravitational acceleration that arises from central gravity and planetary centrifugal (Section 13.10.4), and

$$\boldsymbol{\Omega} = \Omega\, \hat{\boldsymbol{z}} = (f/2)\, \hat{\boldsymbol{z}} \tag{53.2}$$

is the constant angular frequency of the f-plane. Recall from Section 24.5 that the f-plane is based on assuming a locally flat geopotential, in which case the centrifugal acceleration from the rotating reference frame is incorporated into the effective gravitational acceleration. In this manner, each point on the f-plane experiences the same effects from rotation of the reference frame.

As when formulating the Boussinesq approximation in Section 29.1.1, we find it useful to decompose pressure according to a static background hydrostatic pressure, plus a dynamical pressure

$$p = p_0 + \rho\, \varphi \quad \text{where} \quad \mathrm{d}p_0/\mathrm{d}z = -\rho\, g, \tag{53.3}$$

with ρ the constant density and $p_0(z)$ the static background hydrostatic pressure that exactly balances the fluid weight. This decomposition brings the momentum equation 53.1 to the form

$$[\partial_t + (\boldsymbol{v} \cdot \nabla)]\, \boldsymbol{v} + 2\, \boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla \varphi \tag{53.4}$$

There is no buoyancy since density is uniform (Chapter 30).

Furthermore, again since the density is uniform everywhere, and since we are ignoring all boundaries, there can be no hydrostatic pressure induced either by gradients of the density nor by gradients of the boundary[1] As a result, the dynamical pressure is fully non-hydrostatic for the system we are studying here.

[1] Recall that for surface waves in a homogeneous fluid layer, a hydrostatic pressure is generated through undulations of the free ocean surface as given by equation (52.18).

53.1.2 Vorticity equation

In addition to the velocity equation, we make use of the vorticity equation, whose nonlinear form is derived from the vector invariant velocity equation (see Section 40.3.1)

$$\partial_t \boldsymbol{v} + (2\,\boldsymbol{\Omega} + \boldsymbol{\omega}) \times \boldsymbol{v} = -\nabla(\varphi + \mathcal{K}), \tag{53.5}$$

where we introduced the kinetic energy per mass and the relative vorticity

$$\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v}/2 \quad \text{and} \quad \boldsymbol{\omega} = \nabla \times \boldsymbol{v}. \tag{53.6}$$

The vorticity equation (40.42) takes on the following form in this constant density inviscid fluid

$$[\partial_t + (\boldsymbol{v} \cdot \nabla)]\,\boldsymbol{\omega}_{\text{a}} = (\boldsymbol{\omega}_{\text{a}} \cdot \nabla)\,\boldsymbol{v} \quad \text{with} \quad \boldsymbol{\omega}_{\text{a}} = 2\,\boldsymbol{\Omega} + \boldsymbol{\omega}. \tag{53.7}$$

Noting that $\boldsymbol{\Omega}$ is independent of space and time allows us to write the relative vorticity equation

$$\partial_t \boldsymbol{\omega} = [(2\,\boldsymbol{\Omega} + \boldsymbol{\omega}) \cdot \nabla]\,\boldsymbol{v}. \tag{53.8}$$

53.1.3 Energy equations

Taking the scalar product of $\boldsymbol{v}$ with the velocity equation (53.1) yields the equation for the kinetic energy per mass, $\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v}/2$, and gravitational potential energy per mass, $\Phi = g\,z$ (i.e., the geopotential), and their sum (the mechanical energy per mass)

$$\frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} = -\boldsymbol{v} \cdot \nabla p/\rho - w\,g \tag{53.9a}$$

$$\frac{\mathrm{D}\Phi}{\mathrm{D}t} = w\,g \tag{53.9b}$$

$$\frac{\mathrm{D}(\mathcal{K} + \Phi)}{\mathrm{D}t} = -\boldsymbol{v} \cdot \nabla p/\rho. \tag{53.9c}$$

Since the fluid density is uniform and constant, the gravitational potential energy decouples from the kinetic energy through use of the pressure decomposition (53.3), thus leading to

$$\frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} = -\boldsymbol{v} \cdot \nabla\varphi = -\nabla \cdot (\boldsymbol{v}\,\varphi). \tag{53.10}$$

Hence, the kinetic energy is materially modified for flows where the velocity is misaligned with constant dynamic pressure surfaces (e.g., kinetic energy increases when flow is down the pressure gradients), or equivalently where there is a convergence of the dynamical pressure flux.

53.2 Linearized equations

We here formulate the linear equations for an inviscid homogeneous fluid moving on an f-plane, with these equations providing the basis for the study of inertial waves.

53.2.1 Linearized velocity equation

We are interested in small amplitude fluctuations relative to a state of zero motion. Linearization of the velocity equation (53.4) occurs by dropping the self-advection term, $(\boldsymbol{v} \cdot \nabla)\,\boldsymbol{v}$, thus leading to

$$\partial_t \boldsymbol{v} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla\varphi. \tag{53.11}$$

With $\boldsymbol{\Omega}$ independent of time, we see that the velocity projected onto $\boldsymbol{\Omega}$ satisfies

$$\partial_t(\boldsymbol{v} \cdot \boldsymbol{\Omega}) = -\boldsymbol{\Omega} \cdot \nabla\varphi. \tag{53.12}$$

Hence, if there is no pressure gradient along the direction of the rotation axis, then the velocity of the linear flow in that direction remains constant in time. For rotation around the vertical axis, $\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}$, and with no vertical dynamic pressure gradient, $\partial_z\varphi = 0$, then the vertical velocity is static, $\partial_t w = 0$.

53.2.2 Forced oscillator equation for the velocity

Taking a time derivative on the velocity equation (53.11) and back-substituting the velocity equation leads to

$$\partial_{tt}\boldsymbol{v} + 4\,\Omega^2\,\boldsymbol{v} - 4\,\boldsymbol{\Omega}\,(\boldsymbol{v} \cdot \boldsymbol{\Omega}) = 2\,\boldsymbol{\Omega} \times \nabla\varphi - \partial_t\nabla\varphi. \tag{53.13}$$

Now decompose the velocity according to the orientation of the rotation vector

$$\widehat{\boldsymbol{\Omega}} = \boldsymbol{\Omega}/|\boldsymbol{\Omega}| \tag{53.14a}$$
$$\boldsymbol{v} = \boldsymbol{v}_\perp + \boldsymbol{v}_\parallel \tag{53.14b}$$
$$\boldsymbol{v}_\perp = \boldsymbol{v} - \widehat{\boldsymbol{\Omega}}\,(\widehat{\boldsymbol{\Omega}} \cdot \boldsymbol{v}) \tag{53.14c}$$
$$\boldsymbol{v}_\parallel = \boldsymbol{v} - \boldsymbol{v}_\perp = \widehat{\boldsymbol{\Omega}}\,(\widehat{\boldsymbol{\Omega}} \cdot \boldsymbol{v}), \tag{53.14d}$$

which allows us to decompose equation (53.13) into an equation for the parallel velocity and one for the perpendicular velocity

$$\partial_t[\widehat{\boldsymbol{\Omega}} \cdot (\partial_t\boldsymbol{v} + \nabla\varphi)] = 0 \tag{53.15a}$$
$$(\partial_{tt} + 4\,\Omega^2)\,\boldsymbol{v}_\perp = 2\,\widehat{\boldsymbol{\Omega}} \times \nabla\varphi - \partial_t[\nabla\varphi - \widehat{\boldsymbol{\Omega}}\,(\widehat{\boldsymbol{\Omega}} \cdot \nabla\varphi)]. \tag{53.15b}$$

Equation (53.15a) says that the projection of $\partial_t\boldsymbol{v} + \nabla\varphi$ onto the rotation axis remains constant in time. With $\widehat{\boldsymbol{\Omega}} = \hat{\boldsymbol{z}}$ then

$$\partial_t(\partial_t w + \partial_z\varphi) = 0. \tag{53.16}$$

Equation (53.15b) is a forced simple harmonic oscillator equation for motion in the plane perpendicular to the rotation axis. The natural angular frequency is $2\,\Omega$ and the forcing arises from pressure gradients in the perpendicular plane. Again, with $\widehat{\boldsymbol{\Omega}} = \hat{\boldsymbol{z}}$, equation (53.15b) becomes

$$(\partial_{tt} + 4\,\Omega^2)\,\boldsymbol{u} = 2\,\Omega\,\hat{\boldsymbol{z}} \times \nabla\varphi - \partial_t\nabla_{\!\mathsf{h}}\varphi. \tag{53.17}$$

The appearance of an oscillator equation anticipates the simple harmonic oscillations of fluid particles within a linear wave.

53.2.3 Forced oscillator equation for $\nabla_{\!\mathsf{h}} \cdot \boldsymbol{u} = -\partial_z w$

We find it useful to determine expressions for the horizontal velocity divergence in the special case of $f = 2\,\boldsymbol{\Omega} = 2\,\Omega\,\hat{\boldsymbol{z}}$, in which case equation (53.17) has the two components

$$(\partial_{tt} + f^2)\,u = -f\,\partial_y\varphi - \partial_{xt}\varphi \tag{53.18a}$$
$$(\partial_{tt} + f^2)\,v = f\,\partial_x\varphi - \partial_{yt}\varphi. \tag{53.18b}$$

Taking ∂_x on the first equation and ∂_y on the second, and then adding leads to

$$(\partial_{tt} + f^2)\,\nabla_{\!\mathsf{h}} \cdot \boldsymbol{u} = -\nabla_{\!\mathsf{h}}(\partial_t\varphi) \Longleftrightarrow (\partial_{tt} + f^2)\,\partial_z w = \nabla_{\!\mathsf{h}}(\partial_t\varphi). \tag{53.19}$$

Evidently, if the vertical velocity is a linear function of z (as in the long wave limit), then the pressure is independent of z, which in turn from equations (53.18a) and (53.18b) mean that $\partial_z \boldsymbol{u} = 0$. We make use of this property in Section 53.5.2 when discussing inertial waves forced from a moving sinusoidal boundary.

53.2.4 Wave equation for the vertical velocity

Taking the vertical derivative of equation (53.19) and then using equation (53.16) renders the wave equation for the vertical velocity in the case that $\boldsymbol{\Omega} = \hat{\boldsymbol{z}}\,\Omega$

$$(\partial_{tt}\nabla^2 + f^2\,\partial_{zz})w = 0. \tag{53.20}$$

This equation provides the starting point for studies of inertial oscillations on an f-plane. In Section 53.2.6 we derive a slightly more general form of this equation for an arbitrary oriented rotation vector.

53.2.5 Linearized vorticity equation

Taking the curl of the linear velocity equation (53.11) eliminates the pressure gradient and yields the linear vorticity equation

$$\partial_t \boldsymbol{\omega} = 2\,(\boldsymbol{\Omega}\cdot\nabla)\,\boldsymbol{v}. \tag{53.21}$$

To reach this result requires the identity (2.39h) for the curl of a cross product. We also assumed $\boldsymbol{\Omega}$ has no spatial dependence so that all of its derivatives vanish.

The linear vorticity equation (53.21) can also be derived by linearizing the nonlinear vorticity equation (53.8) by dropping the contributions from nonlinear stretching and tilting, which are processes we studied in Section 40.5. So the only source for vorticity in the linear theory arises from stretching and tilting along the rotational axis. That is, from the derivative of velocity in a direction aligned with the rotational axis. With $\boldsymbol{\Omega} = \hat{\boldsymbol{z}}\,\Omega$, the vorticity evolves according to

$$\partial_t \boldsymbol{\omega} = 2\,\Omega\,\partial_z \boldsymbol{v}, \tag{53.22}$$

in which case the horizontal vorticity components evolve according to vertical tilting whereas the vertical component evolves according to vertical stretching[2]

$$\partial_t(\hat{\boldsymbol{x}}\cdot\boldsymbol{\omega}) = 2\,\Omega\,\partial_z u \quad \text{and} \quad \partial_t(\hat{\boldsymbol{y}}\cdot\boldsymbol{\omega}) = 2\,\Omega\,\partial_z v \quad \text{and} \quad \partial_t(\hat{\boldsymbol{z}}\cdot\boldsymbol{\omega}) = 2\,\Omega\,\partial_z w. \tag{53.23}$$

Evidently, inertial waves carry a non-zero vorticity, and that vorticity is directly generated by the rotation vector, $\boldsymbol{\Omega}$, in the presence of velocity gradients.

53.2.6 The inertial wave equation for general $\boldsymbol{\Omega}$

To develop a wave equation, we take a time derivative of the linear vorticity equation (53.21), and make use of the linearized momentum equation (53.11), thus leading to

$$\partial_{tt}\boldsymbol{\omega} = -2\,(\boldsymbol{\Omega}\cdot\nabla)\,(2\,\boldsymbol{\Omega}\times\boldsymbol{v} + \nabla\varphi). \tag{53.24}$$

To eliminate the pressure gradient we take another curl and again make use of the identity (2.39h) to write

$$\nabla\times\boldsymbol{\omega} = \nabla\times(\nabla\times\boldsymbol{v}) = \nabla(\nabla\cdot\boldsymbol{v}) - \nabla^2\boldsymbol{v} = -\nabla^2\boldsymbol{v}, \tag{53.25}$$

where $\nabla\cdot\boldsymbol{v} = 0$ since the fluid density is constant. We also make use of Cartesian tensor calculus from Chapter 2, remembering that $\boldsymbol{\Omega}$ and the permutation symbol are constants, to derive the

[2] We study vortex stretching and tilting in Section 40.5.3.

identity

$$
\begin{aligned}
(\nabla \times [(\boldsymbol{\Omega} \cdot \nabla)\,(\boldsymbol{\Omega} \times \boldsymbol{v})])^m &= \epsilon^{mnp}\,\partial_n[\Omega^s \partial_s\,(\boldsymbol{\Omega} \times \boldsymbol{v})_p] && \text{(53.26a)}\\
&= \epsilon^{mnp}\,\partial_n[\Omega^s \partial_s\,\epsilon_{pqr}\,\Omega^q\,v^r] && \text{(53.26b)}\\
&= \epsilon^{mnp}\,\epsilon_{qrp}\,\Omega^s\,\Omega^q\,\partial_n \partial_s v^r && \text{(53.26c)}\\
&= (\delta^m{}_q\,\delta^n{}_r - \delta^m{}_r\,\delta^n{}_q)\,\Omega^s\,\Omega^q\,\partial_n \partial_s v^r && \text{(53.26d)}\\
&= \Omega^s\,(\Omega^m\,\partial_r\,\partial_s v^r - \Omega^n\,\partial_n\,\partial_s\,v^m) && \text{(53.26e)}\\
&= -(\boldsymbol{\Omega} \cdot \nabla)^2\,v^m, && \text{(53.26f)}
\end{aligned}
$$

where we made use of the ϵ-tensor identity (1.69) as well as $\nabla \cdot \boldsymbol{v} = 0$. We are thus led to the wave equation for inertial waves, which is satisfied separately for each of the Cartesian components of the velocity field

$$
[\partial_{tt}\nabla^2 + (2\,\boldsymbol{\Omega} \cdot \nabla)^2]\,\boldsymbol{v} = 0 \Longleftrightarrow \partial_{tt}(\nabla \times \boldsymbol{\omega}) = (2\,\boldsymbol{\Omega} \cdot \nabla)^2\,\boldsymbol{v}. \tag{53.27}
$$

The vertical component of the first equation reduces to equation (53.20) when $\boldsymbol{\Omega} = \hat{\boldsymbol{z}}\,\Omega$. The second expression makes use of equation (53.25) that relates the curl of the vorticity to the Laplacian of the velocity.

53.3 Plane inertial waves

In this section we study the physics of plane inertial waves moving in an unbounded domain.

53.3.1 Dispersion relation for inertial waves

The inertial wave equation (53.27) provides the starting point for developing mechanical properties of inertial waves. To develop the dispersion relation we consider a traveling plane wave solution of the form

$$
\boldsymbol{v} = \tilde{\boldsymbol{v}}\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)} \quad \text{and} \quad \varphi = \tilde{\varphi}\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)}, \tag{53.28}
$$

with three-dimensional wavevector and wave direction unit vector

$$
\boldsymbol{k} = \hat{\boldsymbol{x}}\,k_x + \hat{\boldsymbol{y}}\,k_y + \hat{\boldsymbol{z}}\,k_z \quad \text{and} \quad \hat{\boldsymbol{k}} = (\hat{\boldsymbol{x}}\,k_x + \hat{\boldsymbol{y}}\,k_y + \hat{\boldsymbol{z}}\,k_z)/|\boldsymbol{k}|. \tag{53.29}
$$

We introduced complex amplitudes, $\tilde{\boldsymbol{v}}$ and $\tilde{\varphi}$, for the velocity and pressure. The angular frequency, $\omega \geq 0$, is determined as a function of the wavevector according to the dispersion relation (53.31) derived below.[3] As we are considering free space waves (no boundaries), there is no preferred length scale for the inertial waves.[4] Furthermore, since the flow is non-divergent and the waves have a three dimensional wavevector, the constraint $\nabla \cdot \boldsymbol{v} = 0$ means that the velocity of fluid particles is perpendicular to the wavevector

$$
\nabla \cdot \boldsymbol{v} = 0 \Longrightarrow \boldsymbol{v} \cdot \boldsymbol{k} = 0. \tag{53.30}
$$

This orientation of wavevector and fluid velocity characterizes *transverse waves*, in which lines of constant wave phase (e.g., wave crests and troughs) are everywhere perpendicular to $\boldsymbol{k}$. We illustrate this property of transverse waves in Figure 53.1.

Plugging the wave ansatz (53.28) into the inertial wave equation (53.27) leads to the *dispersion*

[3] Be careful to distinguish the angular frequency, ω, from the vorticity vector, $\boldsymbol{\omega}$.

[4] Inertial waves in a bounded domain will generally have quantized wavenumbers, as required by the boundary conditions.

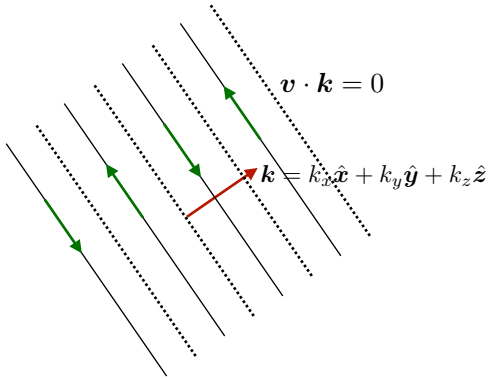

FIGURE 53.1: Illustrating the transverse nature of plane waves appearing in a homogeneous fluid with constant density, whereby $\boldsymbol{v} \cdot \boldsymbol{k} = 0$. The alternating solid-dotted lines depict lines of constant phase that differ by $\pi/2$ radians so that the velocity field switches sign between every π radians.

relation

$$\omega^2 = \varpi^2(\boldsymbol{k}) = (2\,\boldsymbol{\Omega} \cdot \boldsymbol{k})^2/|\boldsymbol{k}|^2 = (2\,\boldsymbol{\Omega} \cdot \hat{\boldsymbol{k}})^2. \tag{53.31}$$

As per our previous encounter with linear waves, we recognize that the disperson relation specifies the inertial wave's angular frequency, ω, once the wavevector is chosen.[5] We illustrate the basics of plane inertial waves in Figure 53.2.

The dispersion relation (53.31) means that the angular frequency of inertial waves is directly proportional to the orientation of the wavevector relative to the rotation vector. Furthermore, it is independent of the magnitude of the wave vector. One way to display these geometric properties is to write

$$\boldsymbol{\Omega} \cdot \hat{\boldsymbol{k}} = |\boldsymbol{\Omega}| \cos\alpha = |\boldsymbol{\Omega}| \sin\gamma \quad \text{with} \quad 0 \leq \alpha \leq \pi \quad \text{and} \quad -\pi/2 \leq \gamma \leq \pi/2, \tag{53.32}$$

where α is the angle between $\boldsymbol{\Omega}$ and $\boldsymbol{k}$, whereas γ is the complement angle. We mostly use α in this chapter, though switch to γ when discussing internal gravity waves and inertia-gravity waves in Chapter 57. The dispersion relation (53.31) thus takes on the particularly compact form

$$\omega^2 = (2\,\Omega\cos\alpha)^2 = (2\,\Omega\sin\gamma)^2. \tag{53.33}$$

Sweeping through the possible orientation angles, α, reveals that the angular frequency (which is a non-negative number) for free space inertial waves spans the continuum range

$$0 \leq \omega \leq 2\,|\Omega|. \tag{53.34}$$

Since the magnitude of the angular frequency is bounded above by $2\,|\Omega| = |f|$, such waves are referred to as *sub-inertial*.[6]

53.3.2 Interpreting the dispersion relation

Since inertial waves are transverse, $\boldsymbol{v} \cdot \boldsymbol{k} = 0$ (Figure 53.2), fluid particle motion associated with inertial waves is parallel to constant phase surfaces, and there is no particle motion in the direction of the wave vector.[7] Dynamical fields have the same geometric structure within a plane

[5] We write $\omega = \varpi(\boldsymbol{k})$ when aiming to distinguish the angular frequency, ω, from the function, ϖ, determining the angular frequency.

[6] In Section 55.8.5 we find that shallow water waves in the presence of gravity and rotation have their angular frequency bounded below by $|f|$, in which case these shallow water *inertia-gravity* waves are *super-inertial*.

[7] It is the oscillatory motion of the fluid particles in the transverse direction that constitutes motion of the phase, thus constituting the traveling wave. A fluid particle moves in the direction of a phase surface. However,

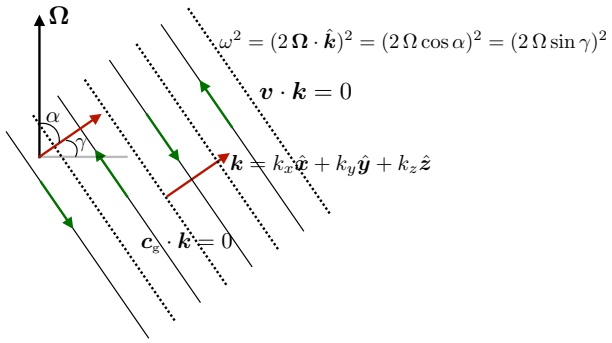

FIGURE 53.2: Illustrating the transverse nature of inertial waves, with their dispersion relation given by equation (53.31), whereby $\omega^2 = (2\,\boldsymbol{\Omega}\cdot\hat{\boldsymbol{k}})^2$. We show lines of constant phase separated by $\pi/2$ radians so that the fluid particle velocity switches sign every alternative line. Evidently, the frequency of inertial waves is maximized when the wavevector, $\boldsymbol{k}$, is aligned with the rotation vector, $\boldsymbol{\Omega}$, in which the angles $\alpha = 0$ and $\gamma = \pi/2$. In contrast, the angular frequency vanishes when the wavevector is orthogonal to $\boldsymbol{\Omega}$. The waves are transverse, $\boldsymbol{v}\cdot\boldsymbol{k} = 0$, so that fluid particle motion occurs within surfaces of constant phase. Maximum frequency waves with $\alpha = 0$ correspond to fluid particle motion on planes orthogonal to the rotation vector, whereby the particles exhibit pure inertial oscillations. Zero frequency waves (standing inertial waves) occur with $\alpha = \pi/2$ and $\gamma = 0$, whereby fluid particle motion is vertical. Vertical particle motion does not feel a Coriolis acceleration so that the wave frequency vanishes in this case. The group velocity is parallel to the fluid particle velocity since, according to equation (53.39), it satisfies $\boldsymbol{c}_g\cdot\boldsymbol{k} = 0$. Note that we make use of the angle α in this chapter, though switch to $\gamma = \pi/2 - \alpha$ when studying internal waves in Chapter 57.

wave, so that all fields are spatially constant along a phase surface. It follows that there is no spatial pressure gradient force along a constant phase surface at any particular time instance. Hence, fluid particles moving parallel to the phase surfaces feel the Coriolis acceleration arising from the projection, $\boldsymbol{k}\cdot\boldsymbol{\Omega}$, of the rotational vector along the wave vector.[8]

Recall that a particle moving in a rotating reference frame exhibits inertial oscillations (Section 14.4) when the particle does not feel any pressure forces. Evidently, fluid particle motion induced by inertial waves exhibits inertial oscillations in the phase plane orthogonal to the wavevector. If the wavevector is aligned parallel to the rotation vector, then a fluid particle feels the full extent of the Coriolis acceleration, whereby inertial oscillations have a squared angular frequency $(2\,\boldsymbol{\Omega}\cdot\hat{\boldsymbol{k}})^2$. This situation corresponds to a particle at either of the planetary poles.[9] When the wavevector is mis-aligned from the rotation vector, then only that portion of the rotation vector projected onto $\hat{\boldsymbol{k}}$ acts to produce inertial oscillations. Finally, if the wavevector is perpendicular to the rotation vector, then the particle feels no Coriolis acceleration, just like a particle on the equator feels no planetary Coriolis acceleration.

53.3.3 Group velocity

As seen from our discussion of wave packets in Section 49.6, the group velocity determines the speed and direction of wave energy propagation within a packet, with the group velocity given

the particle does not remain on a fixed phase surface since the phase travels in the $\hat{\boldsymbol{k}}$ direction and yet particles have $\boldsymbol{v}\cdot\hat{\boldsymbol{k}} = 0$ since the waves are transverse.

[8]The argument here holds either in an Eulerian reference frame, in which case we ignore the nonlinear self-advection contribution as per the linearized velocity equation (53.11), or in a Lagrangian reference frame, in which we are following a material fluid particle. In either case, motion of a fluid particle in an inertial wave, moving in a direction that parallels the constant phase surfaces, only feels the Coriolis acceleration; pressure forces are zero.

[9]From Figure 53.2 we note that the angle α is the co-latitude, so to connect to the planetary Coriolis parameter we set $\phi = \pi/2 - \alpha$ where ϕ is the latitude.

by the wavevector gradient of the dispersion relation

$$\boldsymbol{c}_{\mathrm{g}} = \nabla_{\boldsymbol{k}} \varpi = \hat{\boldsymbol{x}} \frac{\partial \varpi}{\partial k_x} + \hat{\boldsymbol{y}} \frac{\partial \varpi}{\partial k_y} + \hat{\boldsymbol{z}} \frac{\partial \varpi}{\partial k_z}. \tag{53.35}$$

Making use of the dispersion relation (53.31) renders

$$\boldsymbol{c}_{\mathrm{g}} = \frac{4\,(\boldsymbol{\Omega}\cdot\hat{\boldsymbol{k}})\,[\boldsymbol{\Omega} - \hat{\boldsymbol{k}}\,(\boldsymbol{\Omega}\cdot\hat{\boldsymbol{k}})]}{\omega\,|\boldsymbol{k}|} = \frac{(\boldsymbol{\Omega}\cdot\hat{\boldsymbol{k}})}{|\boldsymbol{\Omega}\cdot\hat{\boldsymbol{k}}|}\,\frac{\hat{\boldsymbol{k}}\times(2\,\boldsymbol{\Omega}\times\hat{\boldsymbol{k}})}{|\boldsymbol{k}|} \tag{53.36}$$

where we made use of the vector identity (1.71g). Since

$$\boldsymbol{\Omega}\cdot\hat{\boldsymbol{k}} = \pm|\boldsymbol{\Omega}\cdot\hat{\boldsymbol{k}}| \tag{53.37}$$

we can write the group velocity as

$$\boldsymbol{c}_{\mathrm{g}} = \pm\frac{\hat{\boldsymbol{k}}\times(2\,\boldsymbol{\Omega}\times\hat{\boldsymbol{k}})}{|\boldsymbol{k}|}. \tag{53.38}$$

This expression leads to a particularly remarkable property of the group velocity for inertial waves

$$\boldsymbol{k}\cdot\boldsymbol{c}_{\mathrm{g}} = 0. \tag{53.39}$$

Since the waves are transverse, $\boldsymbol{k}\cdot\boldsymbol{v} = 0$, so that the group velocity is aligned with the fluid particle velocity. The Coriolis acceleration acts perpendicular to the direction of a moving fluid particle. That orientation manifests for inertial waves via $\boldsymbol{k}\cdot\boldsymbol{c}_{\mathrm{g}} = 0$, so that inertial waves carry energy (via the group velocity) in a direction parallel to wave crests (perpendicular to $\boldsymbol{k}$), which is aligned with fluid particle motion. A second property of the group velocity is found by projecting it onto the direction of the rotational axis

$$\boldsymbol{c}_{\mathrm{g}}\cdot\boldsymbol{\Omega} = \pm 2\,[\Omega^2\,\boldsymbol{k}\cdot\boldsymbol{k} - (\boldsymbol{\Omega}\cdot\boldsymbol{k})^2]/|\boldsymbol{k}|^3 = \pm 2\,[\Omega^2 - (\omega/2)^2]/|\boldsymbol{k}| = \pm 2\,(\Omega^2/|\boldsymbol{k}|)\sin^2\alpha, \tag{53.40}$$

where we made use of the expressions (53.31) and (53.33) for the dispersion relation.

53.3.4 Polarization relations for the velocity components

The velocity amplitude, $\tilde{\boldsymbol{v}}$, is generally a complex number, which allows for there to be a variety of phase shifts between the velocity components. We here determine some general relations beween these amplitudes by returning to the linear velocity equation (53.11) and inserting the wave ansatz (53.28) to render

$$-\mathrm{i}\,\omega\,\tilde{u} - f\,\tilde{v} = -\mathrm{i}\,k_x\,\tilde{\varphi} \tag{53.41a}$$
$$-\mathrm{i}\,\omega\,\tilde{v} + f\,\tilde{u} = -\mathrm{i}\,k_y\,\tilde{\varphi} \tag{53.41b}$$
$$-\mathrm{i}\,\omega\,\tilde{w} = -\mathrm{i}\,k_z\,\tilde{\varphi}, \tag{53.41c}$$

where we set $2\,\boldsymbol{\Omega} = f\,\hat{\boldsymbol{z}}$, so that the vertical and horizontal wavenumbers are related by

$$k_z^2 = |\boldsymbol{k}|^2\cos^2\alpha \Longrightarrow k_z^2\sin^2\alpha = (k_x^2 + k_y^2)\cos^2\alpha. \tag{53.42}$$

Equations (53.41a), (53.41b), and (53.41c) define *polarization* relations that specify the relative phases for the velocity components and pressure. We have the freedom to choose how to reference the phases. In the following discussion of kinetic energy, we choose to measure phases relative to the pressure amplitude, which means $\tilde{\varphi}$ is a real amplitude.

53.3.5 Phase averaged kinetic energy

The phase averaged kinetic energy for a plane inertial wave is given by

$$\langle \mathcal{K} \rangle = \langle \mathrm{Re}(\boldsymbol{v}) \cdot \mathrm{Re}(\boldsymbol{v}) \rangle / 2 = (|\tilde{u}|^2 + |\tilde{v}|^2 + |\tilde{w}|^2)/4, \tag{53.43}$$

where we used equation (8.18) for the phase average of the square of a periodic function. To derive the squared amplitudes, multiply the zonal and meridional velocity equations (53.41a) and (53.41b) by $\mathrm{i}\,\omega$, and then back-substitute

$$\tilde{u}\,(f^2 - \omega^2) = -\tilde{\varphi}\,(k_x\,\omega + \mathrm{i} k_y\,f) \tag{53.44a}$$

$$\tilde{v}\,(f^2 - \omega^2) = \tilde{\varphi}\,(-k_y\,\omega + \mathrm{i} k_x\,f), \tag{53.44b}$$

so that

$$|\tilde{u}|^2 = \tilde{\varphi}^2\,\frac{(k_x\,\omega)^2 + (k_y\,f)^2}{(\omega^2 - f^2)^2} = \tilde{\varphi}^2\,\frac{(k_x \cos\alpha)^2 + k_y^2}{f^2 \sin^4\alpha} \tag{53.45a}$$

$$|\tilde{v}|^2 = \tilde{\varphi}^2\,\frac{(k_y\,\omega)^2 + (k_x\,f)^2}{(\omega^2 - f^2)^2} = \tilde{\varphi}^2\,\frac{(k_y \cos\alpha)^2 + k_x^2}{f^2 \sin^4\alpha}, \tag{53.45b}$$

where the second equalities made use of the dispersion relation

$$\omega^2 = f^2 \cos^2\alpha. \tag{53.46}$$

Likewise, equation (53.41c) renders the squared magnitude of the vertical velocity amplitude

$$|\tilde{w}|^2 = \tilde{\varphi}^2\,k_z^2/\omega^2. \tag{53.47}$$

Adding equations (53.45a), (53.45b), and (53.47) then leads to

$$\frac{\langle \mathcal{K} \rangle}{\tilde{\varphi}^2} = \frac{\omega^2\,(k_x^2 + k_y^2)(1 + \cos^2\alpha) + k_z^2\,f^2 \sin^4\alpha}{4\,f^2\,\omega^2 \sin^4\alpha} \tag{53.48a}$$

$$= \frac{f^2 \cos^2\alpha\,(k_x^2 + k_y^2)(1 + \cos^2\alpha) + k_z^2\,f^2 \sin^4\alpha}{4\,f^4 \cos^2\alpha \sin^4\alpha}. \tag{53.48b}$$

Use of equation (53.42) relating the horizontal and vertical wave numbers leads to

$$\langle \mathcal{K} \rangle = \frac{\tilde{\varphi}^2\,k_z^2}{2\,f^2 \cos^2\alpha \sin^2\alpha} = \frac{\tilde{\varphi}^2\,(k_x^2 + k_y^2)}{2\,f^2 \sin^4\alpha}. \tag{53.49}$$

Consider the two limiting cases of $\alpha = 0$ and $\alpha = \pi/2$, which we show are non-singular. A vertical inertial wave, with $\boldsymbol{k} = \hat{\boldsymbol{z}}\,k_z$, $\alpha = 0$, and $\omega^2 = f^2$, has zero vertical particle motion, $\tilde{w} = 0$, so that the pressure fluctuation vanishes, $\tilde{\varphi} = 0$, according to equation (53.41c). As discussed in Section 53.3.6, this case corresponds to free inertial oscillations in the horizontal plane. The complement case of a horizontal inertial wave, with $k_z = 0$, $\alpha = \pi/2$, and $\omega = 0$, has vertical particle motion and is discussed in Section 53.3.7.

53.3.6 High frequency inertial waves with $\omega \approx |f|$

The dispersion relation (53.33) leads to a maximum angular frequency magnitude for a wavevector aligned parallel or anti-parallel to the rotation axis,

$$\boldsymbol{k} \times \boldsymbol{\Omega} = 0 \Longrightarrow \omega = 2\,|\Omega| = |f|. \tag{53.50}$$

Recall that inertial waves are transverse so that $\boldsymbol{v} \cdot \boldsymbol{k} = 0$. This property, in combination with $\boldsymbol{k} \times \boldsymbol{\Omega} = 0$, means that high frequency inertial waves have fluid particle motion in a plane perpendicular to the rotation axis: $\boldsymbol{v} \cdot \boldsymbol{\Omega} = 0$. With a vertical rotation vector, then the wavevector only has a vertical component, $\boldsymbol{k} = k_z \, \hat{\boldsymbol{z}}$. In this case, the plane waves propagate vertically ($k_x = k_y = 0$) while fluid particle motion is restricted to the horizontal plane.

For inertial waves with $\omega = |f| > 0$ and $\boldsymbol{k} = k_z \, \hat{\boldsymbol{z}}$, the fluid velocity amplitude relations (53.41a) and (53.41b) indicate that

$$\tilde{u} = \mathrm{i} \, \tilde{v}, \tag{53.51}$$

so that the horizontal velocity of the wave is given by

$$\boldsymbol{u}/\tilde{u} = \hat{\boldsymbol{x}} \, \mathrm{e}^{\mathrm{i}(k_z z - |f| \, t)} + \hat{\boldsymbol{y}} \, \mathrm{e}^{\mathrm{i}(k_z z - |f| \, t - \pi/2)}, \tag{53.52}$$

which is a vertically propagating plane wave. Taking the real part renders

$$\boldsymbol{u}/\tilde{u} = \hat{\boldsymbol{x}} \cos(k_z z - |f| \, t) + \hat{\boldsymbol{y}} \sin(k_z z - |f| \, t). \tag{53.53}$$

With $k_x = k_y = 0$ in the velocity equations (53.41a) and (53.41b), we see that there is no coupling between the horizontal velocity components and pressure. Hence, the motion of fluid particles reduces to inertial oscillations in the horizontal plane just as we studied for point particle motion in Section 14.4, whereby fluid particle motion occurs with a balance between Coriolis acceleration and centrifugal acceleration (see Figure 14.2). Furthermore, since there is no dependence on the horizontal position (since $k_x = k_y = 0$), fluid particles move together in a coherent oscillation within each horizontal plane while the wave propagates vertically. As a check, we see that for a fixed vertical position, say $z = 0$, the velocity relation (53.53) for inertial waves is identical to the velocity relation (14.15b) for particles undergoing inertial oscillations in a circle with a constant radius

$$\boldsymbol{u}/\tilde{u} = \hat{\boldsymbol{x}} \cos(|f| \, t) - \hat{\boldsymbol{y}} \sin(|f| \, t) \quad \text{for } z = 0 \text{ and } \omega = |f|. \tag{53.54}$$

In oceanography, inertial waves with $\omega \approx |f|$ are referred to as *near inertial waves*, which refers to their angular frequency being close to the Coriolis frequency. Since near inertial waves have their wavevector oriented close to the rotation axis, equation (53.38) indicates that they also have a vanishingly small group velocity.

53.3.7 Low frequency inertial waves with $\omega \approx 0$

Low frequency inertial waves occur when the wavevector is nearly perpendicular to the rotation axis

$$\boldsymbol{\Omega} \cdot \boldsymbol{k} \approx 0 \implies \omega/\Omega \approx 0. \tag{53.55}$$

Hence, the wave number parallel to the rotation axis is vanishingly small. For example, if the rotation axis is vertical, then low frequency inertial waves have a vanishingly small vertical wave number,

$$k_z^2 \ll k_x^2 + k_y^2. \tag{53.56}$$

Correspondingly, for the velocity vector in the form given by equation (53.28), $\boldsymbol{\Omega} \cdot \boldsymbol{k} \approx 0$ means that

$$(\boldsymbol{\Omega} \cdot \nabla) \, \boldsymbol{v} = \mathrm{i} (\boldsymbol{\Omega} \cdot \boldsymbol{k}) \, \boldsymbol{v} \approx 0. \tag{53.57}$$

That is, the velocity vector for low frequency inertial waves is coherent in the direction aligned with the rotation axis. Furthermore, when $\boldsymbol{\Omega} \cdot \boldsymbol{k} \approx 0$, the group velocity (53.40) has a magnitude

$$|\boldsymbol{c}_{\mathrm{g}}| \approx 2 \, |\Omega| / |\boldsymbol{k}|. \tag{53.58}$$

Evidently, low frequency inertial waves with long wavelength (small wavenumber $|\boldsymbol{k}|$) quickly transmit their energy along the direction of the rotation axis. We return to this property in Section 53.5 when considering the Taylor-Proudman effect.

53.4 Radially symmetric high frequency inertial waves

To help further our understanding of inertial oscillations, consider a particularly simple case of a coherent axially symmetric fluid ring within a horizontal f-plane as depicted in Figure 53.3. Slightly perturb the ring by expanding its radius outward and then let the ring move freely. What happens? We study the motion using angular momentum arguments as well as Coriolis arguments, and assume zero pressure gradients throughout the discussion. As we show, the ring oscillates at frequency $\omega = f$ and thus displays a canonical form of inertial oscillations.

53.4.1 Qualitative presentation

The outward radial perturbation gives the ring a larger moment of inertia computed relative to the rotational axis. In Section 24.7, we studied a fluid ring looped around the planet. As in that case, the constraint imposed by angular momentum conservation (computed relative to the rotational axis) requires the ring to rotate anti-cyclonically (clockwise if $\Omega > 0$) in response to a perturbation that increases its radius.[10] Equivalently, radially outward motion induces a Coriolis acceleration that causes the ring to rotate clockwise (anti-cyclonic). In turn, as the ring rotates anti-cyclonically, each fluid particle within the ring experiences a radial Coriolis acceleration pointing towards the center of the ring (to the right of the particle motion). This Coriolis acceleration halts the outward perturbation and returns the ring towards a smaller radius, with the inward motion leading to a further Coriolis acceleration that causes the ring to rotate cyclonically (again, to the right of the inward particle motion). The whole process oscillates between radially outward and anti-cyclonic rotation, and radially inward and cyclonic rotation. The oscillations of a fluid ring exhibit the basic mechanism of inertial waves propagating along the rotational axis ($\boldsymbol{k} \times \boldsymbol{\Omega} = 0$) with frequency f (Section 53.3.6).

53.4.2 Radially symmetric inertial oscillations

The thought experiment in Figure 53.3 can be mathematically described by writing the linearized equation of motion using polar-coordinates from Section 4.22. We assume all fields are axially symmetric around any point, and all motion is two-dimensional on a horizontal plane. We also assume there is no horizontal dynamical pressure gradient acting on the fluid, so that motion is purely inertial. Decomposing the velocity equation (53.4) into radial and angular directions leads to

$$\frac{\mathrm{D}v^r}{\mathrm{D}t} - (f + \dot{\vartheta})\, v^\vartheta = 0 \quad \text{and} \quad \frac{\mathrm{D}v^\vartheta}{\mathrm{D}t} + (f + \dot{\vartheta})\, v^r = 0, \tag{53.59}$$

where we introduced the polar components to the velocity

$$\boldsymbol{v} = (\boldsymbol{v} \cdot \hat{\boldsymbol{r}})\, \hat{\boldsymbol{r}} + (\boldsymbol{v} \cdot \hat{\boldsymbol{\vartheta}})\, \hat{\boldsymbol{\vartheta}} + 0\, \hat{\boldsymbol{z}}, \tag{53.60}$$

and the radial and azimuthal unit vectors

$$\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}} \cos\vartheta + \hat{\boldsymbol{y}} \sin\vartheta \quad \text{and} \quad \hat{\boldsymbol{\vartheta}} = -\hat{\boldsymbol{x}} \sin\vartheta + \hat{\boldsymbol{y}} \cos\vartheta. \tag{53.61}$$

[10] In Figure 24.3 we studied the angular momentum of an axially symmetric ring of fluid around the planet. Axial symmetry means there are no zonal pressure gradients so that axial angular momentum is materially constant for the earth spanning fluid ring. Here we are making use of the same angular momentum constraint for an axially symmetric ring of fluid in a rotating f-plane.

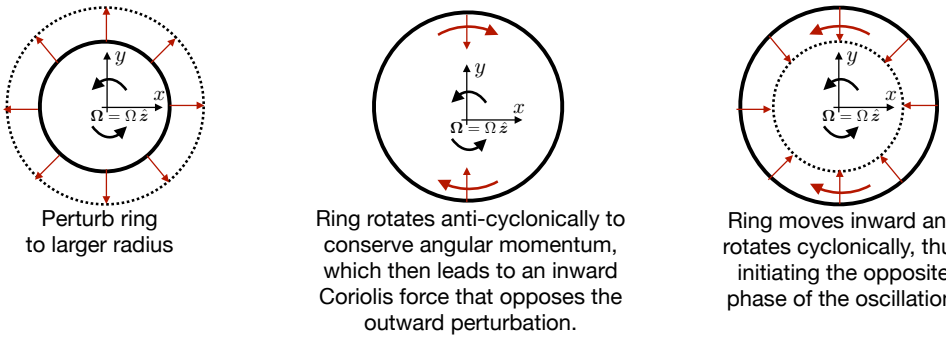

FIGURE 53.3: Schematic of inertial oscillations of an axially symmetric ring of fluid in the horizontal plane in the presence of rotation, $\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}$ with $\Omega > 0$, where the rotation axis extends through the ring center and out of the page. The left panel shows the ring perturbed outward, with this perturbation increasing the ring's moment of inertia about the vertical axis running through the center of the ring. To conserve angular momentum the ring must turn opposite to the sense of the rotating reference frame; that is, it rotates anti-cyclonically, as shown in the middle panel. As it turns anti-cyclonically the ring generates a Coriolis acceleration that points inward (to the right of the motion), thus causing the ring to oscillate back to a smaller radius (right panel), where the oscillation turns around. The physics depicted in this figure, representing a three-way balance between linear acceleration, Coriolis acceleration, and pressure gradient acceleration, is summarized by the linear velocity equation (53.11).

The presence of $\dot{\vartheta}$ along with the Coriolis parameter accounts for the centrifugal acceleration due to the fluid motion (as distinct from the planetary centrifugal acceleration). This is a nonlinear effect that is dropped in the linear analysis.

Linearizing the velocity equation (53.59) leads to

$$\partial_t v^r - f\,v^\vartheta = 0 \quad \text{and} \quad \partial_t v^\vartheta + f\,v^r = 0, \tag{53.62}$$

which then renders a linear oscillator equation satisfied by each velocity component

$$(\partial_{tt} + f^2)\,v^r = 0 \quad \text{and} \quad (\partial_{tt} + f^2)\,v^\vartheta = 0. \tag{53.63}$$

Assuming a monochromatic time dependence

$$v^r = \tilde{v}^r \mathrm{e}^{-\mathrm{i}\,\omega\,t} \quad \text{and} \quad v^\vartheta = \tilde{v}^\vartheta \mathrm{e}^{-\mathrm{i}\,\omega\,t} \tag{53.64}$$

leads to the dispersion relation

$$\omega^2 = f^2. \tag{53.65}$$

The linear velocity equation (53.62) ensures that the velocity components are $\pi/2$ out of phase with

$$\tilde{v}^r = \mathrm{i}\,\tilde{v}^\vartheta = \tilde{v}^\vartheta\,\mathrm{e}^{\mathrm{i}\,\pi/2}. \tag{53.66}$$

The motion is thus a coherent oscillation of the fluid consisting of vascillations between radial and angular motion whereby the Coriolis acceleration acts to turn the motion to the right (assuming $f > 0$). There is no preferred length scale in the horizontal plane. Indeed, since the flow is horizontally non-divergent (there is no vertical fluid particle motion so $\tilde{w} = 0$), and due to the assumed symmetry in the angular direction, there can be no radial dependence to the motion. That is, the radial wavenumber is zero. However, there can be vertical propagation of the waves, just as discussed in Section 53.3.6.

53.5 Low frequency inertial waves and vertical stiffening

We consider two more thought experiments focused on low frequency inertial waves and their connection to the vertical stiffening that arises either from a small aspect ratio flow (as in shallow

water theory) or in flow in a rapidly rotating reference frame (as in the Taylor-Proudman effect). The first experiment is treated heuristically whereas we include some mathematical analysis for the second one.

53.5.1 Slowly oscillating disk

Imagine a slowly oscillating disk that moves in a direction aligned with the axis of rotation, such as depicted in Figure 53.4. If the oscillation frequency is much slower than the rotation frequency, $\omega_{\text{disk}} \ll |\Omega|$, then the disk generates low frequency inertial waves at the frequency of the oscillating disk, $\omega = \omega_{\text{disk}}$. Following from our discussion in Section 53.3.7, we know that the low frequency inertial waves have a wavevector oriented perpendicular to the rotation axis, $\boldsymbol{\Omega} \cdot \boldsymbol{k} = 0$, as depicted in Figure 53.4. Since inertial waves have a group velocity that is itself perpendicular to the wavevector, the low frequency inertial waves have a group velocity parallel to the rotation axis: $\boldsymbol{\Omega} \times \boldsymbol{c}_{\text{g}} = 0$.

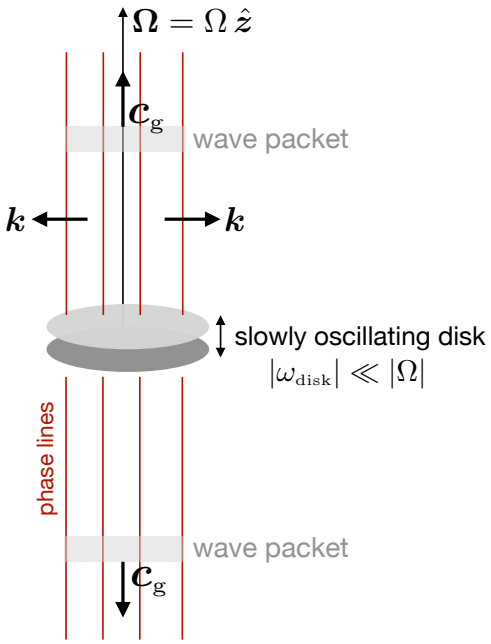

FIGURE 53.4: Schematic of inertial waves generated by a slowly oscillating disk in a rotating homogeneous fluid. The disk moves along the rotation axis (vertical axis) in small amplitude oscillations whose angular frequency is much smaller than the rotational angular frequency, $\omega_{\text{disk}} \ll |\Omega|$. The oscillating disk preferentially generates inertial waves whose frequency is close to ω_{disk}; i.e., low frequency inertial waves as discussed in Section 53.3.7. The phase lines and group velocity for these waves are parallel to the rotation axis, and the wavevector is perpendicular to the rotation axis. We depict two wave packets that send energy vertically away from the disk, with the long wave and low frequency waves having the highest magnitude for the group velocity. Since $\boldsymbol{\Omega} \cdot \boldsymbol{k} = 0$, the fluid particle velocity associated with the inertial waves is constant in the direction along the rotation axis: $(\boldsymbol{\Omega} \cdot \nabla)\,\boldsymbol{v} = \Omega\,\partial_z \boldsymbol{v} = 0$.

As seen by the equation (53.58) for the group velocity magnitude, information (i.e., energy) concerning the oscillating disk is most rapidly transmitted by long wavelength low frequency inertial waves. Such low frequency and long wavelength inertial waves generate fluid particle motion that is independent of the position along the rotational axis since $(\boldsymbol{\Omega} \cdot \nabla)\,\boldsymbol{v} = 0$. Hence, the particle motion is parallel to the rotational axis, and this motion is coherent. We conclude that inertial waves transmit information about stiffening along the rotation axis, thus providing a mechanism for the Taylor-Proudman effect from Section 31.5.3 found when the flow is strictly geostrophic.

53.5.2 Inertial waves from a moving sinusoidal boundary[11]

We here provide a bit more substance to the previous discussion by exploring the steady linear waves generated by a moving sinusoidal lower boundary, as depicted in Figure 53.5. In particular, consider a horizontally unbounded region of homogeneous fluid on an f-plane that is bounded above by a rigid lid at $z = H$ and bounded below by a moving sinusoidal boundary with vertical position

$$z = \eta_b(x,t) = h \sin(q\,x - U\,q\,t) = h \sin(q\,x - \omega_b\,t), \tag{53.67}$$

where we introduced the frequency set by the moving boundary

$$\omega_b = U\,q > 0. \tag{53.68}$$

The amplitude, h, of the lower boundary is assumed to be small compared to the wavenumber of the boundary

$$h\,q \ll 1, \tag{53.69}$$

which ensures that movement of the boundary generates linear waves. Because the fluid is homogeneous and on an f-plane, the undulating bottom boundary forces inertial waves. The excited inertial waves have a horizontal wavenumber given by that of the topography, q, and their vertical wavenumber is set according to the inertial wave equation (53.27). We also require the top and bottom boundary conditions to derive an expression for the vertical velocity

$$w(z=0) = \partial_t \eta_b = -h\,\omega_b \cos(q\,x - \omega_b\,t) \quad \text{and} \quad w(z=H) = 0. \tag{53.70}$$

The bottom boundary condition results from linearizing the kinematic boundary condition,

$$\partial_t \eta_b + \boldsymbol{u} \cdot \nabla \eta_b = w \Longrightarrow w(z=0) \approx \partial_t \eta_b. \tag{53.71}$$

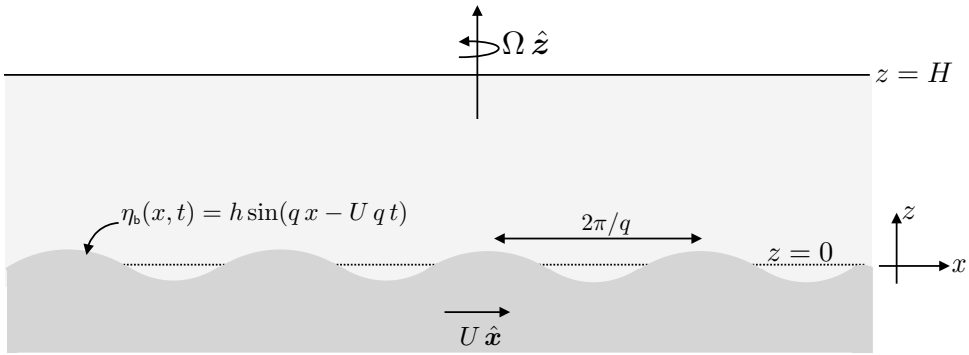

FIGURE 53.5: Schematic for the study of inertial waves generated by a moving sinusoidal lower boundary at $z(x,t) = h_0 \sin(q\,x - \omega_0\,t)$, with the frequency generated by the moving boundary given by $\omega_0 = U\,q$. The region is filled with a homogenous fluid of density ρ and bounded above by a rigid lid at $z = H$.

53.5.3 Stationary wave solution

We examine waves after they have reached a steady state, and as such they are *stationary*. Given the meridional symmetry, we are only concerned with inertial waves that have a zero meridional wavenumber, $k_y = 0$, so that

$$\boldsymbol{k} = k_x\,\hat{\boldsymbol{x}} + k_z\,\hat{\boldsymbol{z}} = q\,\hat{\boldsymbol{x}} + k_z\,\hat{\boldsymbol{z}}, \tag{53.72}$$

[11] This thought experiment comes from Section 2.2 of *Stern* (1975).

where we set $k_x = q$ given the forcing from the lower boundary.

Since the horizontal domain is unbounded, we consider the horizontal fluid velocity arising from a traveling plane wave

$$\boldsymbol{u}(\boldsymbol{x}, t) = \tilde{\boldsymbol{u}}\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}. \tag{53.73}$$

Assuming the waves are indeed inertial with frequency, ω_{b}, and horizontal wavenumber, q, the dispersion relation (53.31) renders the corresponding vertical wavenumber

$$\omega_{\mathsf{b}}^2 = \frac{f^2\, k_z^2}{q^2 + k_z^2} \Longrightarrow k_z^2 = \frac{\omega_{\mathsf{b}}^2\, q^2}{f^2 - \omega_{\mathsf{b}}^2}. \tag{53.74}$$

Evidently, there are two distinct regimes for the excited fluctuations: one that leads to exponential decay away from the lower boundary, with these *evanescent* waves trapped next to the bottom. The other excitation appears as inertial waves

$$\omega_{\mathsf{b}}^2 > f^2 \quad \text{exponential decay away from lower boundary} \tag{53.75a}$$

$$\omega_{\mathsf{b}}^2 < f^2 \quad \text{inertial waves are excited.} \tag{53.75b}$$

We only consider the case of sub-inertial forcing so that $\omega_{\mathsf{b}}^2 < f^2$.

The structure of the vertical velocity associated this forced motion is determined by the following boundary value problem

$$[\partial_{tt}\nabla^2 + (2\,\boldsymbol{\Omega}\cdot\nabla)^2]\, w = 0 \tag{53.76a}$$

$$w(z=0) = -h\,\omega_{\mathsf{b}} \cos(q\,x - \omega_{\mathsf{b}}\, t) \tag{53.76b}$$

$$w(z=H) = 0. \tag{53.76c}$$

To find a particular solution we take the ansatz

$$w(x,t) = w(0)\,\Gamma(z), \tag{53.77}$$

with the non-dimensional structure function satisfying

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}z^2} + k_z^2\,\Gamma = 0 \quad \text{for } 0 < z < H \quad \text{with} \quad \Gamma(0) = 1 \quad \text{and} \quad \Gamma(H) = 0, \tag{53.78}$$

which readily leads to the vertical fluid velocity

$$w(x,z,t) = w(0)\,\frac{\sin[k_z(H-z)]}{\sin(k_z H)} = -h\,\omega_{\mathsf{b}} \cos(q\,x - \omega_{\mathsf{b}}\, t)\,\frac{\sin[k_z(H-z)]}{\sin(k_z H)}. \tag{53.79}$$

53.5.4 Vertically coherent motion

Consider the longwave limit in which

$$\Gamma(z) = \lim_{k_z H \to 0} \frac{\sin[k_z(H-z)]}{\sin(k_z H)} = (H-z)/H, \tag{53.80}$$

so that the vertical velocity is a linear function of z

$$w(x,z,t) \approx -h\,\omega_{\mathsf{b}} \cos(q\,x - \omega_{\mathsf{b}}\, t)\,(H-z)/H. \tag{53.81}$$

As seen in equation (53.19), a linear vertical dependence to w means that the dynamic pressure is independent of z. Correspondingly, equations (53.18a) and (53.18b) reveal that $\partial_z \boldsymbol{u} = 0$, which means that horizontal fluid motion is vertically coherent. This motion corresponds to

the shallow water fluid from Part VI of this book. It also corresponds to the Taylor-Proudman effect discussed in Section 53.5.

To determine the non-dimensional scaling that leads to vertically coherent motion, return to equation (53.78) for the vertical structure function and introduce the non-dimensional vertical coordinate

$$\hat{z} = z/H, \tag{53.82}$$

in which equation (53.78) becomes

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}\hat{z}^2} + (k_z\, H)^2\, \Gamma = 0. \tag{53.83}$$

The vertical structure of the vertical velocity is a linear function of $\hat{z}$ in the limit that $(k_z\, H)^2 \to 0$, which means

$$(k_z\, H)^2 \to 0 \Longrightarrow \frac{(q\, H)^2}{(f/U\, q)^2 - 1} \to 0. \tag{53.84}$$

This limit can be realized if

$$q\, H \ll 1 \quad \text{small aspect ratio (shallow water limit)} \tag{53.85a}$$

$$U\, q/f \ll 1 \quad \text{small Rossby number (Taylor-Proudman limit).} \tag{53.85b}$$

Evidently, a small aspect ratio, with a Rossby number bounded away from unity, leads to vertically coherent motion even if the fluid is not in a rotating reference frame. This motion corresponds to that of shallow water fluid studied in Part VI of this book. As emphasized in Section 35.2.10, the small aspect ratio shallow water fluid displays vertically coherent motion due to the fluid being homogeneous and hydrostatic. Alternatively, we realize vertically coherent columnar motion with a small Rossby number. This motion corresponds to the Taylor-Proudman effect for rotating fluids. It is notable that vertically coherent motion becomes more restricted (i.e., needs a smaller Rossby number) when the upper boundary moves far away, $H \to \infty$, thus moving to the deep water limit.

Chapter 54

BAROTROPIC VORTICITY WAVES

In this chapter we study *vorticity waves*, also called *Rossby waves* or *vortical modes*, which rely on the presence of a gradient in the base state potential vorticity field. We examine a particularly simple realization of Rossby waves as found in the inviscid two-dimensional non-divergent barotropic model on an unbounded β-plane. This model supports two general kinds of vorticity waves. One arises from the gradient of planetary vorticity (i.e., β-effect), which gives rise to *planetary Rossby waves*. The second arises from gradients in the vorticity of the base flow. *Edge waves* are a particularly simple kind of vorticity waves that arise from assuming a jump in the background vorticity field.

READER'S GUIDE TO THIS CHAPTER

We make extensive use of the horizontally non-divergent barotropic model from Chapter 38, as well as the wave kinematics from Chapter 49. Rossby waves are encountered again when discussing shallow water waves in Chapter 55, and edge waves are encountered when studying shear instability in Chapter 61 and baroclinic instability in Chapter 62.

54.2 A single plane wave in the non-divergent barotropic fluid

In this section we study properties of a single plane wave in an inviscid barotropic and horizontally non-divergent fluid on an unbounded beta plane. We then follow in Section 54.3 with a study of Rossby waves in this model.[1] Recall that the barotropic and horizontally non-divergent model was studied in Chapter 38, with the flow fully described by the vorticity equation

$$\frac{\mathrm{D}(\zeta + f)}{\mathrm{D}t} = (\partial_t + \boldsymbol{u} \cdot \nabla)(\zeta + f) = 0, \tag{54.1}$$

where the horizontal velocity is non-divergent and so can be written in terms of a streamfunction

$$\nabla \cdot \boldsymbol{u} = 0 \Longrightarrow \boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi \quad \text{and} \quad \zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) = \nabla^2\psi. \tag{54.2}$$

As we show in this section, a single plane wave in this model exactly satisfies linear velocity and vorticity equations, with such equations summarized in Table 54.1. Since there are no nonlinear terms affecting the single plane wave, there is no need to linearize the equations of motion when studying properties of this wave. We emphasize, however, that this distinct property holds only for a single plane wave. In particular, the advection operator that vanishes for a single wave is nonzero when the flow has more than a single plane wave. Indeed, the nonlinear interactions between distinct wave modes provide the mechanism for the inverse turbulent cascade in this model (e.g., see Chapter 11 of *Vallis* (2017)).

[1] The edge waves studied in Section 54.5 are not plane waves, and so they do not satisfy the special properties described in this section.

NAME	GENERAL RELATION	SINGLE PLANE WAVE
streamfunction	ψ	$\psi = A \cos \mathcal{P}$
velocity	$\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla \psi$	$\boldsymbol{u} = -(\hat{\boldsymbol{z}} \times \boldsymbol{k}) A \sin \mathcal{P}$
velocity tendency	$\partial_t \boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla(\partial_t \psi)$	$\partial_t \boldsymbol{u} = \omega (\hat{\boldsymbol{z}} \times \boldsymbol{k}) \psi$
non-divergence	$\nabla \cdot \boldsymbol{u} = 0$	$\boldsymbol{k} \cdot \boldsymbol{u} = 0$
relative vorticity	$\zeta = \nabla^2 \psi$	$\zeta = -\lvert\boldsymbol{k}\rvert^2 \psi$
β-plane vorticity equation	$(\partial_t + \boldsymbol{u} \cdot \nabla)\zeta = -v \beta$	$\partial_t \zeta = -v \beta$
pressure equation	$-\nabla \cdot (\nabla \varphi - f \nabla \psi) = \boldsymbol{S}^2 - \boldsymbol{R}^2$	$-\nabla \cdot (\nabla \varphi - f \nabla \psi) = 0$
Coriolis acceleration	$-f \hat{\boldsymbol{z}} \times \boldsymbol{u} = f \nabla \psi$	$-f A \boldsymbol{k} \sin \mathcal{P}$
velocity equation	$\partial_t \boldsymbol{u} + (f + \zeta) \hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla(\varphi + \mathcal{K})$	$\partial_t \boldsymbol{u} + f \hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla \varphi$
kinetic energy equation	$\mathrm{D}\mathcal{K}/\mathrm{D}t = -\nabla \cdot (\boldsymbol{u} \varphi)$	$\partial_t \mathcal{K} = -\nabla \cdot (\boldsymbol{u} \varphi)$

TABLE 54.1: Properties of the inviscid horizonally non-divergent barotropic model. The left column holds for a general flow whereas the right column holds for a single plane wave, with $\mathcal{P} = \boldsymbol{k} \cdot \boldsymbol{x} - \omega t$ the phase function. $\boldsymbol{S}$ is the strain rate tensor, with $\boldsymbol{S}^2 = S_{mn} S^{mn}$. Likewise, $\boldsymbol{R}$ is the rotation tensor, with $\boldsymbol{R}^2 = R_{mn} R^{mn}$. Both of these tensors are introduced in Section 18.8. This table highlights the remarkable properties of the single plane wave in the inviscid horizonally non-divergent barotropic model, in which the nonlinear terms in the velocity and vorticity equation vanish identically.

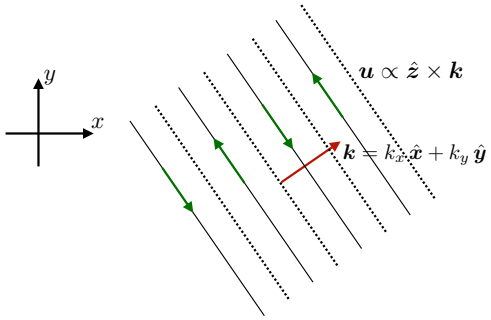

FIGURE 54.1: Illustrating the transverse nature of plane waves appearing in a horizontally non-divergent barotropic model, whereby $\boldsymbol{u} \cdot \boldsymbol{k} = 0$. The alternating solid-dotted lines depict lines of constant phase that differ by $\pi/2$ radians so that the velocity field switches sign between every π radians. Compare this figure to Figure 53.1, which illustrates transverse plane waves in three dimensions.

54.2.1 Transverse plane waves

Consider a plane wave ansatz for the streamfunction

$$\psi(\boldsymbol{x}, t) = A \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega t) \quad \text{with} \quad \boldsymbol{k} = k_x \hat{\boldsymbol{x}} + k_y \hat{\boldsymbol{y}} \quad \text{and} \quad \mathcal{P} = \boldsymbol{k} \cdot \boldsymbol{x} - \omega t, \tag{54.3}$$

with A a constant amplitude. The velocity of fluid particles in the plane wave is thus given by

$$\boldsymbol{u} = -A (\hat{\boldsymbol{z}} \times \boldsymbol{k}) \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega t), \tag{54.4}$$

which then leads to

$$\boldsymbol{k} \cdot \boldsymbol{u} = 0. \tag{54.5}$$

The horizontally propagating plane waves are transverse, as illustrated in Figure 54.1, which arises since the flow is horizontally non-divergent. This property compares to the three dimensional transverse inertial plane waves discussed in Section 53.3.1 and depicted in Figure 53.1.

54.2.2 Absence of inertial waves and gravity waves

Since there is no vertical motion in the two-dimensional non-divergent barotropic model, any wavevector must be horizontal and thus perpendicular to the vertically oriented rotation vector.

Hence, the inertial wave dispersion relation (53.31) only admits a zero frequency mode, which is geostrophic balance. Furthermore, gravity waves are absent from this model since gravity waves vanish with a flow that has zero horizontal divergence (see the discussion of shallow water gravity waves in Section 55.5). We thus conclude that the two-dimensional non-divergent barotropic model has neither inertial waves nor gravity waves.

As we will see, the only wave supported by this model occurs in the presence of a background or base state vorticity gradient, such as from planetary vorticity or the vorticity of a mean flow. In the absence of vorticity gradients, there are no linear waves in the two-dimensional non-divergent barotropic model. Such is the case, for example, in non-rotating and homogeneous two-dimensional flows, which are commonly used to study two-dimensional turbulence.

54.2.3 Zero advection for a single plane wave

Linearizing the equations of motion is a basic step in the development of a dispersion relation. For the vorticity equation appropriate for Rossby waves, linearization means neglecting the advection of relative vorticity. However, quite remarkably, there is no advection of relative vorticity for a plane wave in the horizontally non-divergent barotropic model. That is, the advection operator, $\boldsymbol{u} \cdot \nabla\zeta$, vanishes identically when $\boldsymbol{u}$ and ζ are built from a single plane wave. To see this property, consider a traveling plane wave streamfunction

$$\psi(x, y, t) = A \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) \Longrightarrow \zeta = -|\boldsymbol{k}|^2\, \psi \quad \text{and} \quad \nabla\zeta = -|\boldsymbol{k}|^2\, \nabla\psi, \tag{54.6}$$

in which case we readily find

$$\boldsymbol{u} \cdot \nabla\zeta = (\hat{\boldsymbol{z}} \times \nabla\psi) \cdot (-|\boldsymbol{k}|^2\, \nabla\psi) = 0. \tag{54.7}$$

Evidently, for this model the velocity of fluid particles in a plane wave are aligned parallel to surfaces of constant relative vorticity of the wave. Equivalently, this model supports no nonlinear self-interactions for a single plane wave.

54.2.4 Pressure equation for a single plane wave

Recall the discussion in Section 38.4 where we showed that pressure in the horizontally non-divergent barotropic model satisfies the Poisson equation (38.84)

$$-\nabla \cdot (\nabla\varphi - f\, \nabla\psi) = 2\, [(\partial_{xy}\psi)^2 - \partial_{xx}\psi\, \partial_{yy}\psi]. \tag{54.8}$$

Making use of the traveling plane wave (54.6) readily reveals that the nonlinear source term vanishes identically

$$(\partial_{xy}\psi)^2 - \partial_{xx}\psi\, \partial_{yy}\psi = 0. \tag{54.9}$$

Although the plane wave supports a nonzero strain rate tensor and a nonzero rotation tensor, their respective squares cancel identically. As a result, the pressure source from a plane wave is due only to the Coriolis acceleration

$$-\nabla \cdot (\nabla\varphi - f\, \nabla\psi) = -\nabla \cdot (\nabla\varphi + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}) = 0. \tag{54.10}$$

Consequently,

$$\nabla\varphi + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -\hat{\boldsymbol{z}} \times \nabla\lambda, \tag{54.11}$$

where $\lambda(x, y, t)$ is a gauge function. In Section (54.2.5) we show that $\nabla\lambda = \nabla(\partial_t\psi)$.

54.2.5 Velocity equation for a single plane wave

So what velocity equation does a single plane wave satisfy for the inviscid horizontally non-divergent barotropic model? To answer that question we make use of the vector-invariant velocity equation (38.5) written in the form

$$\partial_t \boldsymbol{u} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} + \nabla\varphi = -(\nabla\mathcal{K} + \hat{\boldsymbol{z}} \times \zeta\,\boldsymbol{u}) \quad \text{with} \quad \mathcal{K} = \boldsymbol{u}\cdot\boldsymbol{u}/2. \tag{54.12}$$

Introducing the streamfunction brings the right hand side terms into the form

$$\nabla\mathcal{K} + \hat{\boldsymbol{z}} \times \zeta\,\boldsymbol{u} = \hat{\boldsymbol{x}}\,(\partial_y\psi\,\partial_{xy}\psi - \partial_x\psi\,\partial_{yy}\psi) + \hat{\boldsymbol{y}}\,(\partial_x\psi\,\partial_{xy}\psi - \partial_y\psi\,\partial_{xx}\psi) \tag{54.13a}$$

$$= \hat{\boldsymbol{x}}\,[\hat{\boldsymbol{z}}\cdot(\partial_y\nabla\psi \times \nabla\psi)] + \hat{\boldsymbol{y}}\,[\hat{\boldsymbol{z}}\cdot(\partial_x\nabla\psi \times \nabla\psi)]. \tag{54.13b}$$

We readily find that each of these nonlinear terms vanishes when the streamfunction is given by the single plane wave function (54.3)

$$\partial_y\nabla\psi \times \nabla\psi = A^2\,k_y(\boldsymbol{k}\times\boldsymbol{k})\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) = 0 \tag{54.14a}$$

$$\partial_x\nabla\psi \times \nabla\psi = A^2\,k_x(\boldsymbol{k}\times\boldsymbol{k})\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) = 0. \tag{54.14b}$$

Evidently, a single plane wave in the horizontally non-divergent barotropic model exactly satisfies the linear velocity equation

$$\partial_t \boldsymbol{u} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla\varphi. \tag{54.15}$$

Comparing to the result from the pressure equation (54.11) reveals that $\nabla\lambda = \nabla(\partial_t\psi)$. Furthermore, recall that we made no assumptions about f in arriving at equation (54.15), so that f can be a function of latitude as per the β-plane. Indeed, f can be an arbitrary function of space, $f(x, y)$. Finally, equation (54.15) indicates that a stationary plane wave ($\omega = 0$) is in exact geostrophic balance. We further discuss this result in Section 54.2.6 when studying the structure of a single plane wave.

54.2.6 Structure of a single plane wave

TERM	$\mathcal{P} = 0$	$\mathcal{P} = \pi/2$	$\mathcal{P} = \pi$	$\mathcal{P} = 3\pi/2$	$\mathcal{P} = 2\pi$
$\boldsymbol{u}$	0	$-A\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})$	0	$A\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})$	0
$-f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}$	0	$-A\,f\,\boldsymbol{k}$	0	$A\,f\,\boldsymbol{k}$	0
$-\nabla\varphi$	$A\,\omega\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})$	$A\,f\,\boldsymbol{k}$	$-A\,\omega\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})$	$-A\,f\,\boldsymbol{k}$	$A\,\omega\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})$
$\partial_t\boldsymbol{u}$	$A\,\omega\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})$	0	$-A\,\omega\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})$	0	$A\,\omega\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})$

TABLE 54.2: Values for plane wave terms in the velocity equation as the phase, $\mathcal{P} = \boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t$, moves from 0 to 2π. The time tendency, $\partial_t\boldsymbol{u}$, is always perpendicular to the wavevector, which accords with the transverse nature of the wave. Also note that the time tendency is $\pi/2$ out of phase with the velocity itself. When the time tendency vanishes, then the pressure gradient and Coriolis accelerations are in geostrophic balance, with this balance occuring every π radians.

In Table 54.1 we summarize the properties satisfied by a single plane wave in the horizontally non-divergent barotropic model. In particular, note that the pressure gradient has been decomposed into linearly independent directions parallel to the wave, $\hat{\boldsymbol{k}}$, and perpendicular to the wave, $\hat{\boldsymbol{z}} \times \hat{\boldsymbol{k}}$

$$-\nabla\varphi = A\,[\omega\,(\hat{\boldsymbol{z}} \times \boldsymbol{k})\cos\mathcal{P} + f\,\boldsymbol{k}\sin\mathcal{P}]. \tag{54.16}$$

Table 54.2 considers the values for each term in the velocity equation as the phase moves around the unit circle, and Figure 54.2 provides a schematic. Evidently, the transverse plane waves oscillate between geostrophic balance, with $\partial_t\boldsymbol{u} = 0$, and pressure driven tendency, where $\partial_t\boldsymbol{u} = -\nabla\varphi$.

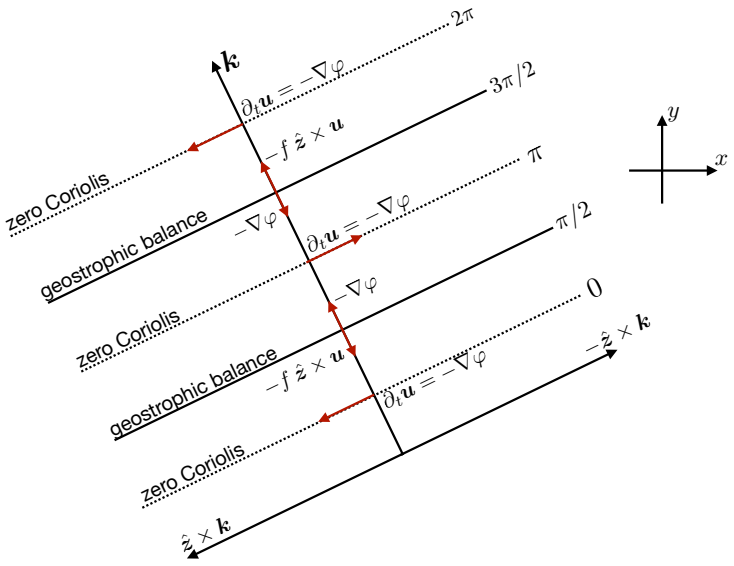

FIGURE 54.2: Schematic of the terms appearing in a horizontally propagating plane wave in the horizontally non-divergent barotropic model. We display terms as a function of the phase, $\mathcal{P} = (\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)$, whose value is shown for $\mathcal{P} = 0, \pi/2, \pi, 3\pi/2, 2\pi$. The terms correspond to those given in Table 54.2. Note the oscillation between geostrophic balance, with zero time tendency, with a phase where there is a downgradient acceleration (i.e. ageostrophic motion). Also note that the pressure gradient rotates in a clockwise direction when the phase increases.

54.2.7 Kinetic energy of a single plane wave

Taking the scalar product of the velocity with the velocity equation (54.12) leads to the kinetic energy equation (38.10)

$$\frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} = -\nabla\cdot(\boldsymbol{u}\,\varphi). \tag{54.17}$$

Likewise, taking the scalar product with the linear velocity equation (54.15) satisfied by the single plane wave renders

$$\partial_t\mathcal{K} = -\nabla\cdot(\boldsymbol{u}\,\varphi). \tag{54.18}$$

As for the velocity, we see that the kinetic energy of the plane wave experiences no advection. Furthermore, making use of the wave ansatz (54.3) leads to the kinetic energy per mass within a single plane wave

$$\mathcal{K} = (A^2\,|\boldsymbol{k}|^2/2)\sin^2\mathcal{P}, \tag{54.19}$$

thus indicating more energy in higher wavenumber waves. In contrast, the gravitational potential energy is constant given that the fluid has a uniform density and rigid lid. Hence, as the kinetic energy fluctuates within a wave, there is no exchance with potential energy. Instead, there is an exchange with the external dynamical system that affects a rigid lid on the fluid.

The phase average of the kinetic energy (54.19) is

$$\langle\mathcal{K}\rangle = A^2\,|\boldsymbol{k}|^2/4. \tag{54.20}$$

Now consider the energy flux convergence, again as rendered by the single plane wave

$$-\nabla\cdot(\boldsymbol{u}\,\varphi) = -\boldsymbol{u}\cdot\nabla\varphi = \omega\,A^2|\boldsymbol{k}|^2\sin\mathcal{P}\cos\mathcal{P}, \tag{54.21}$$

where we made use of equation (54.16) for the pressure gradient. The phase average of this flux convergence vanishes

$$\langle\nabla\cdot(\boldsymbol{u}\,\varphi)\rangle = 0. \tag{54.22}$$

Evidently, the zero kinetic energy flux convergence arises since the plane wave is present throughout space, so that there is no means to converge phase averaged wave energy to any particular region. Only when there is a symmetry breaking, such as by modulating the plane wave into a localized packet, will there be a nonzero phase average flux convergence.

54.3 Barotropic and non-divergent Rossby waves

In this section we build on the general properties of the plane wave as developed in Section 54.2. The key new ingredient considered here is the dispersion relation that couples the wavevector to the wave angular frequency. As we see, the fluctuations are organized into *Rossby waves*, which are waves that carry a nonzero vorticity and are reliant on gradients in the background potential vorticity field.

54.3.1 The vorticity mechanism for planetary Rossby waves

Before developing the detailed properties of Rossby waves, we discuss the underlying mechanism for planetary Rossby waves. This discussion serves as both a motivation and guide for the mathematics to follow. The foundational principle is that fluctuations constrained by material conservation of potential vorticity organize into Rossby waves when they are presented with a background potential vorticity gradient. The background potential vorticity gradient can arise from the meridional gradient of the planetary vorticity (giving rise to planetary waves), gradients in the vorticity of the base flow (e.g., edge waves), and, in more general models, buoyancy gradients and topography gradients (topographic Rossby waves). Note that the seeds for these arguments were planted in Section 38.5 when studying vorticity constraints on the flow for the non-divergent barotropic model.

Westward phase propagation

In Figure 54.3 we display the essential physics of planetary Rossby waves as realized in the horizontally non-divergent barotropic model. As described in the figure caption, the constraint of absolute vorticity conservation for fluctuating fluid parcels, in the presence of $\beta > 0$, gives rise to the westward phase propagation of the planetary Rossby wave. As we see in Section 54.5.6, a pseudo-westward propagation arises for edge waves generated by vorticity jumps. This preferred direction for propagation is a canonical property of vorticity waves, and it distinguishes these waves from other waves whose phase propagation has no directional preference.

Vorticity and momentum arguments

The argument offered in Figure 54.3 does not consider forces. Rather, we make use of the constraint imposed by materical conservation of absolute vorticity and infer the motion of fluid parcels by noting how the relative vorticity anomaly induces flow of a particular orientation. Rossby waves carry vorticity, so vorticity arguments offer the natural means to understand their mechanism. Even so, a complementary approach to understanding Rossby waves considers the forces acting in the wave, and as such is referred to as a *momentum argument*. This argument is concerned with the nature of pressure fluctuations within the wave. We note in Section 54.2.5 that plane waves in an inviscid horizonally non-divergent barotropic model oscillate between a state with exact geostrophic balance and a state with zero Coriolis acceleration so that acceleration is down the pressure gradient.

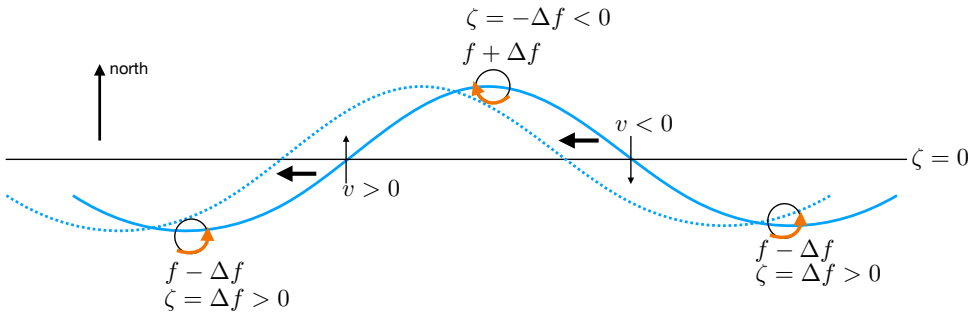

FIGURE 54.3: The westward phase propagation of a planetary Rossby wave arises from the presence of $\beta > 0$ and the constraint that absolute vorticity ($\zeta_a = f + \zeta$) is materially constant for a two-dimensional non-divergent and inviscid barotropic flow. In this figure we consider a material curve within the fluid in either the northern or southern hemispheres. The background flow is assumed to be static to allow us to focus on the role of the planetary vorticity gradient as measured by β. The relative vorticity is assumed to vanish for points on the straight constant latitude line, so that $\zeta_a = f$ must be maintained by any latitudinal perturbation. For a northward perturbation relative to the latitude line, a fluid parcel finds itself at a latitude with Coriolis parameter more positive than its original value ($f \to f + \Delta f > f$, with absolute vorticity conservation requiring the parcel to pick up a negative relative vorticity anomaly, $\zeta = -\Delta f < 0$. The opposite occurs for a southward perturbation. The counter-rotating secondary flow induced by the relative vorticity anomaly acts to move the wave pattern westward, so that the solid wave pattern is, at a future time, moved to the dashed wave pattern. We depict that the meridional motion induced by the wave as the pattern crosses the constant latitude line. In the absence of β, the meridional movement of parcels does not render a change in the planetary vorticity since in this case f is a constant. So for the f-plane there is no induced relative vorticity anomaly so there is no coherent movement of the wave pattern. We thus see the central role of $\beta \neq 0$ for planetary Rossby waves. We also see that the sign of the Coriolis parameter is not relevant; it is only $\beta > 0$ that determines the westward wave motion in both northern and southern hemispheres. A generic way to orient the phase is to note that when looking in the phase direction, higher planetary vorticity is to the right, with this rule holding for Rossby waves arising from potential vorticity gradients other than planetary β.

54.3.2 Flow relative to a zonal base state

We here examine wave fluctuations relative to a static base flow whose vorticity satisfies

$$\boldsymbol{u}_b \cdot \nabla(f + \zeta_b) = 0, \tag{54.23}$$

along with a corresponding velocity potential so that

$$\boldsymbol{u}_b = \hat{\boldsymbol{z}} \times \nabla \psi_b \quad \text{and} \quad \zeta_b = \nabla^2 \psi_b. \tag{54.24}$$

This base flow maintains a materially constant absolute vorticity, so that it is an exact static solution to the equations of motion for the inviscid two-dimensional non-divergent barotropic model, and thus serves as a suitable base flow to study wave fluctuations.[2]

We focus in this chapter on a static background zonal flow written in the form[3]

$$\boldsymbol{u}_b = \hat{\boldsymbol{x}}\, U(y) \quad \text{with} \quad \psi_b = -\int^y u_b(y')\, dy' \quad \text{and} \quad \zeta_b = -\partial_y u_b = \partial_{yy} \psi_b. \tag{54.25}$$

As we show, the base flow with constant $u_b = U$ (and thus with $\zeta_b = 0$) supports plane waves. The study of wave fluctuations on general base states requires more general methods, such as the asymptotics from Chapter 50. We encounter another case not admitting plane waves when studying edge waves in Section 54.5. Although not admitting plane waves, the edge waves do support interfacial waves similar to the surface waves in Chapter 52.

[2] Although we cannot generally determine an analytic expression for the base flow, we know that a pressure can be found that accords with the flow configuration and the non-divergent nature of the flow (see Section 38.4).

[3] Recall that the streamfunction is arbitrary up to a constant (Section 21.4). It is for this reason that we have no concern for the lower integration limit in equation (54.25).

54.3.3 Equations for the fluctuating vorticity and streamfunction

In the presence of a base state flow, we write the vorticity, velocity, and streamfunction in the form[4]

$$\zeta_{\text{full}} = \zeta + \zeta_{\text{b}} \quad \text{and} \quad \boldsymbol{u}_{\text{full}} = \boldsymbol{u} + \boldsymbol{u}_{\text{b}} \quad \text{and} \quad \psi_{\text{full}} = \psi + \psi_{\text{b}}, \tag{54.26}$$

with the vorticity equation

$$[\partial_t + (\boldsymbol{u} + \boldsymbol{u}_{\text{b}}) \cdot \nabla](\zeta + \zeta_{\text{b}} + f) = 0. \tag{54.27}$$

Again, from equation (54.23) we assume the static base state satisfies $\boldsymbol{u}_{\text{b}} \cdot \nabla(f + \zeta_{\text{b}}) = 0$, which means the vorticity equation (54.27) reduces to the equation for the fluctuating vorticity

$$\partial_t \zeta + (\boldsymbol{u} + \boldsymbol{u}_{\text{b}}) \cdot \nabla \zeta + \boldsymbol{u} \cdot \nabla(f + \zeta_{\text{b}}) = 0. \tag{54.28}$$

Introducing a streamfunction for the fluctuating flow, $\zeta = \nabla^2 \psi$, brings the vorticity equation (54.28) into the form

$$\partial_t(\nabla^2 \psi) + \hat{\boldsymbol{z}} \cdot [\nabla \psi \times \nabla(\nabla^2 \psi + f + \nabla^2 \psi_{\text{b}})] + \hat{\boldsymbol{z}} \cdot [\nabla \psi_{\text{b}} \times \nabla(\nabla^2 \psi)] = 0. \tag{54.29}$$

As we show below, this equation supports traveling plane vorticity waves. It is notable that it has only one time derivative, which contrasts to all the other wave equations we have encountered in this book (e.g., equation (51.34) for acoustic waves, equation (52.119) for surface gravity waves, and equation (53.27) for inertial waves). It leads to an asymmetric phase propagation of the linear wave fluctuations.

54.3.4 Rossby wave dispersion relation

To develop a dispersion relation we substitute the plane wave ansatz (54.3) into the vorticity equation (54.29). For the plane wave ansatz to lead to a self-consistent dispersion relation requires the background vorticity field to be extremely simple. In particular, the background velocity and background vorticity gradient must both be independent of space

$$\nabla f = \text{constant} \quad \text{and} \quad \boldsymbol{u}_{\text{b}} = U\,\hat{\boldsymbol{x}} \implies \zeta_{\text{b}} = 0, \tag{54.30}$$

with the first assumption holding for the β plane. In general, these assumptions ensure that the angular frequency for the plane wave is independent of space. In Section 54.5 we consider a slightly less trivial background state that supports edge waves rather than plane waves.

Given our focus on plane waves, assume a domain without boundaries and consider a horizontal traveling plane wave ansatz in the form of equation (54.6). Plugging this ansatz into the vorticity equation (54.29), and recalling that $\boldsymbol{u} \cdot \nabla \zeta = 0$ for a plane wave as discussed in Section 54.2.3, leads to

$$A \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)[-\omega\, |\boldsymbol{k}|^2 + (\boldsymbol{k} \cdot \boldsymbol{u}_{\text{b}})\, |\boldsymbol{k}|^2 - (\hat{\boldsymbol{z}} \times \boldsymbol{k}) \cdot \nabla f] = 0. \tag{54.31}$$

This equation is generally satisfied only when the bracketed term vanishes, which gives the dispersion relation that expresses the angular frequency as a function of the wavevector, the base flow, and geophysical parameters

$$\varpi = \underbrace{\boldsymbol{k} \cdot \boldsymbol{u}_{\text{b}}}_{\text{Doppler}} \; \underbrace{+(\boldsymbol{k} \times \hat{\boldsymbol{z}}) \cdot \nabla f / |\boldsymbol{k}|^2}_{\text{planetary vorticity gradient}} = k_x\,(U - \beta/|\boldsymbol{k}|^2). \tag{54.32}$$

[4] An alternative notation is to write $\zeta = \zeta' + \zeta_{\text{b}}$, where ζ' is the fluctuating vorticity. We choose the notation in equation (54.26) to reduce the abundance of primes appearing in the equations.

As noted at the end of Section 54.3.2, the Rossby wave dispersion relation (54.32) results from a wave equation with only a single time derivative. We commented in Section 49.3.3 on such wave equations as being notable for possessing a preferred direction for wave propagation, which we see in Section 54.3.6 results in Rossby waves having a phase that moves westward.

Doppler shift from the base flow

The term

$$\varpi_{\text{Doppler}} \equiv \boldsymbol{k} \cdot \boldsymbol{u}_{\mathfrak{b}} = k_x U \tag{54.33}$$

provides a shift in the angular frequency relative to the case with zero base flow. If the wave direction is aligned with the base flow, then $\varpi_{\text{Doppler}} > 0$, so that the angular frequency of the wave is increased. In contrast, the wave frequency is decreased when the wave is directed anti-parallel to the base flow. This frequency shift is referred to as a *Doppler shift*. A Doppler shift is familiar from acoustic waves when, for example, the frequency of a train whistle received by a stationary listener is higher when the train approaches and lower when it is moving away.

Rossby waves supported by a gradient in the planetary vorticity

The planetary beta effect leads to the term

$$\varpi_\beta \equiv -(\hat{\boldsymbol{z}} \times \hat{\boldsymbol{k}}) \cdot \nabla f / |\boldsymbol{k}| = -\beta\, k_x / |\boldsymbol{k}|^2, \tag{54.34}$$

which gives rise to the *planetary wave* or *planetary Rossby wave*. We see that planetary Rossby waves rely on planetary curvature, in which case $\beta \neq 0$. Equivalently, planetary Rossby waves rely on a nonzero gradient in the planetary vorticity, $\nabla f = \beta\, \hat{\boldsymbol{y}}$, so that planetary Rossby waves do not exist on an f-plane.

The dispersion relation (54.34) reveals that long planetary waves (small wavenumber) have higher angular frequency than short planetary waves. The maximum angular frequency is given by the Rossby wave with zero meridional wavenumber

$$\omega_{\beta\text{-max}} = \beta / |k_x|. \tag{54.35}$$

This frequency corresponds to a purely zonal Rossby wave with no meridional structure. Correspondingly, the transverse nature of the waves means that fluid particles are moving meridionally in the presence of a zonal Rossby wave. Evidently, the frequency of the waves is directly related to the degree to which fluid particles move through the background potential vorticity field, with highest frequency for particles moving meridionally and zero frequency for particles moving zonally.

We compute the ratio of the maximum angular frequency for a Rossby wave to the central value of the Coriolis parameter, $f_\circ$, used for the beta-plane approximation (Section 24.5)

$$\omega_{\beta\text{-max}} / f_\circ = \beta / |k_x\, f_\circ| = \beta\, L_x / |f_\circ| \ll 1. \tag{54.36}$$

In this equation we set the zonal wavenumber equal to the inverse of a zonal length scale of the flow, $k_x = 1/L_x$. The ratio $\beta\, L_x / |f_\circ|$ is much less than unity so long as the β-plane approximation is accurate.[5] We thus see that the maximum angular frequency of the Rossby waves is much smaller than the Coriolis frequency, thus making the planetary Rossby wave a *sub-inertial wave*.

[5] See Section 24.5.4 for more on the β-plane approximation.

54.3.5 Extrinsic and intrinsic angular frequency

We here introduce some terminology sometimes applied to waves in the presence of a background mean flow. For this purpose, consider again the dispersion relation, ϖ, given by equation (54.32). This relation renders the angular frequency as measured by an observer stationary with respect to the moving frame. As such, it is sometimes referred to as the *ground-based frequency* or the *extrinsic frequency*

$$\text{extrinsic frequency} = \varpi = \boldsymbol{k} \cdot \boldsymbol{u}_{\text{b}} + (\boldsymbol{k} \times \hat{\boldsymbol{z}}) \cdot \nabla f / |\boldsymbol{k}|^2 = k_x \, (U - \beta / |\boldsymbol{k}|^2). \tag{54.37}$$

The frequency measured by an observer moving with the background flow does not have a Dopper contribution, motivating the name *intrinsic frequency*

$$\text{intrinsic frequency} = \varpi - \boldsymbol{k} \cdot \boldsymbol{u}_{\text{b}} = -\beta / |\boldsymbol{k}|^2. \tag{54.38}$$

The intrinsic frequency is also sometimes referred to as the *Doppler-shifted frequency*, but that name should perhaps more clearly be the "frequency with the Doppler shift removed".

The above definitions for extrinsic and intrinsic angular frequencies accord with the conventional definitions. However, it is notable than Section 6.2 of *Sutherland* (2010) offers the exact opposite definitions. One should thus be mindful of these different naming conventions.

54.3.6 Concerning the westward phase velocity

The phase velocity, $\boldsymbol{c}_{\text{p}} = (\omega / |\boldsymbol{k}|) \, \hat{\boldsymbol{k}}$ (see equation (49.26)), takes on the following form for a barotropic Rossby wave[6]

$$\boldsymbol{c}_{\text{p}} = \hat{\boldsymbol{k}} \left[\hat{\boldsymbol{k}} \cdot \boldsymbol{u}_{\text{b}} - (\hat{\boldsymbol{z}} \times \hat{\boldsymbol{k}}) \cdot \nabla f / |\boldsymbol{k}|^2 \right] = \hat{\boldsymbol{k}} \left[\hat{\boldsymbol{k}} \cdot \boldsymbol{u}_{\text{b}} + \hat{\boldsymbol{k}} \cdot (\hat{\boldsymbol{z}} \times \nabla f) / |\boldsymbol{k}|^2 \right] = \hat{\boldsymbol{k}} \, (\hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{x}}) \, (U - \beta \, / |\boldsymbol{k}|^2). \tag{54.39}$$

The phase velocity arising from planetary beta

$$[\boldsymbol{c}_{\text{p}}]_\beta = -\beta \, \hat{\boldsymbol{k}} \, (\hat{\boldsymbol{x}} \cdot \hat{\boldsymbol{k}}) / |\boldsymbol{k}|^2 \tag{54.40}$$

has a sign-definite zonal component

$$\left[\boldsymbol{c}_{\text{p}} \cdot \hat{\boldsymbol{x}} \right]_\beta = -(\hat{\boldsymbol{x}} \cdot \hat{\boldsymbol{k}})^2 / |\boldsymbol{k}|^2 = -k_x^2 \, \beta / |\boldsymbol{k}|^4 < 0. \tag{54.41}$$

We depict this property of the Rossby wave phase velocity in Figure 54.4. This westward phase propagation holds for both hemispheres since $\beta \geq 0$ over the globe. Furthermore, the westward propagation is larger in magnitude at lower latitudes where β is larger, with a ratio given by

$$\frac{\left[\boldsymbol{c}_{\text{p}}(\phi_1) \cdot \hat{\boldsymbol{x}} \right]_\beta}{\left[\boldsymbol{c}_{\text{p}}(\phi_2) \cdot \hat{\boldsymbol{x}} \right]_\beta} = \frac{\cos \phi_1}{\cos \phi_2}. \tag{54.42}$$

For example, $\boldsymbol{c}_{\text{p}}(\phi_1) \cdot \hat{\boldsymbol{x}}$ at 60° latitude is one-half that at the equator. Both the westward phase propagation and the faster phase speed at lower latitudes are canonical features of planetary Rossby waves. These properties are readily seen in large-scale flow patterns in both the atmosphere and ocean.

[6] In this book, we eschew the notion of components to the phase speed since the phase speed is not a vector and so it has no components. Rather, as discussed in Section 49.5.2, the phase speed is the magnitude of the phase velocity, $C_{\text{p}} = \boldsymbol{c}_{\text{p}} \cdot \hat{\boldsymbol{k}} = \omega / |\boldsymbol{k}| \geq 0$, with the phase velocity $\boldsymbol{c}_{\text{p}} = C_{\text{p}} \, \hat{\boldsymbol{k}}$.

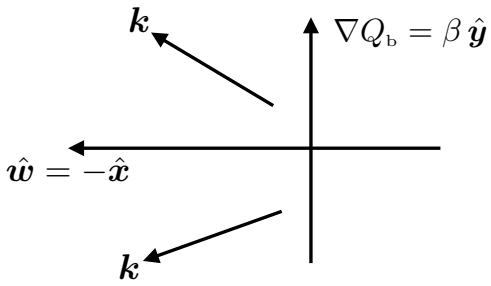

FIGURE 54.4: Illustrating the westward phase propagation of a planetary Rossby wave. In this case the westward unit vector is $\hat{\boldsymbol{w}} = -\hat{\boldsymbol{x}}$, and the phase velocity is projected in the westward direction, $\big[\boldsymbol{c}_{\mathrm{p}} \cdot \hat{\boldsymbol{w}}\big]_\beta > 0$. We show two possible wavevectors, $\boldsymbol{k} = k_x\,\hat{\boldsymbol{x}} + k_y\,\hat{\boldsymbol{y}}$, with $k_x < 0$ so the wavevector has a westward component, but the meridional component can be either positive or negative.

Westward phase velocity implied by positive angular frequency

Another indication that Rossby waves have a westward phase propagation is to recall that the angular frequency of a wave is positive (Section 49.2.3). This convention is maintained by noting that the direction of the phase propagation is carried by the wavevector

$$\boldsymbol{k} = \hat{\boldsymbol{x}}\,k_x + \hat{\boldsymbol{y}}\,k_y, \tag{54.43}$$

rather than allowing the angular frequency to be negative.[7] Planetary Rossby waves in two-dimensional non-divergetnt barotropic flow have the dispersion relation (54.34)

$$\varpi_\beta = -\beta\,k_x/|\boldsymbol{k}|^2. \tag{54.44}$$

The resulting angular frequency is positive if $k_x < 0$, meaning that propagating planetary waves have a westward component to the phase velocity.

The result (54.44) generalizes by considering the dispersion relation arising from a more general background potential vorticity[8]

$$\varpi_{\mathrm{base}+\beta} \equiv -(\hat{\boldsymbol{z}} \times \hat{\boldsymbol{k}}) \cdot \nabla Q_{\mathrm{b}}/|\boldsymbol{k}|, \tag{54.45}$$

with non-negative values assured only for wavevectors oriented in the pseudo-westward direction so that

$$(\hat{\boldsymbol{z}} \times \hat{\boldsymbol{k}}) \cdot \nabla Q_{\mathrm{b}} = -(\hat{\boldsymbol{z}} \times \nabla Q_{\mathrm{b}}) \cdot \hat{\boldsymbol{k}} = -(\hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{w}})\,|\hat{\boldsymbol{z}} \times \nabla Q_{\mathrm{b}}| < 0, \tag{54.46}$$

where we introduced the *pseudo-westward* unit vector

$$\hat{\boldsymbol{w}} \equiv \frac{\hat{\boldsymbol{z}} \times \nabla Q_{\mathrm{b}}}{|\hat{\boldsymbol{z}} \times \nabla Q_{\mathrm{b}}|}. \tag{54.47}$$

Emphasizing the special nature of the westward phase velocity

The westward phase velocity is a very distinct feature of Rossby waves. As seen in Section 54.3.1, it results from the constraint of material conservation of potential vorticity in the presence of a background potential vorticity gradient. Other waves that we have studied, such as acoustic waves (Chapter 51), surface waves (Chapter 52), and inertial waves (Chapter 53), support an arbitrary orientation for their phase velocity. As a result, a source for these sorts of waves will

[7] Our use of a positive angular frequency is not universally maintained in the literature. For example, *Pedlosky* (2003) considers $\omega < 0$ for Rossby waves.

[8] For the angular frequency to be independent of spatial position (assumed for plane waves) requires ∇Q_{b} to be spatially independent. See discussion in Section 54.3.2 for more on the restrictions of the background flow enabling plane waves.

generate waves whose phases are oriented in directions constrained by details of the source rather than by any intrinsic property of the waves. In contrast, an arbitrary source for Rossby waves can only produce Rossby waves with a westward oriented phase. There are no Rossby waves with an eastward phase propagation. In this manner, Rossby waves are *anisotropic waves*.

54.3.7 Stationary Rossby waves

Stationary Rossby waves have zero phase velocity, which occurs if the base flow satisfies

$$\boldsymbol{c}_{\text{p}} = 0 \Longrightarrow \hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{x}} \, (U - \beta/|\boldsymbol{k}|^2) = 0. \tag{54.48}$$

That is, the zonal portion of the Doppler shift exactly cancels the westward phase propagation from planetary β

$$U = \beta/|\boldsymbol{k}|^2. \tag{54.49}$$

The corresponding wavelength, $\Lambda = 2\pi/|\boldsymbol{k}|$, is given by

$$\Lambda_{\text{stationary}} = 2\pi \sqrt{U/\beta}. \tag{54.50}$$

For example, assuming an eastward base flow speed of $U = 1$ m s^{-1} (as in portions of the Antarctic Circumpolar Current) at $\phi = 60°$S, where $\beta = (2\,\Omega/R) \cos\phi \approx 1.14 \times 10^{-11}$ m^{-1} s^{-1}, renders a stationary barotropic Rossby wavelenth of $\Lambda_{\text{stationary}} \approx 1860$ km, whereas for the atmosphere with $\boldsymbol{u}_{\text{b}} \cdot \hat{\boldsymbol{x}} = 25$ m s^{-1} we find $\Lambda_{\text{stationary}} \approx 9300$ km. Evidently, at these large scales the Rossby waves feel the Coriolis acceleration and thus properly earn the name *planetary wave*.

54.3.8 Group velocity

If Rossby waves were non-dispersive, then the westward phase velocity would introduce a puzzle: how can all the wave energy propagate only in the westward direction? Since wave energy follows the group velocity (Section 49.6), would there be an unbounded accumulation of Rossby wave energy in the western side of a domain? In fact, this puzzle does not arise since Rossby waves are dispersive, with their group velocity not constrained to be westward. We here introduce the group velocity and then follow up in Sections 54.4.1 and 54.4.2 by focusing on the group and phase velocities for planetary Rossby waves.

The Rossby wave group velocity, $\boldsymbol{c}_{\text{g}} = \nabla_{\boldsymbol{k}} \varpi$, is given by

$$\boldsymbol{c}_{\text{g}} = \boldsymbol{u}_{\text{b}} + \frac{\hat{\boldsymbol{z}} \times \nabla f - 2\,\hat{\boldsymbol{k}}\,[\hat{\boldsymbol{k}} \cdot (\hat{\boldsymbol{z}} \times \nabla f)]}{|\boldsymbol{k}|^2} = U\,\hat{\boldsymbol{x}} - \frac{\beta\,[\hat{\boldsymbol{x}} - 2\,\hat{\boldsymbol{k}}\,(\hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{x}})]}{|\boldsymbol{k}|^2}. \tag{54.51}$$

The presence of $U \neq 0$ signals the bulk transport of a Rossby wave packet by the base flow. The remaining terms can be related to the phase velocity (54.39) by projecting onto the wavevector direction

$$(\boldsymbol{c}_{\text{g}} - \boldsymbol{c}_{\text{p}}) \cdot \hat{\boldsymbol{k}} = 2\,\beta\,\hat{\boldsymbol{x}} \cdot \hat{\boldsymbol{k}}/|\boldsymbol{k}|^2. \tag{54.52}$$

Since wave dispersion is signaled by a difference between the phase velocity and group velocity, equation (54.52) indicates that Rossby wave dispersion arises from a nonzero gradient in the planetary vorticity, $\nabla Q_{\text{b}} = \nabla f = \beta\,\hat{\boldsymbol{y}}$, along with a nonzero projection of the wavevector onto the westward direction.

54.4 Geometry of planetary Rossby waves

We here focus on some special properties of planetary Rossby waves revealed by studying the geometry of the group velocity using a diagrammatic method developed by *Longuet-Higgins*

(1964).

54.4.1 Group and phase velocities for planetary Rossby waves

We start by focusing on the relation between group and phase velocities for planetary Rossby waves. The β contribution to the group velocity (54.51) is given by

$$[\boldsymbol{c}_{\text{g}}]_\beta = \frac{\beta\,[(k_x^2 - k_y^2)\,\hat{\boldsymbol{x}} + 2\,k_x\,k_y\,\hat{\boldsymbol{y}}]}{|\boldsymbol{k}|^4} \Longrightarrow [\boldsymbol{c}_{\text{g}} \cdot \boldsymbol{c}_{\text{g}}]_\beta = \beta^2/|\boldsymbol{k}|^4. \tag{54.53}$$

Recall the westward component of the phase velocity arising from planetary beta as discussed in Section 54.3.6. In contrast, the zonal component to the group velocity

$$[\boldsymbol{c}_{\text{g}} \cdot \hat{\boldsymbol{x}}]_\beta = \frac{\beta\,(k_x^2 - k_y^2)}{|\boldsymbol{k}|^4} = -[\boldsymbol{c}_{\text{p}} \cdot \hat{\boldsymbol{x}}]_\beta - \frac{\beta\,k_y^2}{|\boldsymbol{k}|^4}, \tag{54.54}$$

can be directed in either direction. Note that to reach this equality we used equation (54.41) for $[\boldsymbol{c}_{\text{p}} \cdot \hat{\boldsymbol{x}}]_\beta$.

Evidently, the group velocity (54.53) for planetary Rossby waves depends on the shape of the wave as characterized by $(k_x^2 - k_y^2)\,\hat{\boldsymbol{x}} + 2\,k_x\,k_y\,\hat{\boldsymbol{y}}$. Consequently, the group velocity has the following properties for its zonal component

$$[\boldsymbol{c}_{\text{g}} \cdot \hat{\boldsymbol{x}}]_\beta > 0 \quad \text{if } k_x^2 > k_y^2 \quad \Rightarrow \text{eastward } \boldsymbol{c}_{\text{g}} \text{ for short zonal planetary waves} \tag{54.55a}$$

$$[\boldsymbol{c}_{\text{g}} \cdot \hat{\boldsymbol{x}}]_\beta < 0 \quad \text{if } k_x^2 < k_y^2 \quad \Rightarrow \text{westward } \boldsymbol{c}_{\text{g}} \text{ for long zonal planetary waves} \tag{54.55b}$$

$$[(\boldsymbol{c}_{\text{g}} + \boldsymbol{c}_{\text{p}}) \cdot \hat{\boldsymbol{x}}]_\beta = 0 \quad \text{if } k_y = 0 \quad \Rightarrow \text{eastward } \boldsymbol{c}_{\text{g}} \text{ for } k_y = 0 \text{ planetary waves.} \tag{54.55c}$$

Wave energy moves eastward in packets of zonally short ($k_x^2 > k_y^2$) planetary Rossby waves, whereas wave energy is westward in zonally long ($k_x^2 < k_y^2$) planetary Rossby waves. That is, zonally elongated Rossby waves have westward group velocity whereas zonally compressed Rossby waves have eastward group velocity, where "elongated" and "compressed" are relative to the meridional structure. Indeed, if $k_y = 0$, in which case there is no meridional structure to the wave, then Rossby waves of any zonal wavenumber have eastward group velocity, even while the phase velocity is westward

$$[\boldsymbol{c}_{\text{g}} \cdot \hat{\boldsymbol{x}}]_\beta = -[\boldsymbol{c}_{\text{p}} \cdot \hat{\boldsymbol{x}}]_\beta > 0 \quad \text{if } k_y = 0. \tag{54.56}$$

This property is consistent with the ratio

$$\frac{[\boldsymbol{c}_{\text{p}} \cdot \boldsymbol{c}_{\text{p}}]_\beta}{[\boldsymbol{c}_{\text{g}} \cdot \boldsymbol{c}_{\text{g}}]_\beta} = \frac{k_x^2}{|\boldsymbol{k}|^2} = (\hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{x}})^2, \tag{54.57}$$

which then allows us to write the dispersion relation in the form

$$[\omega^2]_\beta = |\boldsymbol{k}|^2\,[\boldsymbol{c}_{\text{p}} \cdot \boldsymbol{c}_{\text{p}}]_\beta = k_x^2\,[\boldsymbol{c}_{\text{g}} \cdot \boldsymbol{c}_{\text{g}}]_\beta. \tag{54.58}$$

54.4.2 Dispersion circle for planetary Rossby waves

Figure 54.5 illustrates the geometry of the phase and group velocity as realized for planetary Rossby waves. We refer to this diagram as the *dispersion circle*, and it arises from noting that the dispersion relation, $\omega = -\beta\,k_x/|\boldsymbol{k}|^2$, can be written as an equation for a circle in the (k_x, k_y) plane

$$[k_x + \beta/(2\,\omega)]^2 + k_y^2 = [\beta/(2\,\omega)]^2. \tag{54.59}$$

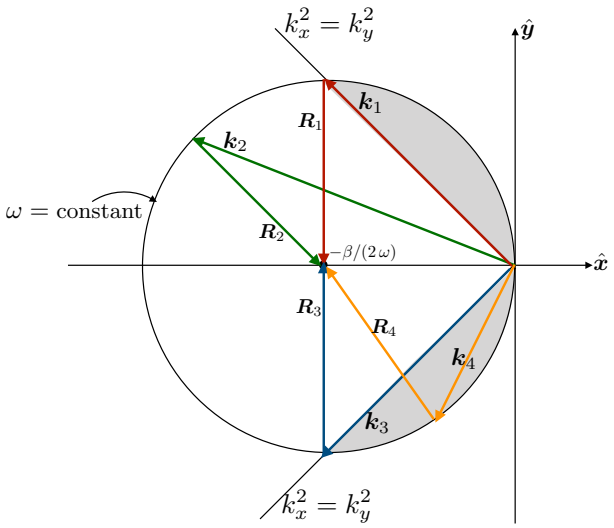

FIGURE 54.5: Dispersion circle for planetary Rossby waves, with this diagram orienting the group velocity and phase velocity in wavevector space, (k_x, k_y). The angular frequency, ω, determines a particular dispersion circle. We depict four example wavevectors, $\boldsymbol{k} = k_x\,\hat{\boldsymbol{x}} + k_y\,\hat{\boldsymbol{y}}$, that orient the phase velocity, $\boldsymbol{c}_\mathsf{p} = \hat{\boldsymbol{k}}\,\omega/|\boldsymbol{k}|$. Each wavevector extends from the origin to a point on the dispersion circle perimeter, $[k_x + \beta/(2\omega)]^2 + k_y^2 = [\beta/(2\omega)]^2$, with the circle having center at $\boldsymbol{k}_\text{center} = -\beta/(2\,\omega)\,\hat{\boldsymbol{x}}$ and radius $\beta/(2\,\omega)$. Each wavevector has an associated group velocity orientation vector, $\boldsymbol{R} = -\boldsymbol{k} - \beta/(2\,\omega)\,\hat{\boldsymbol{x}}$, that points from the circle perimeter to the circle center. The group velocity is westward for those wavevectors that intersect the circle perimeter within the gray-shaded region. Such wavevectors characterize Rossby waves with zonal wavenumbers that are smaller than their meridional wavenumbers; i.e., relatively long zonal Rossby waves. The group velocity has an eastward component for wavevectors outside the gray region, with the lines $k_x^2 = k_y^2$ separating these regions where the group velocity is eastward or westward. Such wavevectors characterize Rossby waves with zonal wavenumbers that are larger than their meridional wavenumbers; i.e., relatively short zonal Rossby waves. The group velocity for wavevector $\boldsymbol{k}_1$ is exactly southward; for $\boldsymbol{k}_2$ it is southeastward; for $\boldsymbol{k}_3$ it is exactly northward, and for k_4 it is northwestward. This figure is taken after *Longuet-Higgins* (1964).

The center of the circle is at the wavevector

$$\boldsymbol{k}_{\text{center}} = -\beta/(2\,\omega)\,\hat{\boldsymbol{x}}, \tag{54.60}$$

and with a radius equal to $\beta/(2\,\omega)$. The circle has angular frequency, ω, acting as a parameter, with lower frequency Rossby waves yielding larger circles. We further reveal the geometry of the group velocity (54.53) by writing it in the form

$$[\boldsymbol{c}_{\text{g}}]_\beta = \frac{\beta\,[(k_x^2 - k_y^2)\,\hat{\boldsymbol{x}} + 2\,k_x\,k_y\,\hat{\boldsymbol{y}}]}{|\boldsymbol{k}|^4} = -\frac{2\,\omega\,\big[[k_x + \beta/(2\,\omega)]\,\hat{\boldsymbol{x}} + k_y\,\hat{\boldsymbol{y}}\big]}{|\boldsymbol{k}|^2}. \tag{54.61}$$

Furthermore, we introduce the group velocity orientation vector

$$\boldsymbol{R} = -\boldsymbol{k} - \beta/(2\,\omega)\,\hat{\boldsymbol{x}} = -[k_x + \beta/(2\,\omega)]\,\hat{\boldsymbol{x}} - k_y\,\hat{\boldsymbol{y}} \quad \text{with} \quad |\boldsymbol{R}| = \beta/(2\omega), \tag{54.62}$$

so that the group velocity can be written in the rather tidy form

$$[\boldsymbol{c}_{\text{g}}]_\beta = 2\,\omega\,\boldsymbol{R}/|\boldsymbol{k}|^2. \tag{54.63}$$

Notice that $\boldsymbol{R}$ has magnitude equal to the radius of the circle. Furthermore, this vector points from the circle perimeter to the circle center, as seen since $\boldsymbol{R} + \boldsymbol{k} = -\beta/(2\,\omega)\,\hat{\boldsymbol{x}} = \boldsymbol{k}_{\text{center}}$.

The geometry depicted in Figure 54.5 partitions the group velocity according to the wavevector. Again, the phase velocity always has a westward component, yet the group velocity can be westward or eastward. Additionally, for each angular frequency there is one wave whose group velocity is precisely northward and another that is southward. The squared magnitude of the group velocity is given by equation (54.53)

$$[\boldsymbol{c}_{\text{g}} \cdot \boldsymbol{c}_{\text{g}}]_\beta = \beta^2/|\boldsymbol{k}|^4, \tag{54.64}$$

so that longer waves (smaller wavenumber) have higher group velocity magnitude.

54.4.3 Reflection of planetary Rossby waves

The diagrammatic method developed in Section 54.4.2 provides a basis to characterize the reflection of Rossby wave packets from a smooth solid boundary. In the left panel of Figure 54.6 we depict a straight and smooth wall sloped with angle γ in the counter-clockwise direction from the positive x-axis. An incident southwestward group velocity carries a Rossby wave packet to the wall at an angle, θ_{i}, relative to the wall's normal direction, $\hat{\boldsymbol{n}}$. We assume the group velocity represents a packet whose central carrier Rossby wave has a wavevector $\boldsymbol{k}_{\text{i}}$, and seek information about the reflected wave packet's carrier wavevector, $\boldsymbol{k}_{\text{r}}$. Geometric optics from Section 50.3 provides the foundation for the approach taken in the following, in which we describe a diagrammatic approach for understanding how the wave packet reflects. Details are summarized in the right panel of Figure 54.6. We assume that the waves reflect from the boundary without dissipation (i.e., perfectly smooth and straight wall), so that reflection only involves kinematic boundary conditions.

Kinematic boundary condition at the wall

The kinematic boundary condition along the wall requires the velocity of fluid particles in the wave to have zero normal component at the wall, so that the the streamfunction must be constant along the wall

$$\boldsymbol{u} \cdot \hat{\boldsymbol{n}} = (\hat{\boldsymbol{z}} \times \nabla\psi) \cdot \hat{\boldsymbol{n}} = (\hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}}) \cdot \nabla\psi = -\hat{\boldsymbol{t}} \cdot \nabla\psi = 0, \tag{54.65}$$

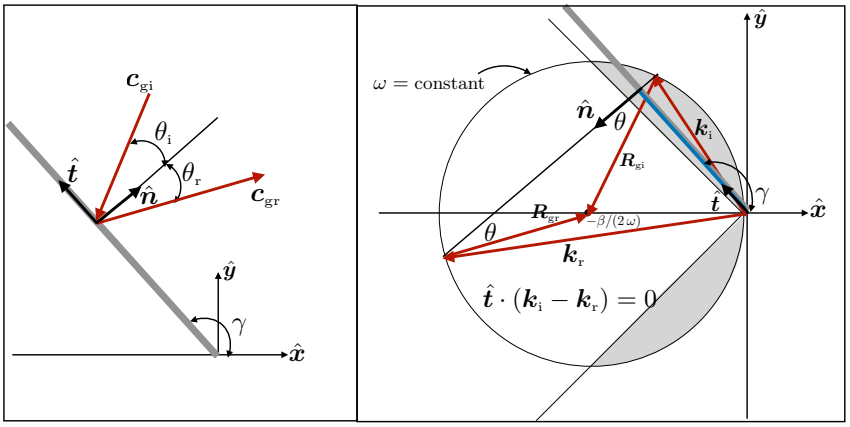

FIGURE 54.6: Depicting the reflection of a Rossby wave packet from a solid wall. The left panel shows the wall sloped at an angle, γ, relative to the positive x-axis. We orient the wall using both its tangential unit vector, $\hat{\boldsymbol{t}} = \hat{\boldsymbol{z}} \times \hat{\boldsymbol{n}} = \hat{\boldsymbol{x}} \cos\gamma + \hat{\boldsymbol{y}} \sin\gamma$, as well as its unit normal, $\hat{\boldsymbol{n}} = \hat{\boldsymbol{x}} \sin\gamma - \hat{\boldsymbol{y}} \cos\gamma$. The incident wave packet has group velocity $\boldsymbol{c}_{gi}$ directed to the southwest and reflected group velocity $\boldsymbol{c}_{gr}$ directed to the northeast. The angle of incidence equals to the angle of reflectance, $\theta_i = \theta_r = \theta$, as required by the kinematic boundary condition (54.67). The right panel shows the wave packet reflection using the dispersion diagram from Figure 54.5. Since the incident and reflected wave have the same angular frequency, we can use the same circle for deriving the wavevectors. The incident and reflected group velocities are oriented by the vectors $\boldsymbol{R}_{gi}$ (southwest) and $\boldsymbol{R}_{gr}$ (northeast) that point from the perimeter to the center of the ω-circle. They both make an angle of θ with respect to the wall's normal direction, $\hat{\boldsymbol{n}}$. The incident and reflected wavevectors satisfy equation (54.72), which says $(\boldsymbol{k}_i - \boldsymbol{k}_r) \cdot \hat{\boldsymbol{t}} = 0$. This relation provides the means to determine the reflected wavevector, $\boldsymbol{k}_r$ using the diagrammatic method illustrated here. Note that the right panel depicts the orientation of the western wall relative to the wavevectors and group velocities in wavevector space. One should not interpret this depiction as somehow making the western wall boundary into an eastern wall.

where we introduced the wall's unit tangent vector

$$\hat{\boldsymbol{t}} = \hat{\boldsymbol{z}} \times \hat{\boldsymbol{n}} = \hat{\boldsymbol{x}} \cos\gamma + \hat{\boldsymbol{y}} \sin\gamma. \tag{54.66}$$

The streamfunction can be any constant on the wall, which we take to be zero without loss of generality

$$\psi(\boldsymbol{x} = \boldsymbol{x}_{\text{wall}}, t) = 0, \tag{54.67}$$

with $\boldsymbol{x}_{\text{wall}}$ the coordinate for a point on the wall.

Relating incident and reflected wave properties

Write the velocity streamfunctions for the incident and reflected carrier waves as

$$\psi_i = A_i \cos(\boldsymbol{k}_i \cdot \boldsymbol{x} - \omega_i t) \quad \text{and} \quad \psi_r = A_r \cos(\boldsymbol{k}_r \cdot \boldsymbol{x} - \omega_r t), \tag{54.68}$$

where A_i and A_r are the real wave amplitudes, $\boldsymbol{k}_i$ and $\boldsymbol{k}_r$ are the wavevectors, and ω_i and ω_r are the angular frequencies. At any point in the fluid, the streamfunction is the sum of the streamfunctions for the incident and reflected waves

$$\psi(\boldsymbol{x}, t) = \psi_i(\boldsymbol{x}, t) + \psi_r(\boldsymbol{x}, t). \tag{54.69}$$

Satisfaction of the boundary condition (54.67) requires

$$A_i \cos(\boldsymbol{k}_i \cdot \boldsymbol{x}_{\text{wall}} - \omega_i t) + A_r \cos(\boldsymbol{k}_r \cdot \boldsymbol{x}_{\text{wall}} - \omega_r t) = 0. \tag{54.70}$$

For this equality to hold at each point along the wall and for all time requires

$$\omega_i = \omega_r \quad \text{equal incident and reflected angular frequency} \tag{54.71a}$$

$$A_i = -A_r \quad \text{equal wave amplitudes but opposite sign} \tag{54.71b}$$

$$(\boldsymbol{k}_i - \boldsymbol{k}_r) \cdot \hat{\boldsymbol{t}} = 0 \quad \text{equal projection of wavevectors onto } \hat{\boldsymbol{t}}. \tag{54.71c}$$

The final equality means that there is an equal projection of the incident and reflected wavevectors onto the wall's tangential direction. It arises by writing the position for a point on the wall as

$$\boldsymbol{x}_{\text{wall}} = |\boldsymbol{x}_{\text{wall}}| \, \hat{\boldsymbol{t}} \Longrightarrow \boldsymbol{k}_i \cdot \hat{\boldsymbol{t}} = \boldsymbol{k}_r \cdot \hat{\boldsymbol{t}}. \tag{54.72}$$

Considering the wall to be an extreme case of a static inhomogeneous media, we can connect these relations to the ray equations in Section 50.3.6. In that discussion we found that a wave packet moving through a static but inhomogeneous media maintains a constant angular frequency along a ray, whereas the wavevector changes.

Geometry of the reflection in wavevector space

Our considerations thus far have been generic, holding for any wave packet described by a wave function such as the velocity streamfunction. To determine further details of the reflected Rossby wavevector, return to the Rossby wave dispersion diagram in Figure 54.5, depicting the reflection process in wavevector space. We only need one dispersion circle since both the incident and reflected waves have the same angular frequency, as required by the kinematic boundary condition (54.70).

To construct the dispersion diagram we start with the known incident group velocity, $\boldsymbol{c}_{gi}$, which is assumed to be directed towards the southwest. Draw the corresponding group velocity orientation vector, $\boldsymbol{R}_{gi}$, from the circle perimeter to the center, also oriented in the same southwesterly direction. From knowledge of $\boldsymbol{R}_{gi}$, draw the incident carrier wavector, $\boldsymbol{k}_i$, extending from the origin to where $\boldsymbol{R}_{gi}$ meets the perimeter. Next make use of the kinematic condition (54.72) that allows us to compute the unique reflected carrier wavevector, $\boldsymbol{k}_r$, constructed by setting $\boldsymbol{k}_r \cdot \hat{\boldsymbol{t}} = \boldsymbol{k}_i \cdot \hat{\boldsymbol{t}}$. Finally, we can now compute the reflected group velocity orientation vector, $\boldsymbol{R}_{gr}$, which points to the center of the circle from the point where $\boldsymbol{k}_r$ hits the circle perimeter. It is through this construction that we find the incident and reflected group velocities make the same angle with the wall normal:

$$\theta_i = \theta_r = \theta. \tag{54.73}$$

Reflections that satisfy this property are known as *specular*.

Features of the incident and reflected waves

Both the incident and reflected carrier wavevectors have a westward component, as required for Rossby waves. However, the southwestward orientation of the incident group velocity is reflected at the wall into a northeastward group velocity. The reflected wave packet, moving eastward, has a larger zonal wavenumber than the incident wave packet:

$$|\boldsymbol{k}_r| > |\boldsymbol{k}_i|. \tag{54.74}$$

This increase in wavenumber arises from an increase in zonal wavevector component, so that the zonal wavelength of the waves within the reflected eastward wave packet are shorter than those in the the incident wave packet. The larger wavenumber decreases the group velocity, so that the northeastward reflected packet is slower than the southwestward incident packet. In a fluid with dissipation, such as through viscosity (see Section 25.8), we expect smaller scale features to

be dissipated more readily than larger scale features. Hence, the northeastward reflected wave packet is expected to be dissipated more readily than the southwestward incident packet.

The reflection of westerly moving Rossby wave packets off a western boundary hold in their converse for the reflection at easterly packets hitting an eastern wall. Namely, a slowly moving easterly wave packet, which is comprised of short wavelength Rossby waves, is reflected off the eastern wall as a faster moving westerly packet of longer wavelength Rossby waves. These results have particular relevance to the ocean, such as through middle latitude western boundary current intensification and the El Niño / Southern Oscillation phenomena in the tropics (see *Vallis* (2017) for further discussion).

54.4.4 Further study

In addition to working through the geometry of planetary waves on a β-plane, *Longuet-Higgins* (1964) studies planetary waves on a sphere, thus making use of spherical harmonics.

54.5 Edge waves

Edge waves are vorticity fluctuations that live on the interface separating two regions of different background vorticity.[9] As vorticity waves, the edge waves of this section share many features with planetary Rossby waves studied in Section 54.3. Additionally, edge waves share features with surface waves studied in Chapter 52, in that they travel along the interface while exponentially decaying in the direction away from the interface.

54.5.1 Base state and the meridionally modulated wave ansatz

Following the decomposition (54.26) we write the relative vorticity as

$$\zeta_{\text{full}} = \zeta + \zeta_{\text{b}} \tag{54.75}$$

where ζ_{b} is a static base state vorticity and ζ the vorticity fluctuating around the base state. The absolute vorticity equation thus takes the form

$$\mathrm{D}(\zeta + \zeta_{\text{b}} + f)/\mathrm{D}t = 0, \tag{54.76}$$

in which we see that the base state vorticity, ζ_{b}, plays a role directly analogous to planetary vorticity, f. This analog allows us to transfer concepts of planetary Rossby waves from Section 54.3 directly over to the edge waves of this section.

We are concerned with a base state comprised of a meridionally dependent zonal flow and corresponding vorticity

$$\boldsymbol{u}_{\text{b}} = \hat{\boldsymbol{x}}\, u_{\text{b}}(y) \quad \text{and} \quad \zeta_{\text{b}} = \zeta_{\text{b}}(y) = -\partial_y u_{\text{b}}. \tag{54.77}$$

In particular, to generate edge waves we assume in Section 54.5.3 that the background vorticity has a jump at $y = y_0$. The vorticity equation (54.28) describing fluctuations relative to the background flow (54.77) is given by

$$\partial_t \zeta + (\boldsymbol{u} + \hat{\boldsymbol{x}}\, u_{\text{b}}) \cdot \nabla\zeta + v\,(\beta + \partial_y \zeta_{\text{b}}) = 0, \tag{54.78}$$

which, when introducing the streamfunction $\zeta = \nabla^2\psi$, leads to

$$\partial_t(\nabla^2\psi) + \hat{\boldsymbol{z}} \cdot [\nabla\psi \times \nabla(\nabla^2\psi)] + u_{\text{b}}\, \partial_x(\nabla^2\psi) + \partial_x\psi\,(\beta + \partial_y\zeta_{\text{b}}) = 0. \tag{54.79}$$

[9] *Sutherland* (2010) in his section 2.6.2 refers to edge waves as *Rayleigh waves*.

If we substitute the plane wave ansatz (54.3) into the vorticity equation (54.79), assuming the angular frequency and wavevector are spatially independent, then we are led to

$$\omega = k_x\, u_{\mathrm{b}} - \frac{k_x\,(\beta + \partial_y u_{\mathrm{b}})}{|\boldsymbol{k}|^2} \qquad \text{inconsistent equation.} \tag{54.80}$$

This equation looks like a straightforward generalization of the Rossby wave dispersion relation (54.32). However, since the background flow, $u_{\mathrm{b}}(y)$, has a meridional dependence, the plane wave assumption that ω and $\boldsymbol{k}$ are spatial constants is, in fact, flawed. We conclude that the vorticity equation (54.79) does not admit a plane wave solution when the background flow is not a constant.

For the case of a background $u_{\mathrm{b}}(y)$ that is gently varying, we can make use of the asymptotic methods from Chapter 50. However, for the edge waves considered in this section we can make progress with a somewhat simpler approach, in which we assume the streamfunction is a zonal traveling wave modulated by a meridionally dependant amplitude

$$\psi(x, y, t) = \widetilde{\psi}(y) \cos(k\,x - \omega\,t). \tag{54.81}$$

We pursue this ansatz in the following.

54.5.2 Rayleigh-Kuo equation

The plane wave properties studied in Section 54.2 do not hold for the meridionally modulated wave (54.81). Consequently, to derive a dispersion relation requires us to linearize the vorticity equation (54.79), which takes the form

$$\partial_t(\nabla^2\psi) + u_{\mathrm{b}}\,\partial_x(\nabla^2\psi) + \partial_x\psi\,(\beta + \partial_y\zeta_{\mathrm{b}}) = 0. \tag{54.82}$$

Substituting the modulated wave ansatz (54.81) into the linearized vorticity equation (54.82) gives

$$\partial_t(\nabla^2\psi) = \omega\,(-k^2 + \partial_{yy})\widetilde{\psi}\sin(k\,x - \omega\,t) \tag{54.83a}$$

$$u_{\mathrm{b}}\,\partial_x(\nabla^2\psi) = -u_{\mathrm{b}}\,k\,(-k^2 + \partial_{yy})\widetilde{\psi}\sin(k\,x - \omega\,t) \tag{54.83b}$$

$$\partial_x\psi\,(\beta + \partial_y\zeta_{\mathrm{b}}) = -k\,(\beta + \partial_y\zeta_{\mathrm{b}})\widetilde{\psi}\sin(k\,x - \omega\,t), \tag{54.83c}$$

which then leads to the *Rayleigh-Kuo* equation for the meridional wave amplitude function[10]

$$(u_{\mathrm{b}} - c)\,(\partial_{yy} - k^2)\,\widetilde{\psi} + (\beta - \partial_{yy}u_{\mathrm{b}})\,\widetilde{\psi} = 0 \quad \text{with} \quad c = \omega/k, \tag{54.84}$$

which can also be written in the form

$$\partial_y[(u_{\mathrm{b}} - c)\,\partial_y\widetilde{\psi} - \widetilde{\psi}\,\partial_y u_{\mathrm{b}}] + [\beta - k^2\,(u_{\mathrm{b}} - c)]\,\widetilde{\psi} = 0. \tag{54.85}$$

The Rayleigh-Kuo equation is fundamental to our study of barotropic shear instability in Chapter 61. For current purposes we use it to derive the dispersion relation for edge waves.

[10] Kuo extended the original Rayleigh equation to account for the β effect. In the absence of β we refer to just the *Rayleigh equation*.

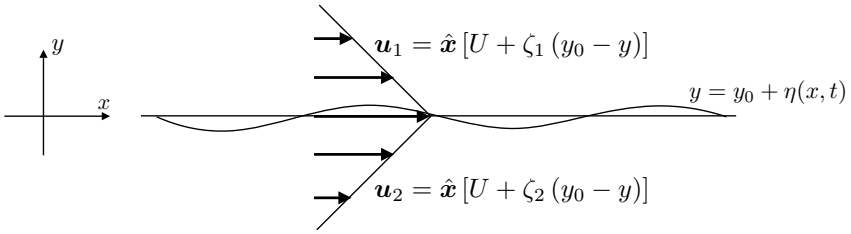

FIGURE 54.7: A zonal point jet in the horizontal x-y plane with the jet maxima at $y = y_0$. The velocity is linear on both sides of the maxima and there is a finite jump in the vorticity at the maxima. Vorticity in the upper region is given by $\zeta_1 = -\partial_y u_1$ and in the lower region $\zeta_2 = -\partial_y u_2$, with $\zeta_1 > 0$ and $\zeta_2 < 0$ depicted in this figure. Oscillations of the material interface, $y = y_0 + \eta(x,t)$, are known as *edge waves*, which exist due to the jump in the vorticity. The top half-plane is referred to as region 1 and the lower half-plane is region 2. Any surface with a finite vorticity jump supports edge waves, with the symmetric point jet shown in this figure a prototypical case.

54.5.3 The point jet

Figure 54.7 illustrates the zonal flow characterizing a *point jet*, in which there is a linear velocity profile on both sides of a maxima

$$\boldsymbol{u}_\mathrm{b} = u_\mathrm{b}(y)\,\hat{\boldsymbol{x}} \quad \text{with} \quad u_\mathrm{b}(y) = U + (y_0 - y) \begin{cases} \zeta_1 & \text{for } y > y_0 \\ \zeta_2 & \text{for } y < y_0, \end{cases} \tag{54.86}$$

where ζ_1 and ζ_2 are constants that measure the vorticity in the two half-planes

$$\zeta_\mathrm{b} = -\partial_y u_\mathrm{b} = \begin{cases} \zeta_1 & \text{for } y > y_0 \\ \zeta_2 & \text{for } y < y_0. \end{cases} \tag{54.87}$$

Because of the finite vorticity jump at $y = y_0$, the meridional derivative of the vorticity is proportional to the Dirac delta[11]

$$\partial_y \zeta_\mathrm{b}(y = y_0) = \lim_{\epsilon \to 0} \frac{\zeta_\mathrm{b}(y = y_0 + \epsilon/2) - \zeta_\mathrm{b}(y = y_0 - \epsilon/2)}{\epsilon} = (\zeta_1 - \zeta_2)\,\delta(y - y_0). \tag{54.88}$$

As a check on this expression, we take an integral across the interface to find

$$\int_{y_0-\epsilon/2}^{y_0+\epsilon/2} \partial_y \zeta_\mathrm{b}\,\mathrm{d}y = \zeta_\mathrm{b}(y_0 + \epsilon/2) - \zeta_\mathrm{b}(y_0 - \epsilon/2) = (\zeta_1 - \zeta_2) \int_{y_0-\epsilon/2}^{y_0+\epsilon/2} \delta(y - y_0)\,\mathrm{d}y. \tag{54.89}$$

Finally, note that the point yet is zonally symmetric so that the base flow only has a nonzero meridional pressure gradient

$$\nabla \varphi_\mathrm{b} = \hat{\boldsymbol{y}}\,\partial_y \varphi_\mathrm{b}. \tag{54.90}$$

We study waves traveling on the material vorticity interface at $y = y_0 + \eta(x,t)$, and written in the form

$$\eta(x,t) = \tilde{\eta} \cos(k\,x - \omega\,t). \tag{54.91}$$

To develop properties of the flow on each side of the interface requires us to develop the kinematic and dynamic boundary conditions at the interface. Furthermore, the amplitude, $\tilde{\eta}$, is assumed to be much smaller than the wavelength, thus allowing us to linearize the boundary conditions and to evaluate the conditions at $y = y_0$.[12] Note that we assume the interface undulation has the same phase as the streamfunction (54.81), and this assumption will be seen to be self-consistent.

[11] See Chapter 7 for more on the Dirac delta. In particular, note that the Dirac delta, $\delta(y)$, has dimensions of inverse length.

[12] We took the same approach for the surface gravity waves in Section 52.3.4.

54.5.4 Kinematic boundary condition at the interface

The material nature of the interface means that the meridional velocity of a fluid particle at the interface is given by[13]

$$v = \mathrm{D}\eta/\mathrm{D}t = (\partial_t + u\,\partial_x)\eta \approx (\partial_t + u_\mathrm{b}\,\partial_x)\eta, \tag{54.92}$$

where the approximation follows from linearization. This kinematic boundary condition holds on both sides of the interface so that

$$(\partial_t + u_1\,\partial_x)\eta = \partial_x\psi_1 \quad \text{and} \quad (\partial_t + u_2\,\partial_x)\eta = \partial_x\psi_2. \tag{54.93}$$

Applying this relation to the wave ansatz (54.91) for the interface, and the wave ansatz (54.81) for the streamfunction as evaluated at $y = y_0$, leads to

$$(u_1 - c)\,\tilde{\eta} = \widetilde{\psi}_1 \quad \text{and} \quad (u_2 - c)\,\tilde{\eta} = \widetilde{\psi}_2. \tag{54.94}$$

Since $u_1(y_0) = u_2(y_0) = U$, the kinematic boundary condition says that the streamfunctions match at the interface

$$\widetilde{\psi}_1 = \widetilde{\psi}_2 \quad \text{at } y = y_0. \tag{54.95}$$

54.5.5 Dynamic boundary condition at the interface

For the dynamic boundary condition we assume there is no surface tension on the interface, in which case pressure matches

$$\varphi_1 = \varphi_2 \quad \text{at } y = y_0. \tag{54.96}$$

To make use of this boundary condition, consider the zonal velocity equation (38.1) with the zonal flow decomposed as in equation (54.26)

$$\partial_t(u + u_\mathrm{b}) + (\boldsymbol{u} + \boldsymbol{u}_\mathrm{b}) \cdot \nabla(u + u_\mathrm{b}) - f\,v = -\partial_x\varphi, \tag{54.97}$$

which linearizes to

$$(\partial_t + u_\mathrm{b}\,\partial_x)\,u + v\,(\partial_y u_\mathrm{b} - f) = -\partial_x\varphi \implies (\partial_t + u_\mathrm{b}\,\partial_x)\,\partial_y\psi - \partial_x\psi\,(\partial_y u_\mathrm{b} - f) = \partial_x\varphi, \tag{54.98}$$

where we set $\partial_x\varphi_\mathrm{b} = 0$ as per the assumed zonal symmetry of the background state in equation (54.90). Consider an ansatz for the pressure in the same form as for the streamfunction

$$\varphi(x, y, t) = \widetilde{\varphi}(y)\cos(k\,x - \omega\,t), \tag{54.99}$$

which, along with the streamfunction ansatz (54.81), brings the velocity equation (54.98) to

$$[(u_\mathrm{b} - c)\,\partial_y + (f - \partial_y u_\mathrm{b})]\,\widetilde{\psi} = \widetilde{\varphi} \quad \text{at } y = y_0. \tag{54.100}$$

Invoking continuity of pressure at the interface yields

$$[(U - c)\,\partial_y + (f - \partial_y u_1)]\,\widetilde{\psi}_1 = [(U - c)\,\partial_y + (f - \partial_y u_2)]\,\widetilde{\psi}_2 \quad \text{at } y = y_0. \tag{54.101}$$

This dynamic boundary condition also follows from integrating the Rayleigh-Kuo equation (54.85) across the interface and noting that $[\beta - k^2\,(u_\mathrm{b} - c)]\,\widetilde{\psi}$ is continuous at the interface. We can further simplify the dynamic boundary condition (54.101) by making use of the kinematic

[13] Equation (54.92) is the direct analog of the kinematic boundary condition developed in Section 19.6.2 for vertical position of a material surface, $z = \eta(x, y, t)$.

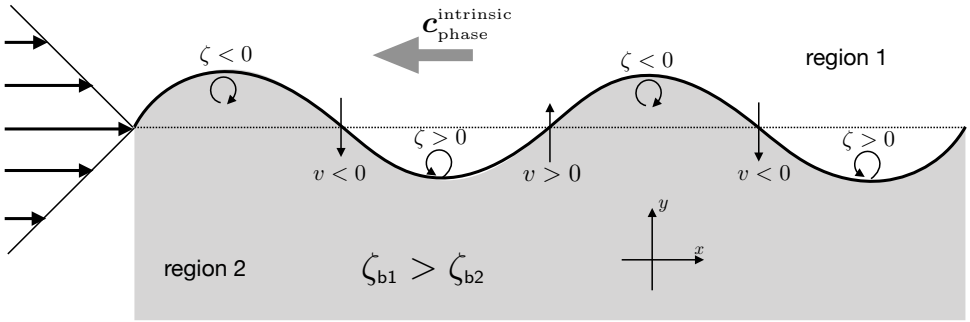

FIGURE 54.8: Depicting the *pseudo-westward* intrinsic phase propagation of an edge wave along a material surface separating two regions of vorticity. Here the larger background relative vorticity is oriented to the north, $\zeta_{b1} > \zeta_{b2}$, so that the intrinsic phase velocity for the edge wave propagates to the west. We also show the point jet velocity profile, whose relative vorticity jump supports the westward phase velocity of the edge wave. The variables, v and ζ, are the anomalies relative to the unperturbed reference state, as per the decomposition equation (54.26). The vorticity mechanism for the phase propagation is identical to that for planetary Rossby waves depicted in Figure 54.3, where the background vorticity jump from the point jet serves the same role as the planetary vorticity gradient. Consider a material line initially along $y = y_0$ and whose relative vorticity equals to that of the background point jet. A southward extension of this line leads to a local positive relative vorticity anomaly, $\zeta' > 0$, since the particle moves into a region with lower background relative vorticity. This anomaly is depicted by the counterclockwise induced secondary flow. Conversely, a northward extension leads to a local negative vorticity anomaly and associated clockwise secondary flow. The anomalous meridional motion is depicted every π radians, with maximal anomalies at wave nodes. The action of the coherent counter-rotating secondary vortices leads to westward propagation of the phase. In general, the phase moves with the higher vorticity to the right, which means that it moves from the convex side of the velocity profile towards the concave side.

boundary condition (54.95), $\widetilde{\psi}_1 = \widetilde{\psi}_2$ at $y = y_0$. Doing so eliminates the Coriolis term and yields

$$(U - c)\,(\partial_y \widetilde{\psi}_1 - \partial_y \widetilde{\psi}_2) = [\partial_y u_1 - \partial_y u_2]\,\widetilde{\psi} \quad \text{at } y = y_0. \tag{54.102}$$

54.5.6 Edge wave dispersion relation

Set $\beta = 0$ to focus on wave solutions arising just from the point jet, in which the Rayleigh-Kuo equation (54.84) simplifies to

$$(u_{\text{b}} - c)\,(\partial_{yy} - k^2)\,\widetilde{\psi} - \partial_{yy} u_{\text{b}}\,\widetilde{\psi} = 0. \tag{54.103}$$

Evaluating this equation on the two sides of the interface, and assuming the base flow is distinct from the phase velocity so that $u_{\text{b}} \neq c$, leads to

$$\widetilde{\psi} = \psi_0 \begin{cases} \mathrm{e}^{-|k|(y-y_0)} & \text{for } y > y_0 \\ \mathrm{e}^{+|k|(y-y_0)} & \text{for } y < y_0. \end{cases} \tag{54.104}$$

As anticipated, the edge wave exponentially decays away from the interface. Just like the surface waves in Chapter 52, the horizontal wave number, $|k|$, determines the exponential decay scale.

Using equation (54.104) in the dynamic boundary condition (54.102) yields the phase velocity[14]

$$c = \omega/k = U + \frac{\partial_y u_1 - \partial_y u_2}{2\,|k|} = \underbrace{U}_{\text{Doppler}} \underbrace{-\frac{(\zeta_1 - \zeta_2)}{2\,|k|}}_{\text{intrinsic}}. \tag{54.105}$$

The background zonal flow, U, provides a Doppler shift to the phase velocity. The second piece arises from the vorticity jump across the interface, and we refer to it as the *intrinsic* portion

[14]The phase of the edge wave only moves in the zonal direction, with $c > 0$ for a phase velocity in the $+\hat{\boldsymbol{x}}$ direction and $c < 0$ for a phase velocity in the $-\hat{\boldsymbol{x}}$ direction.

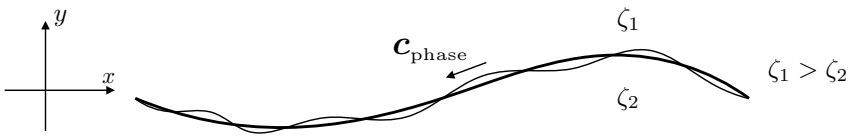

FIGURE 54.9: Edge waves moving along a jump in the background vorticity field, with the background vorticity equal to ζ_1 north of the jump and ζ_2 to the south. The phase velocity is oriented with the higher relative vorticity to the right when facing in the direction of the phase velocity.

to the phase velocity. If the vorticity increases northward, so that $\zeta_1 - \zeta_2 > 0$, then $c - U < 0$, thus signaling a westward phase velocity relative to the background flow. This behavior is precisely that found for planetary Rossby waves, thus prompting some to refer to edge waves as prototypical Rossby waves. In Figure 54.8, we summarize the vorticity mechanism for the *pseudo-westward* phase velocity, with the mechanism identical to the planetary Rossby wave in Figure 54.3. In general, the phase velocity for edge waves is directed so that the region of higher vorticity is to the right when facing in the direction of the phase velocity, with this orientation defining "pseudo-westward". This terminology is taken from the truly westward phase velocity corresponding to planetary waves, in which the larger planetary vorticity is to the north. Figure 54.9 provides a schematic for a curved vorticity jump line, whereby the edge waves propagate along the jump, again with the phase in the pseudo-westward direction.

54.5.7 Further study

A similar treatment of edge waves can be found in Section 3.12 of *Smyth and Carpenter* (2019) and Section 9.2.3 of *Vallis* (2017). As studied in Chapter 61, interactions between vorticity waves can lead to shear instabilities, with such instabilities forming a fundamental feature of unstable and turbulent geophysical flows.

54.6 Exercises

EXERCISE 54.1: ROSSBY WAVES IN A ZONAL CHANNEL

In Section 54.3 we examined the physics of Rossby waves on an unbounded β-plane. Here we consider a zonal channel on a β-plane, with the channel unbounded in the zonal direction but bounded meridionally. The meridional domain is given by $y_{\text{s}} \leq y \leq y_{\text{n}}$ where $y_{\text{n}} - y_{\text{s}} = L$, and with rigid material walls at the meridional boundaries. Everything else is just as in Section 54.3, with a zonal and constant base flow, $\boldsymbol{u}_{\text{b}} = U\,\hat{\boldsymbol{x}}$.

(a) Write a single plane wave mode that travels in the zonal direction but is standing in the meridional direction. Hint: the plane wave ansatz (54.6) should be modified so that $\hat{\boldsymbol{n}} \cdot (\hat{\boldsymbol{z}} \times \nabla\psi) = 0$ at the northern and southern walls. The boundary condition imposes a constraint on the meridional wavenumber. What is the constraint?

(b) What is the dispersion relation for the Rossby waves in this channel?

Hint: recall our study of standing gravity wave modes in Section 52.8, with such modes occuring when waves live in a bounded domain and thus can no longer travel freely. Instead, the wave modes must fit inside of the domain in a manner that satisfies the boundary conditions. We can think of such standing wave modes as a superposition of two oppositely traveling waves with the same frequency and wavenumber that are locked in-phase in a manner that satisfies

the boundary conditions. For example, the sum of a right and left moving wave with equal amplitude, wavenumber, and frequency is given by the standing pattern

$$A\cos(k\,x-\omega\,t)+A\cos(-k\,x-\omega\,t)=2\,A\cos(\omega\,t)\cos(k\,x). \tag{54.106}$$

EXERCISE 54.2: VORTEX MECHANISM FOR EDGE WAVES

Provide a sketch like Figure 54.8 but for edge waves in the case with $\zeta_1 < \zeta_2$. Hint: be sure to orient the wave so that it moves from the convex side of the velocity profile towards the concave side.

Chapter 55

SHALLOW WATER WAVES

In this chapter we develop the basic theory for waves appearing in the shallow water fluid. In the literature these waves are sometimes referred to as *long waves* since the shallow water approximation applies when the horizontal length scale is much larger than the vertical, in which case the horizontal wavelength is larger than the fluid depth. Our presentation focuses on the case of a single shallow water layer, but we offer brief discussions of two-layer cases to illustrate the generalizations to multiple layers. Notably, the algebraic tedium increases greatly when adding layers. Hence, for theoretical analysis concerned with the role of stratification, it is typically more fruitful to move to the continuous vertical stratification in Chapter 57, rather than study waves in more than two stacked shallow water layers.

We first consider general features of both the nonlinear and then the linear shallow water equations. For the linearized system, we develop a unified wave equation for the free surface. The derivation of this equation is rather detailed and the resulting linear equation somewhat complicated. Even so, it serves to unify across the full suite of linear shallow water waves on a rotating β-plane, and offers insights into both the methods used to derive wave equations and the scalings used to extract their core physical features. In unpacking this wave equation we pursue a focused study of gravity waves, inertia-gravity waves, and Rossby waves. We also consider the case of a Kelvin wave, which relies on a boundary in the presence of the Coriolis parameter.

READER'S GUIDE TO THIS CHAPTER

This chapter builds from the shallow water studies in Chapters 35 and 36, as well as other waves chapters in this part of the book. In Chapter 56 we extend the study of shallow water waves by considering a variety of case studies. The first half of this video offers a pedagogical introduction to non-rotating shallow water waves.

55.1 Loose threads

- Equatorial waves
- Energetics of Rossby waves as per Section 6.6 of *Vallis* (2017).

55.2 Shallow water equations

The shallow water equations of motion are given by the velocity equation (35.12) and thickness equation (35.19), written here in their Eulerian form and with zero atmospheric pressure

$$\partial_t \boldsymbol{u} + (\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -g\, \nabla \eta \tag{55.1a}$$

$$\partial_t h + \nabla \cdot (h\, \boldsymbol{u}) = 0. \tag{55.1b}$$

In Section 55.3 we linearize these shallow water equations and study their properties in anticipation of later study of their wave fluctuations. Before doing so, however, we formulate a wave-like equation that holds for the nonlinear shallow water model. Doing so anticipates certain features of the linear equations while offering yet another view of the shallow water system beyond that provided in Chapters 35 and 36. We pursued the analogous manipulations for acoustic waves in Section 51.4.1.

55.2.1 Nonlinear wave equation

Consider the shallow water equations written using the material time derivative

$$\mathrm{D}\boldsymbol{u}/\mathrm{D}t + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -g\,\nabla\eta \quad \text{and} \quad \mathrm{D}h/\mathrm{D}t = -h\,\nabla\cdot\boldsymbol{u}. \tag{55.2}$$

Taking the material time derivative of the thickness equation, and then using the velocity equation, yields

$$\begin{aligned}
\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{1}{h}\frac{\mathrm{D}h}{\mathrm{D}t}\right] &= -\frac{\mathrm{D}(\nabla\cdot\boldsymbol{u})}{\mathrm{D}t} && \text{(55.3a)}\\
&= -\nabla\cdot\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + \partial_m u^n\,\partial_n u^m && \text{(55.3b)}\\
&= -\nabla\cdot(-f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} - g\,\nabla\eta) + \boldsymbol{S}^m{}_n\,\boldsymbol{S}^n{}_m - \boldsymbol{R}^m{}_n\,\boldsymbol{R}^n{}_m, && \text{(55.3c)}
\end{aligned}$$

where $\boldsymbol{S}$ is the strain rate tensor and $\boldsymbol{R}$ is the rotation tensor (both are discussed in Section 18.8). Rearrangement then leads to

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{1}{h}\frac{\mathrm{D}h}{\mathrm{D}t}\right] - g\,\nabla^2\eta = \nabla\cdot(f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}) + \boldsymbol{S}^m{}_n\,\boldsymbol{S}^n{}_m - \boldsymbol{R}^m{}_n\,\boldsymbol{R}^n{}_m, \tag{55.4}$$

which corresponds to equation (51.19) holding for the compressible fluid. We interpret this equation as a generalized wave equation holding for movement following a shallow water fluid column. The second order material time operator acts on the thickness to propagate signals relative to the moving fluid. The linear terms, $g\,\nabla^2\eta$ and $\nabla\cdot(f\,\hat{\boldsymbol{z}}\times\boldsymbol{u})$, also appear in the linearized equations and will be discussed later, whereas $\boldsymbol{S}^m{}_n\,\boldsymbol{S}^n{}_m - \boldsymbol{R}^m{}_n\,\boldsymbol{R}^n{}_m$ is a nonlinear source arising from gradients in the fluid velocity. We drop the nonlinear source when working with the linearized equations, and likewise the material time derivative becomes a local time derivative.

55.2.2 Another form of the nonlinear wave equation

To align more closely with the linear wave equation derived in Section (55.3), we consider again the velocity and thickness equations in the form of equation (55.2) yet first determine the evolution equation for the divergence of the thickness flux. For this purpose, multiply the thickness equation by the velocity and the velocity equation by the thickness, and then add to find

$$\mathrm{D}(h\,\boldsymbol{u})/\mathrm{D}t = -f\,h\,\hat{\boldsymbol{z}}\times\boldsymbol{u} - g\,h\,\nabla\eta - (h\,\boldsymbol{u})\,\nabla\cdot\boldsymbol{u}. \tag{55.5}$$

Divergence of the left hand side of this equation is given by

$$\nabla\cdot[\mathrm{D}(h\,\boldsymbol{u})/\mathrm{D}t] = \mathrm{D}[\nabla\cdot(h\,\boldsymbol{u})]/\mathrm{D}t + (\partial_m\boldsymbol{u})\cdot\nabla(h\,u^m) = -\mathrm{D}(\partial_t h)/\mathrm{D}t + (\partial_m\boldsymbol{u})\cdot\nabla(h\,u^m), \tag{55.6}$$

where we used the thickness equation for the final equality. Combining with the divergence of the right hand side of equation (55.5) yields

$$-\mathrm{D}(\partial_t h)/\mathrm{D}t + \partial_m\boldsymbol{u}\cdot\nabla(h\,u^m) = -\nabla\cdot(f\,h\,\hat{\boldsymbol{z}}\times\boldsymbol{u}) - \nabla\cdot(g\,h\,\nabla\eta) - \nabla\cdot(h\,\boldsymbol{u}\,\nabla\cdot\boldsymbol{u}), \tag{55.7}$$

with rearrangement leading to the nonlinear wave equation

$$\frac{\mathrm{D}}{\mathrm{D}t}\frac{\partial \eta}{\partial t} - \nabla \cdot (g\, h\, \nabla \eta) = \nabla \cdot (f\, h\, \hat{\boldsymbol{z}} \times \boldsymbol{u}) + \partial_m \boldsymbol{u} \cdot \nabla (h\, u^m) + \nabla \cdot (h\, \boldsymbol{u}\, \nabla \cdot \boldsymbol{u}), \tag{55.8}$$

where we noted that $\partial_t h = \partial_t \eta$. This nonlinear equation corresponds directly to the linear wave equation (55.31) derived below. It is this alternative form that readily offers a direct decomposition of the various waves appearing in the shallow water fluid. Namely, in the linear equations we drop the nonlinear sources on the the right hand side, and convert the material time derivative to the local Eulerian time derivative.

55.2.3 Comments

This section stopped short of pursuing an analysis of nonlinear wave solutions. However, as in the analogous discussion of the compressible fluid in Section 51.4.1, these manipulations signal that wave-like equations are not restricted to linearized equations. Rather, they are basic to the nonlinear equations, though with a more complex mathematical structure that generally requires numerical or asymptotic methods to penetrate.

For the remainder of this chapter we focus on the linearized set of equations, thus enabling the use of linear analysis methods. Even though much simpler than the nonlinear equations, we uncover a rich and complex variety of linear wave phenomena within the shallow water model.

55.3 Linearized shallow water equations

In this section we linearize the shallow water velocity equation (55.1a) and thickness equation (55.1b) in a manner that supports subsequent analysis of small amplitude fluctuations. In the process we derive a linear wave equation for free surface undulations, with a number of source terms that support the variety of waves studied in later sections. This wave equation is the linearized version of the nonlinear shallow water equation (55.8).

55.3.1 Linearized thickness and velocity equations

We linearize the equations around a base state that is at rest and thus with a flat free surface. Referring to Figure 35.1 leads to the expressions for the layer thickness

$$h(x,y,t) = [\overline{\eta} + \eta'(x,y,t)] - [\overline{\eta_{\mathrm{b}}} + \eta'_{\mathrm{b}}(x,y)] = H + \eta'(x,y,t) - \eta'_{\mathrm{b}}(x,y), \tag{55.9}$$

along with the corresponding velocity

$$\boldsymbol{u}(x,y,t) = 0 + \boldsymbol{u}'(x,y,t). \tag{55.10}$$

The terms $\overline{\eta}$ and $\overline{\eta_{\mathrm{b}}}$ are area means for the free surface and bottom topography, whereas η' and η'_{b} are deviations from these means. We assume there are no boundary sources of volume so that $\overline{\eta}$ is constant in time. The prime on the velocity in equation (55.10) acts as a reminder that it is driven by gradients in the fluctuating free surface, η'.

We make the following assumptions about the terms comprising the layer thickness.

- The layer thickness is everywhere positive, $h > 0$, thus ensuring there is water at each point in the layer at each time. We make this assumption since a vanishing layer thickness represents a nontrivial change in the domain that requires the full nonlinear equations.
- A nonzero η'_{b} allows for local variations in the bottom topography. We assume these

variations are bounded by the mean thickness,

$$H_r \equiv H - \eta'_b > 0, \tag{55.11}$$

thus ensuring the resting thickness, H_r, is nonzero everywhere. This assumption does not place strong constraints on η'_b. In particular, we do not generally assume η'_b is small beyond assuming that $H_r > 0$. However, we do assume that η'_b is small when studying the quasi-geostrophic motion associated with Rossby waves in Sections 55.9.

- We assume the free surface undulations are much smaller than the resting thickness

$$|\eta'| \ll H_r. \tag{55.12}$$

This is the key assumption in the linearization process. It follows from our interest in studying linear wave fluctuations of the free surface.

The above assumptions lead to the linearized version of the thickness equation (55.1b)

$$\partial_t \eta' + \nabla \cdot (H_r \, \boldsymbol{u}') = 0. \tag{55.13}$$

This equation says that a time tendency of the free surface is driven by the convergence of a thickness flux, where the thickness is approximated by its resting value

$$h = H + \eta' - \eta'_b \approx H - \eta'_b = H_r. \tag{55.14}$$

We conclude from equation (55.13) that free surface transients (i.e., waves) require a nonzero horizontal convergence, $-\nabla \cdot (H_r \, \boldsymbol{u}') \neq 0$. It follows that waves in a flat bottom domain arise only when there is a nonzero convergence in the horizontal flow, $-\nabla \cdot \boldsymbol{u}' \neq 0$. Such horizontal convergences are fundamental to the shallow water fluid, and provide the key distinction from waves appearing in the horizontally non-divergent barotropic fluid from Chapter 54.

The linearized version of the shallow water velocity equation (55.1a) is

$$\partial_t \boldsymbol{u}' + f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}' = -g \, \nabla \eta', \tag{55.15}$$

which is reached by dropping the nonlinear advection, $(\boldsymbol{u}' \cdot \nabla)\boldsymbol{u}'$. Advection is indeed smaller than the other terms since velocity tendencies are driven by the assumed small amplitude fluctuations in the free surface, thus making $(\boldsymbol{u}' \cdot \nabla)\boldsymbol{u}'$ second order in small terms.

55.3.2 Energetics

We studied energetics of a single layer of shallow water fluid in Section 36.5. We here summarize how the energetics appear for the linearized thickness equation (55.13) and velocity equation (55.15). As per the norm with energetics of linearized systems (e.g., see the study of acoustic energy in Section 51.6 and surface waves in Section 52.4), we work to second order accuracy in fluctuating fields.

The gravitational potential energy per horizontal area is given by

$$\mathcal{P}^{\text{sw}} = g \, \rho \int_{\eta_b}^{\eta} z \, \mathrm{d}z = (g \, \rho / 2) \, (\eta^2 - \eta_b^2), \tag{55.16}$$

and its time tendency is

$$\partial_t \mathcal{P}^{\text{sw}} = g \, \rho \, (\overline{\eta} + \eta') \, \partial_t \eta' \approx -g \, \rho \, (\overline{\eta} + \eta') \, \nabla \cdot (H_r \, \boldsymbol{u}'). \tag{55.17}$$

Likewise, the kinetic energy per area is

$$\mathcal{K}^{\text{sw}} = \frac{\rho}{2} \int_{\eta_{\text{b}}}^{\eta} \boldsymbol{u} \cdot \boldsymbol{u} \, \mathrm{d}z = (\rho/2) \, h \, \boldsymbol{u}' \cdot \boldsymbol{u}' \approx (\rho/2) \, H_{\text{r}} \, \boldsymbol{u}' \cdot \boldsymbol{u}', \tag{55.18}$$

and its time tendency is

$$\partial_t \mathcal{K}^{\text{sw}} = \rho \, H_{\text{r}} \, \boldsymbol{u}' \cdot \partial_t \boldsymbol{u}' = -g \, \rho \, H_{\text{r}} \, \boldsymbol{u}' \cdot \nabla \eta' = -g \, \rho \, H_{\text{r}} \, \boldsymbol{u}' \cdot \nabla(\overline{\eta} + \eta'). \tag{55.19}$$

The time tendency for the mechanical energy is thus given by

$$\partial_t (\mathcal{K}^{\text{sw}} + \mathcal{P}^{\text{sw}}) = -g \, \rho \, \nabla \cdot [H_{\text{r}} \, (\overline{\eta} + \eta') \, \boldsymbol{u}']. \tag{55.20}$$

This equation is a linearized version of the mechanical energy equation (36.119). Here, we only have the transfer of energy due to the advection of pressure, whereas the nonlinear equations also have the advection of kinetic energy and potential energy.

55.3.3 Potential vorticity

The shallow water potential vorticity (Section 39.3) is given by

$$Q = \frac{f + \zeta}{h} = \frac{f + \zeta}{H - \eta'_{\text{b}} + \eta'} \approx Q' \tag{55.21}$$

where, to first order in primed quantities,

$$Q' = \frac{f + \zeta'}{H_{\text{r}}} - \frac{f \, \eta'}{H_{\text{r}}^2} \approx \frac{f}{H} + \frac{H \, \zeta' + f \, (\eta'_{\text{b}} - \eta')}{H^2}, \tag{55.22}$$

with the approximation following from assuming $|\eta'| \ll H_{\text{r}} = H - \eta'_{\text{b}} \approx H$. That is, we assume both small amplitude free surface fluctuations, and small amplitude bottom topography variations. Note that for the f-plane, the f/H term can be dropped since it is a constant. Use of the linearized thickness equation (55.13) and linearized velocity equation (55.15), yields the time tendency for the linearized potential vorticity (see Exercise 55.1)

$$\partial_t Q' + \boldsymbol{u}' \cdot \nabla (f / H_{\text{r}}) = 0. \tag{55.23}$$

For a flat bottom f-plane domain, the linearized potential vorticity remains static at each point in the fluid, $\partial_t Q' = 0$. In contrast, nonzero gradients in f or H_{r} cause the linearized potential vorticity to be modified through advection of f/H_{r}, with f/H_{r} the potential vorticity of the background rest state. Hence, if f and/or H_{r} are spatially varying, solutions to the linear equations, including waves, have an evolving potential vorticity.

55.3.4 Traveling plane wave ansatz and $\nabla \cdot \boldsymbol{v} = 0$

To derive the dispersion relation for the various shallow water waves, we consider the traveling plane wave ansatz from Section 49.5, here written in the form

$$(u', v', \eta') = (\tilde{u}, \tilde{v}, \tilde{\eta}) \, \mathrm{e}^{\mathrm{i}(\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t)}, \tag{55.24}$$

where the real part of the right hand side is assumed. The amplitudes $(\tilde{u}, \tilde{v}, \tilde{\eta})$ are generally complex numbers that are independent of space and time. Recall from Section 35.2 that the horizontal velocity has no depth dependence in the shallow water layer, which follows from making the hydrostatic approximation in the homogeneous fluid layer. Hence, a plane wave solution to the shallow water wave equations must have a zero vertical component to the

wavevector, $k_z = 0$, so that

$$\boldsymbol{k} = \hat{\boldsymbol{x}}\, k_x + \hat{\boldsymbol{y}}\, k_y. \tag{55.25}$$

Evidently, the phase of shallow water plane waves (55.24) travels horizontally within a layer.

As a layer with a constant density, the fluid in the shallow water layer is incompressible so that $\nabla \cdot \boldsymbol{v} = 0$. For plane waves moving in three-dimensions, this non-divergence constraint means that the velocity of the plane waves satisfies, $\boldsymbol{k} \cdot \boldsymbol{u} + k_z\, w = 0$, (e.g., see our study of inertial waves in Chapter 53). However, for the shallow water system we saw above that $k_z = 0$, which would then seem to imply that $\boldsymbol{k} \cdot \boldsymbol{u} = 0$. Yet shallow water waves do *not* satisfy $\boldsymbol{k} \cdot \boldsymbol{u} = 0$ since they are horizontally divergent.

The resolution of this quandary concerns the vertical velocity in a shallow water layer. Namely, the vertical velocity component is diagnosed via the horizontal convergence, $\partial_z w = -\nabla \cdot \boldsymbol{u}$. The depth independence of the horizontal velocity leads to a linear depth-dependence of the vertical velocity component (equation (35.39))

$$\nabla \cdot \boldsymbol{u} + \partial_z w = 0 \Longrightarrow w(z) = w(\eta_\mathsf{b}) - (z - \eta_\mathsf{b})\, \nabla \cdot \boldsymbol{u}, \tag{55.26}$$

which for the plane wave (55.24) leads to

$$w(z) = w(\eta_\mathsf{b}) - \mathrm{i}\, (z - \eta_\mathsf{b})\, \boldsymbol{k} \cdot \tilde{\boldsymbol{u}}\, \mathrm{e}^{\mathrm{i}(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}. \tag{55.27}$$

The factor of $\mathrm{i} = \sqrt{-1}$ out front means that the vertical velocity component is $\pi/2$ out of phase with the horizontal velocity. Also note that $|z - \eta_\mathsf{b}|\, |\boldsymbol{k}| \leq H\, |\boldsymbol{k}|$. Since $H\, |\boldsymbol{k}| \ll 1$ for shallow water flow, we see that the vertical velocity component has a much smaller magnitude than the horizontal velocity.

55.4 Unified shallow water wave equation

In this section we combine the linearized thickness equation (55.13) and linearized velocity equation (55.15) to render a unified wave equation for the free surface.[1] We start by closely following the steps taken for the nonlinear wave equation in Section 55.2.2. Yet we go much further for the purpose of obtaining a linear equation with the free surface as the only prognostic field. Although the unified wave equation is rather tedious, it does serve to unify the variety of waves supported by the rotating shallow water system. Once deriving this wave equation (equation (55.42)), we study its scaling for high frequency ($\omega^2 > f^2$; super-inertial) and low frequency ($\omega^2 < f^2$; sub-inertial) wave motion. That discussion anticipates analysis pursued in more depth in the remaining sections of this chaper.

55.4.1 Use of the divergence equation

We start by forming an equation for the evolution of the divergence of $H_\mathrm{r}\, \boldsymbol{u}'$, which is found by multiplying the linearized velocity equation (55.15) by H_r and then taking the divergence

$$\partial_t [\nabla \cdot (H_\mathrm{r}\, \boldsymbol{u}')] + \nabla \cdot (\hat{\boldsymbol{z}} \times f\, H_\mathrm{r}\, \boldsymbol{u}') = -\nabla \cdot (g\, H_\mathrm{r}\, \nabla \eta'), \tag{55.28}$$

where the divergence and time derivative commute. The thickness equation (55.13) can be used to eliminate the divergence, in which case we are led to

$$\partial_{tt} \eta' - \nabla \cdot (g\, H_\mathrm{r}\, \nabla \eta') = -\hat{\boldsymbol{z}} \cdot [\nabla \times (f\, H_\mathrm{r}\, \boldsymbol{u}')]. \tag{55.29}$$

[1] Many of the manipulations in this section follow Lecture 14 of *Pedlosky* (2003).

where we made use of the identity

$$\nabla \cdot (\hat{\boldsymbol{z}} \times f\, H_r\, \boldsymbol{u}') = -\hat{\boldsymbol{z}} \cdot [\nabla \times (f\, H_r\, \boldsymbol{u}')]. \tag{55.30}$$

The wave equation (55.29) is the linear analog of the nonlinear equation (55.8). We can expand the cross product on the right hand side to identify the variety of physical processes supporting shallow water waves

$$\partial_{tt}\eta' = \underbrace{\nabla \cdot (g\, H_r\, \nabla \eta')}_{\text{gravity waves}} \; \underbrace{-\hat{\boldsymbol{z}} \cdot (f\, H_r\, \nabla \times \boldsymbol{u}')}_{\text{inertial waves}} \; \underbrace{-\hat{\boldsymbol{z}} \cdot (H_r\, \nabla f \times \boldsymbol{u}')}_{\text{planetary Rossby waves}} \; \underbrace{-\hat{\boldsymbol{z}} \cdot (f\, \nabla H_r \times \boldsymbol{u}')}_{\text{topographic Rossby waves}}. \tag{55.31}$$

Although suggestive, it is useful to further manipulate this equation into one that involves a single prognostic field, here chosen to be the free surface. In so doing we provide a unified discussion of the dispersion relation for the various waves admitted by the shallow water model, and allow for a seamless decomposition of these motions in terms of space and time scales. We pursue the somewhat tedious manipulations in Section 55.4.2, but only after considering a heuristic discussion of the physical processes in equation (55.31).

Non-rotating gravity waves

Without rotation ($f = 0$) yet with gravity ($g \neq 0$), equation (55.31) reduces to the shallow water gravity wave equation

$$\partial_{tt}\eta' - \nabla \cdot (g\, H_r\, \nabla \eta') = 0. \tag{55.32}$$

With a flat bottom, these waves are non-dispersive plane gravity waves, whereas the case with a gently sloping bottom requires the WKBJ method developed in Section 51.9. These waves are sometimes referred to as *long gravity waves*, in contrast to the shorter waves that occur in deep water (see Section 52.6). We study shallow water gravity waves in Section 55.5.

Inertia-gravity waves

The wave equation

$$\partial_{tt}\eta' - \nabla \cdot (g\, H_r\, \nabla \eta') = -f\, H_r\, \zeta' \tag{55.33}$$

describes dispersive inertia-gravity waves in a shallow water layer. The inertial portion of the waves rely on both rotation ($f \neq 0$) and vorticity ($\zeta' \neq 0$). In Chapter 53 we studied inertial waves in a homogeneous fluid. The key difference here is that the shallow water fluid is hydrostatic, which, as we will see, alters the dispersion relation relative to that derived for the non-hydrostatic homogeneous fluid in Chapter 53. It furthermore motivates us to examine inertial waves along with gravity waves since a hydrostatic fluid only arises in a gravity field. Such *inertia-gravity* or *Poincaré waves*, as they appear in the shallow water fluid, are the topic of Section 55.8

Planetary and topographic Rossby waves

The remaining two terms on the right hand side of equation (55.31) lead to waves supported by a background vorticity gradient. The *planetary Rossby waves* rely on a nonzero planetary vorticity gradient (i.e., the β effect), whereas *topographic Rossby waves* rely on a nonzero gradient in the bottom topography. Both of these waves are dispersive, and both have frequencies lower than inertia-gravity waves. As shown in Section 55.4.6, and as already detailed for the horizontally non-divergent barotropic model in Section 54.3, the wave equation for Rossby waves has just a single time derivative acting on the free surface. This situation contrasts to the two time derivatives found for inertia-gravity waves and currently appearing in equation (55.31). Although

shallow water Rossby waves rely on a nonzero $\nabla(H_r f) \times \boldsymbol{u}'$, we postpone writing their wave equation until working through some more technical details.

In Chapter 54 we studied many properties of Rossby waves in the horizontally non-divergent barotropic fluid, with these waves also relying on a gradient in the background (potential) vorticity. It is thus not surprising that shallow water Rossby waves share key physical properties with Rossby waves in the non-divergent barotropic flow. We require more technical steps to extract the physics within the shallow water model, and to expose their key distinction from Rossby waves in the horizontally non-divergent barotropic model. Note also that the shallow water model supports topographic Rossby waves. In contrast, no such waves appear in the horizontally non-divergent barotropic model, since that flow is restricted to strictly move along constant depth contours, with no cross isobath motion.

55.4.2 Use of the vorticity equation

We now return to the wave equation (55.31) and perform some further manipulations in a quest to derive an equation that only has the free surface along with geophysical parameters. Start by writing the divergence equation (55.29) in its form that extracts the β term

$$\partial_{tt}\eta' - \nabla \cdot (g\, H_r\, \nabla\eta') = -f\, \hat{\boldsymbol{z}} \cdot [\nabla \times (H_r\, \boldsymbol{u}')] + \beta\, H_r\, u. \tag{55.34}$$

Next work with $\hat{\boldsymbol{z}} \cdot [\nabla \times (H_r\, \boldsymbol{u}')]$, which is the vorticity of the thickness (resting thickness) weighted velocity. To compute its time evolution, multiply the velocity equation (55.15) by H_r and take the curl

$$\begin{aligned} \nabla \times \partial_t(H_r\, \boldsymbol{u}') &= -\nabla \times (\hat{\boldsymbol{z}} \times f\, H_r\, \boldsymbol{u}') - g\, \nabla H_r \times \nabla\eta' && \text{(55.35a)} \\ &= -\hat{\boldsymbol{z}}\, [\nabla \cdot (f\, H_r\, \boldsymbol{u})] - g\, \nabla H_r \times \nabla\eta', && \text{(55.35b)} \end{aligned}$$

where the second equality made use of the identity

$$\nabla \times (\hat{\boldsymbol{z}} \times f\, H_r\, \boldsymbol{u}') = \hat{\boldsymbol{z}}\, [\nabla \cdot (f\, H_r\, \boldsymbol{u})]. \tag{55.36}$$

Now take the time derivative of the divergence equation (55.34) and use the vorticity equation (55.35b) to find

$$\begin{aligned} \partial_t\, [\partial_{tt}\eta' - \nabla \cdot (g\, H_r\, \nabla\eta')] &= -f\, \hat{\boldsymbol{z}} \cdot [\nabla \times \partial_t(H_r\, \boldsymbol{u}')] + \beta\, H_r\, \partial_t u' && \text{(55.37a)} \\ &= f\, \nabla \cdot (f\, H_r\, \boldsymbol{u}) + f\, g\, \hat{\boldsymbol{z}} \cdot (\nabla H_r \times \nabla\eta') + \beta\, H_r\, \partial_t u' && \text{(55.37b)} \\ &= -f^2\, \partial_t\eta' + f\, g\, \hat{\boldsymbol{z}} \cdot (\nabla H_r \times \nabla\eta') + \beta\, H_r\, (f\, v' + \partial_t u'). && \text{(55.37c)} \end{aligned}$$

Rearrangement leads to

$$\partial_t\, [\mathcal{L}(\eta') - \nabla \cdot (g\, H_r\, \nabla\eta')] = f\, g\, \hat{\boldsymbol{z}} \cdot (\nabla H_r \times \nabla\eta') + \beta\, H_r\, (f\, v' + \partial_t u'), \tag{55.38}$$

where we introduced the linear time operator as a shorthand

$$\mathcal{L} = \partial_{tt} + f^2. \tag{55.39}$$

This operator commutes with time derivatives but commutes with space derivatives only for the f-plane. For the case of $\beta = 0$, equation (55.38) only has the free surface height as a prognostic field. Hence, this equation is suited to developing the dispersion relation for gravity waves and inertial waves. Yet, as we show in the following, we need more work for sub-inertial Rossby waves.

55.4.3 The unified wave equation just with η'

The final step is to eliminate the term $f\,v' + \partial_t u'$ from equation (55.38) in favor of terms proportional to the free surface. The key step is to make use of the following identities derived in Exercise 55.2

$$\mathcal{L}(u') = -g\,(\partial_{xt}\eta' + f\,\partial_y\eta') \quad \text{and} \quad \mathcal{L}(v') = -g\,(\partial_{yt}\eta' - f\,\partial_x\eta'). \tag{55.40}$$

Acting with $\mathcal{L}$ on equation (55.38), and using the identities (55.40), yield

$$\partial_t\big[\mathcal{L}[\mathcal{L}(\eta') - \nabla\cdot(g\,H_r\,\nabla\eta')]\big] = f\,g\,\hat{\boldsymbol{z}}\cdot[\nabla H_r\times\nabla\mathcal{L}(\eta')] + \beta\,H_r\,f\,\mathcal{L}(v') + \beta\,H_r\,\partial_t\mathcal{L}(u'). \tag{55.41}$$

Expanding the linear operator and rearranging leads to the desired unified equation

$$\partial_t\big[\mathcal{L}[\mathcal{L}(\eta')-\nabla\cdot(g\,H_r\,\nabla\eta')]\big] = f\,g\,\hat{\boldsymbol{z}}\cdot[\nabla H_r\times\nabla\mathcal{L}(\eta')]+g\,\beta\,H_r\,(f^2\,\partial_x\eta'-2\,f\,\partial_{yt}\eta'-\partial_{xtt}\eta'). \tag{55.42}$$

As shown in the following sections, this linear partial differential equation encapsulates the full suite of linear wave processes active in a shallow water layer on a β-plane with topography. However, it is not so simple to parse in its current form, thus motivating the examination of limiting forms of this equation. In particular, we consider super-inertial waves ($\omega^2 > f^2$) versus sub-inertial waves ($\omega^2 < f^2$). In both cases we assume horizontal length scales according to the β-plane, along with small fluctuations of the topography.

55.4.4 Scaling for the β-plane with small topography

To help analyze the super-inertial and sub-interial wave motions contained in equation (55.42), introduce the following length and time scales of the motions

$$L = \text{horizontal scale} \quad \text{and} \quad \omega = \text{angular frequency}. \tag{55.43}$$

We work under the assumptions of a β-plane approximation (see equation (24.50)) so that the horizontal scales of motion satisfy

$$\beta\,L \ll |f_o|, \tag{55.44}$$

where we wrote the Coriolis parameter as $f = f_o + \beta\,y$. We also assume the topography undulation, η'_b, is much smaller than the mean layer thickness,

$$\eta'_b \ll H. \tag{55.45}$$

Both approximations (55.44) and (55.45) are familiar from the development of quasi-geostrophy theory in Section 43.5.1. Finally, assume $f > 0$ as per the northern hemisphere, with occurances of f changed to $|f|$ for southern hemisphere results.

Introducing the above scales into the wave equation (55.42) leads to

$$\partial_t\mathcal{L}^2(\eta') \sim \omega\,(\omega^2 + f^2)^2\,\eta' \tag{55.46a}$$

$$\partial_t\mathcal{L}[\nabla\cdot(g\,H_r\,\nabla\eta')] \sim \omega\,(\omega^2 + f^2)\,(g\,H_r/L^2)\,\eta' \tag{55.46b}$$

$$f\,g\,\nabla H_r\times\nabla\mathcal{L}(\eta') \sim (f\,g\,\eta'_b/L^2)\,(\omega^2 + f^2)\,\eta' \tag{55.46c}$$

$$g\,\beta\,H_r\,f^2\,\partial_x\eta' \sim (g\,\beta\,H_r\,f^2/L)\,\eta' \tag{55.46d}$$

$$-2\,\beta\,g\,H_r\,f\,\partial_{yt}\eta' \sim (\beta\,g\,H_r\,f\,\omega/L)\,\eta' \tag{55.46e}$$

$$\beta\,g\,H_r\,\partial_{xtt}\eta' \sim \beta\,g\,H_r\,(\omega^2/L)\,\eta'. \tag{55.46f}$$

Next, we separately examine the super-inertial regime, $\omega^2 > f^2$, and the sub-inertial regime, $\omega^2 < f^2$.

55.4.5 Super-inertial wave equation

In this subsection we derive an approximate wave equation relevant for super-inertial motions ($\omega^2 > f^2$).

Super-inertial scaling for the LHS of equation (55.42)

From equations (55.46a) and (55.46b), the two terms on the left hand side of the wave equation (55.42) scale as

$$\text{LHS} = \partial_t \mathcal{L}^2(\eta') - \partial_t \mathcal{L}[\nabla \cdot (g\, H_r\, \nabla \eta')] \sim \omega^3 \left[\omega^2 + g\, H_r / L^2\right] \eta'. \tag{55.47}$$

Assuming the horizontal length scale is given by the inverse wavenumber, $L = |\boldsymbol{k}|^{-1}$, yields

$$g\, H_r / L^2 \approx c_{\text{grav}}^2\, |\boldsymbol{k}|^2 \approx \omega^2 \implies L^2 \sim g\, H_r / \omega^2. \tag{55.48}$$

The first approximation follows from assuming $\eta_b' \ll H$ so that $g\, H_r \approx g\, H = c_{\text{grav}}^2$, and the second approximation follows from assuming a non-rotating gravity wave dispersion relation.[2] In essence, we are assuming the two terms in equation (55.47) scale the same, which holds so long as the length scale of the super-inertial waves satisfies $L^2 \sim g\, H_r / \omega^2$.

Ratio of RHS terms to the LHS

Now consider the magnitude for each term on the right hand side of the wave equation (55.42) relative to the left hand side terms just found in equation (55.47). The ratio for terms in equation (55.46c) satisfy

$$\frac{f\, g\, \nabla H_r \times \nabla \mathcal{L}(\eta')}{\text{LHS}} \sim \frac{\omega^2\, f\, g\, \eta_b' / L^2}{\omega^3\, g\, H_r / L^2} = \frac{f\, \eta_b'}{\omega\, H_r} \ll 1, \tag{55.49}$$

where the inequality follows from assuming that the bottom topography undulation is small as per equation (55.45). The ratio for the remaining three terms (equations (55.46d), (55.46e), and (55.46f)) are also much less than unity, with these inequalities following from the β-plane approximation (55.44)

$$\frac{g\, \beta\, H_r\, f^2\, \partial_x \eta'}{\text{LHS}} \sim \frac{g\, \beta\, H_r\, f^2 / L}{\omega^3\, g\, H_r / L^2} = (\beta\, L/\omega)\, (f/\omega)^2 < (\beta\, L/f)\, (f/\omega)^2 \ll 1 \tag{55.50a}$$

$$\frac{-2\, f\, \partial_{yt} \eta'}{\text{LHS}} \sim \frac{\beta\, g\, H_r\, f\, \omega / L}{\omega^3\, g\, H_r / L^2} = (\beta\, L/\omega)\, (f/\omega) < (\beta\, L/f)\, (f/\omega) \ll 1 \tag{55.50b}$$

$$\frac{\beta\, g\, H_r\, \partial_{xtt} \eta'}{\text{LHS}} \sim \frac{\beta\, g\, H_r\, (\omega^2 / L)}{\omega^3\, g\, H_r / L^2} = (\beta\, L/\omega) < (\beta\, L/f) \ll 1. \tag{55.50c}$$

Inertia-gravity wave equation for super-inertial waves

We thus conclude that for super-inertial waves on a β-plane and with small amplitude topography, then the two terms on the left hand side of equation (55.42) balance so that

$$\partial_t \mathcal{L}\left[\mathcal{L}(\eta') - \nabla \cdot (g\, H_r\, \nabla \eta')\right] \approx 0. \tag{55.51}$$

This relation can be maintained by setting

$$(\partial_{tt} + f_o^2)\, \eta' - \nabla \cdot (g\, H_r\, \nabla \eta') = 0, \tag{55.52}$$

[2] We derive the shallow water gravity wave dispersion relation in equation (55.80). Also, see the discussion of long surface gravity waves in Section 52.5.3.

which is the equation for inertia-gravity waves on an f-plane with small amplitude topography. Note that we put $f = f_o$ in equation (55.52) since the β effect is most crucial for sub-inertial wave motions as discussed in Section 55.4.6, rather than super-inertial motions. We study non-rotating gravity waves in Section 55.5 and inertia-gravity waves in Section 55.8.

55.4.6 Sub-inertial wave equation

We here derive an equation relevant for sub-inertial wave motions ($\omega^2 < f^2$). In fact, we further restrict the motion to those that are very low frequency so that

$$\omega/f \sim \beta\, L/f_o \sim \eta'_b/H \ll 1. \tag{55.53}$$

We also assume that the horizontal length scales are on the order of

$$L \sim L_d = c_{grav}/f = \sqrt{g\,H}/f, \tag{55.54}$$

which is known as the *deformation radius* for the shallow water layer, first introduced in Section 43.3.6 . This length scale appears throughout our discussion of rotating shallow water waves.

The assumed scalings (55.53) along with (55.54) are precisely those assumed for shallow water quasi-geostrophy as detailed in Section 43.5. The corresponding sub-inertial waves are referred to as *planetary Rossby waves* and *topographic Rossby waves*. We here derive the wave equation for these waves, with further details of their dispersion relation provided in Section 55.9.

Sub-inertial scaling for the LHS of equation (55.42)

For the sub-inertial scalings (55.53), the linear operator is order $\mathcal{L} \sim \mathcal{O}(f^2)$, so that the left hand side of the wave equation (55.42) scales as

$$\text{LHS} = \partial_t \mathcal{L}^2(\eta') + \partial_t \mathcal{L}[\nabla \cdot (g\,H_r\,\nabla\eta')] \sim \omega\, f^2\, [f^2 + g\,H_r/L^2]\,\eta'. \tag{55.55}$$

As for the super-inertial waves in Section 55.4.5, we assume the two terms in the right expression scale the same. To ensure that scaling holds, we focus on horizontal length scales satisfying

$$L^2 \sim g\,H_r/f^2 \sim g\,H/f^2 = c_{grav}^2/f^2 = L_d^2. \tag{55.56}$$

This assumption of deformation scale motions for sub-inertial waves can be compared to the super-inertial length scale in equation (55.48). We find that super-inertial motions are generally smaller than the deformation radius whereas sub-inertial motions are on the order or larger than the deformation radius.

With the above scaling (55.56) for the horizontal length, the left hand side of the wave equation (55.42) scales as

$$\text{LHS} \sim (\omega\, f\, g\, H_r/L^2)\,\eta'. \tag{55.57}$$

We will later replace f with f_o in equation (55.57), with that replacement warranted by the β-plane approximation, $\beta\, L \ll f_o$. For now, we reduce clutter by just writing f.

Ratio of RHS terms to the LHS

Now consider the magnitude for each term on the right hand side of the wave equation (55.42) relative to the left hand side terms just found in equation (55.57). The ratio for terms in equation

(55.46c) is given by

$$\frac{f\, g\, \nabla H_\mathsf{r} \times \nabla \mathcal{L}(\eta')}{\text{LHS}} \sim \frac{f^3\, g\, \eta'_\mathsf{b}/L^2}{\omega\, f^2\, g\, H_\mathsf{r}/L^2} = \frac{f\, \eta'_\mathsf{b}}{\omega\, H_\mathsf{r}} = \mathcal{O}(1), \tag{55.58}$$

with the final equality following from the assumed scales in equation (55.53). We also find that the ratio for terms in equation (55.46d) is given by

$$\frac{g\, \beta\, H_\mathsf{r}\, f^2\, \partial_x \eta'}{\text{LHS}} \sim \frac{g\, \beta\, H_\mathsf{r}\, f^2/L}{\omega\, f^2\, g\, H_\mathsf{r}/L^2} = \beta\, L/\omega = \mathcal{O}(1), \tag{55.59}$$

where we again made use of equation (55.53) for the final equality. In contrast to these order unity ratios, the ratios involving terms in equations (55.46e) and (55.46f) are much less than unity

$$\frac{-2\, f\, \partial_{yt} \eta'}{\text{LHS}} \sim \frac{\beta\, g\, H_\mathsf{r}\, f\, \omega/L}{\omega\, f^2\, g\, H_\mathsf{r}/L^2} = \beta\, L/f \ll 1 \tag{55.60a}$$

$$\frac{\beta\, g\, H_\mathsf{r}\, \partial_{xtt} \eta'}{\text{LHS}} \sim \frac{\beta\, g\, H_\mathsf{r}\, (\omega^2/L)}{\omega\, f^2\, g\, H_\mathsf{r}/L^2} = (\beta\, L/f)\, (\omega/f) \ll 1. \tag{55.60b}$$

The first inequality follows from the β-plane approximation (55.44), and the second follows also from the β-plane approximation as well as the low frequency assumption, $\omega^2 \ll f^2$.

Shallow water planetary and topographic Rossby wave equation

The above scalings lead to the approximate wave equation for sub-inertial waves moving on a β-plane with small amplitude bottom topography

$$\partial_t \left[f^2\, \eta' - \nabla \cdot (g\, H\, \nabla \eta') \right] = f\, g\, \hat{\boldsymbol{z}} \cdot (\nabla H_\mathsf{r} \times \nabla \eta') + g\, H\, \beta\, \partial_x \eta'. \tag{55.61}$$

Note that we set $H_\mathsf{r} = H$ everywhere except where it is differentiated, with this replacement consistent with the assumed $\eta'_\mathsf{b} \ll H$ (equation (55.53)). A slightly more tidy version arises by introducing the squared gravity wave speed $c^2_\mathsf{grav} = g\, H$ and the deformation radius, $L_\mathsf{d} = c_\mathsf{grav}/f$, so that

$$\partial_t \left[(L_\mathsf{d}^{-2} - \nabla^2)\, \eta' \right] = (f/H)\, \hat{\boldsymbol{z}} \cdot (\nabla H_\mathsf{r} \times \nabla \eta') + \beta\, \partial_x \eta'. \tag{55.62}$$

The first term on the right hand side gives rise to topographic Rossby waves, whereas the second term gives rise to planetary Rossby waves. It is notable that this equation has only a single time derivative, which contrasts with the super-inertial wave equation (55.52).

Rossby waves are supported by potential vorticity gradients

We can write the right hand side of equation (55.62) in the following equivalent form

$$\partial_t \left[(L_\mathsf{d}^{-2} - \nabla^2)\, \eta' \right] = H\, \hat{\boldsymbol{z}} \cdot (\nabla \eta' \times \nabla Q_\mathsf{r}). \tag{55.63}$$

In this manner we see that both planetary Rossby waves and topographic Rossby waves are supported by gradients in the resting fluid's potential vorticity[3]

$$Q_\mathsf{r} = f/H_\mathsf{r}. \tag{55.64}$$

[3]When studying waves in the horizontally non-divergent barotropic fluid (Section 54.3), we also noted the need for a background potential vorticity gradient to support Rossby wave modes.

Equation (55.63) reveals that shallow water Rossby waves arise from a mis-alignment between contours of constant resting state potential vorticity and contours of constant surface height.

The effective β vector

We offer one further expression for the Rossby wave equation

$$\partial_t \left[(L_{\mathrm{d}}^{-2} - \nabla^2)\, \eta' \right] = \hat{\boldsymbol{z}} \cdot (\nabla \eta' \times \boldsymbol{\beta}_{\mathrm{eff}}), \tag{55.65}$$

where we introduced the effective beta vector that combines the planetary vorticity gradient with the topographic gradient

$$\boldsymbol{\beta}_{\mathrm{eff}} = \nabla f - Q_{\mathrm{r}} \nabla H_{\mathrm{r}} = \beta\, \hat{\boldsymbol{y}} - Q_{\mathrm{r}} \nabla H_{\mathrm{r}}. \tag{55.66}$$

Again, this form exhibits the parallel role of both planetary beta and topographic slopes in supporting Rossby waves. Equation (55.65) says that shallow water Rossby waves arise from a mis-alignment between the effective beta vector and free surface height gradients.

55.4.7 Comments on bottom topography

Throughout this section we allowed for the bottom topography, as defined by $H_{\mathrm{r}} = H - \eta'_{\mathrm{b}}$ (equation (55.11)), to have arbitrary (x, y) spatial dependence. In the following sections we make simplifications to the topography, thus facilitating the study of plane waves, planetary waves, and topographically trapped waves. The study of waves with more general bottom topographies requires the asymptotic methods from Chapter 50.

55.5 Shallow water gravity waves

In this section we study shallow water gravity waves in the absence of planetary rotation ($f = 0$). We already encountered features of these waves in Chapter 52 when studying surface gravity waves. Even so, it is useful to start from the shallow water equations to directly derive the properties of the non-dispersive gravity waves. Additionally, we here do not introduce a velocity potential as done for the surface gravity waves, even though the non-rotating shallow water gravity waves are irrotational. We do not introduce the velocity potential since the other waves studied in this chapter carry vorticity, thus making the velocity potential an incomplete description for those cases.

55.5.1 Flat bottom gravity waves

Setting $\eta'_{\mathrm{b}} = 0$ in equation (55.32) yields the shallow water gravity wave equation holding for a flat bottom domain

$$(\partial_{tt} - c_{\mathrm{grav}}^2 \nabla^2)\, \eta' = 0, \tag{55.67}$$

where the gravity wave speed is determined by the two geophysical properties of the system

$$c_{\mathrm{grav}} = \sqrt{g\, H}. \tag{55.68}$$

To help emphasize a few key properties, we return to the linear thickness equation (55.13) and linear velocity equation (55.15), now written with $f = 0$ and $\eta'_{\mathrm{b}} = 0$

$$\partial_t \eta' = -H\, \nabla \cdot \boldsymbol{u}' \quad \text{and} \quad \partial_t \boldsymbol{u}' = -g\, \nabla \eta'. \tag{55.69}$$

Taking the time derivative of the thickness equation and then using the velocity equation readily yields the wave equation (55.67). Conversely, taking the horizontal divergence of the velocity equation yields

$$\partial_t(\nabla \cdot \boldsymbol{u}') = -g\,\nabla^2\eta', \tag{55.70}$$

so that time changes in the horizontal divergence are driven by curvature in the free surface. Taking the time derivative of this equation, and using the thickness equation, reveals that the horizontal divergence also satisfies the wave equation

$$(\partial_{tt} - c_{\text{grav}}^2\nabla^2)\,(\nabla \cdot \boldsymbol{u}') = 0. \tag{55.71}$$

Hence, both the free surface and the horizontal divergence travel as non-dispersive gravity waves in the flat bottom non-rotating shallow water layer.

Finally, observe that the linearized potential vorticity equation (55.23), in the presence of $f = 0$ and $\eta_{\text{b}}' = 0$, means that the relative vorticity is static at each point in the fluid

$$\partial_t\zeta' = 0. \tag{55.72}$$

Hence, these gravity wave fluctuations do not alter the flow vorticty. In particular, if the flow starts with zero vorticity then shallow water gravity wave fluctuations retain the zero vorticity.

55.5.2 Structure of the gravity wave

Substituting the plane wave ansatz (55.24) into the linearized thickness and velocity equation (55.69) allows us to connect the wave amplitudes for the free surface and velocity

$$\omega\,\tilde{\boldsymbol{u}} = g\,\boldsymbol{k}\,\tilde{\eta} \Longrightarrow \boldsymbol{k} \times \tilde{\boldsymbol{u}} = 0 \qquad \text{and} \qquad \omega\,\tilde{\eta} = H\,\boldsymbol{k} \cdot \tilde{\boldsymbol{u}}. \tag{55.73}$$

The identity $\boldsymbol{k} \times \tilde{\boldsymbol{u}} = 0$ for the plane wave means that the fluid particle's horizontal velocity is oriented parallel to the horizontal wave vector, so that

$$\tilde{\boldsymbol{u}} = \hat{\boldsymbol{k}}\,(\hat{\boldsymbol{k}} \cdot \tilde{\boldsymbol{u}}) \quad \text{with} \quad \hat{\boldsymbol{k}} = \boldsymbol{k}/|\boldsymbol{k}|. \tag{55.74}$$

This alignment of the horizontal velocity with the wavevector is a direct result of the irrotational nature of the gravity waves, which was already noted when discussing the linearized vorticity equation (55.72). Additionally, with a real wavevector and real angular frequency, the amplitude relation $\omega\,\tilde{\boldsymbol{u}} = g\,\boldsymbol{k}\,\tilde{\eta}$ also holds for the traveling plane wave velocity and free surface so that

$$\omega\,\boldsymbol{u} = g\,\boldsymbol{k}\,\eta \Longrightarrow \boldsymbol{k} \cdot \boldsymbol{u} = g|\boldsymbol{k}|^2\eta/\omega \quad \text{and} \quad \boldsymbol{u} = \hat{\boldsymbol{k}}\,(g/c_{\text{grav}})\,\tilde{\eta}\cos\mathcal{P}, \tag{55.75}$$

where

$$\mathcal{P} = \boldsymbol{k} \cdot \boldsymbol{x} - \omega\,t \tag{55.76}$$

is the phase.

Alignment of the horizontal fluid particle velocity with the wavevector (equation (55.75)) indicates that motion in the shallow water gravity wave is horizontally longitudinal. However, as noted in Section 55.3.4, a shallow water fluid has a nonzero vertical velocity component that is a linear function of depth, as given by equations (55.26) and (55.27). The presence of vertical motion within the wave means that the waves are not longitudinal in three dimensions. Rather, a fluid particle moves horizontally in the direction of the wavevector but the particle also moves vertically, thus tracing out an elliptical path in the vertical-horizontal plane.

To describe the vertical particle motion in the wave, make use of equation (55.27) for the

vertical velocity and equation (55.75) for the horizontal velocity, thus leading to

$$w = -\mathrm{i}\,(z - \eta_{\mathsf{b}})\,\boldsymbol{k}\cdot\tilde{\boldsymbol{u}}\,\mathrm{e}^{\mathrm{i}(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)} = (z-\eta_{\mathsf{b}})\,(g\,|\boldsymbol{k}|^2\,\tilde{\eta}/\omega)\,(-\mathrm{i}\cos\mathcal{P} + \sin\mathcal{P}), \tag{55.77}$$

where we set $w(\eta_{\mathsf{b}}) = 0$ for a flat bottom. Taking the real part renders the vertical velocity within the shallow water gravity wave

$$w = (z-\eta_{\mathsf{b}})\,(g\,|\boldsymbol{k}|^2/\omega)\,\tilde{\eta}\sin\mathcal{P} = (z-\eta_{\mathsf{b}})\,|\boldsymbol{k}|\,(g/c_{\mathsf{grav}})\,\tilde{\eta}\sin\mathcal{P} \tag{55.78}$$

The vertical velocity is $\pi/2$ out of phase with both the free surface and the horizontal velocity. Furthermore, the ratio of the maximum magnitude for the vertical and horizontal velocities is given by

$$\frac{|w|_{\max}}{|\boldsymbol{u}|_{\max}} = (z-\eta_{\mathsf{b}})\,|\boldsymbol{k}|. \tag{55.79}$$

Shallow water gravity waves are characterized by wavelengths that are long relative to the fluid depth. Hence, even at the free upper surface, the ratio (55.79) is much less than unity. As a result, the elliptical particle paths are longer in the horizontal direction than vertical direction. Furthermore, since the horizontal motion is depth-independent, the elliptical particle trajectories have the same excursion along the major axis (the horizontal axis) throughout the layer depth. This behavior contrasts to the deepwater gravity waves studied in Chapter 52, whose amplitude in all directions decreases with depth. In Figure 55.1, we depict the motion of fluid particles with a shallow water gravity wave. In Section 52.11.4 we study the Stokes drift resulting from the phase averaged particle motion in these waves.

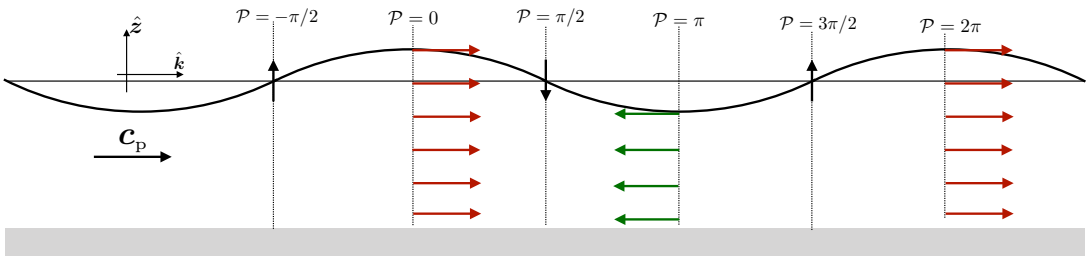

FIGURE 55.1: Illustrating motion within a shallow water gravity wave over a flat bottom, here depicted at a fixed point in time with the phase velocity to the right. The horizontal arrows are the horizontal velocity as per equation (55.75), and the vertical arrows are for the vertical velocity as per equation (55.78). The horizontal and vertical velocity components are $\pi/2$ out of phase, so that the vertical velocity vanishes when the horizontal velocity has maximum magnitude, and vice versa. This figure is a slightly simplified version of the lower panel in Figure 52.2.

55.5.3 Dispersion relation

Substitution of the plane wave ansatz (55.24) into the wave equation (55.67) leads to

$$\omega^2 = g\,H\,|\boldsymbol{k}|^2 = c_{\mathsf{grav}}^2\,|\boldsymbol{k}|^2. \tag{55.80}$$

Taking the positive square root then leads to the shallow water gravity wave dispersion relation[4]

$$\omega = |\boldsymbol{k}|\,c_{\mathsf{grav}} \Longrightarrow C_{\mathsf{p}} = \omega/|\boldsymbol{k}| = c_{\mathsf{grav}}, \tag{55.81}$$

[4]Recall that we always consider the angular frequency of waves to be non-negative (Section 49.2), hence we only take the positive root for the dispersion relation (55.81).

where we identified the phase speed as the gravity wave speed

$$C_{\mathsf{p}} = c_{\mathsf{grav}} = \sqrt{g\,H}. \tag{55.82}$$

Each wavevector propagates at the same speed since the phase speed is only dependent on geophysical parameters (gravitational acceleration and the resting layer thickness). Equivalently, higher wavenumber waves have correspondingly higher frequency, and the relation between the two is linear. We conclude that non-rotating shallow water gravity waves are *non-dispersive*.

55.5.4 Steady one-dimensional flow over an obstacle

Consider a steady one-dimensional inviscid flow of a single shallow water layer of fluid in a channel with a varying bottom, $z = \eta_{\mathsf{b}}(x)$, such as depicted in Figure 55.2. This flow approximates that in a straight canal as water moves over a *weir*. The thicker water upstream of the weir creates a pressure gradient that speeds up the flow as it moves over the weir. Throughout the analysis we assume the fluid has a positive layer thickness, $h > 0$, so that there is no region where the fluid layer vanishes.

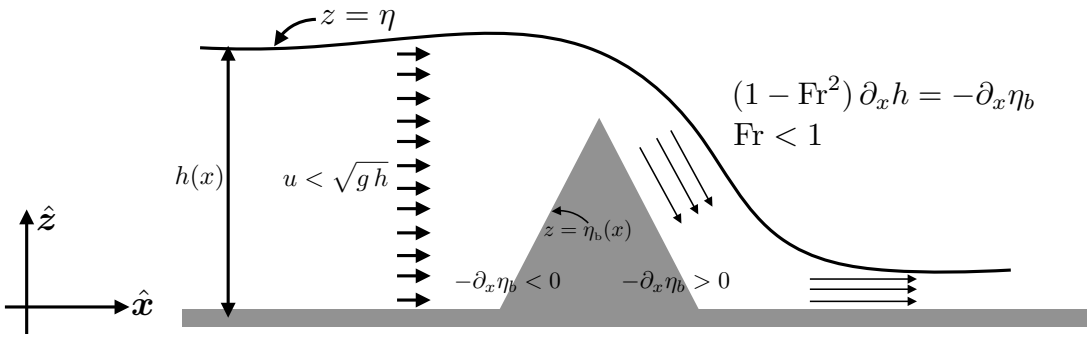

FIGURE 55.2: One-dimensional flow of a shallow water fluid layer in a channel with an obstacle. This flow approximates that for water flowing over a weir in a straight canal. If a fluid particle moves faster than the locally defined gravity wave speed, $u > \sqrt{g\,h}$ or $\mathrm{Fr} > 1$, then the flow is said to undergo a *hydraulic jump*, which typically occurs first at the peak of the weir with $u = \sqrt{g\,h}$ or $\mathrm{Fr} = 1$. Flow that is faster than the gravity wave speed is said to be *super-critical*, whereas slower flow is *sub-critical*. We here depict sub-critical flow where the local Froude number is everywhere less than unity, $\mathrm{Fr} < 1$. The fluid is thicker upstream than downstream of the weir as per equation (55.89), thus enabling a higher pressure upstream to create a pressure drop across the weir.

The steady, one-dimensional, non-rotating shallow water equations take the form

$$u\,\partial_x u = -g\,\partial_x(\eta_{\mathsf{b}} + h) \tag{55.83a}$$

$$u\,\partial_x h + h\,\partial_x u = 0, \tag{55.83b}$$

where we wrote the free surface height, η, as the sum of the bottom topography position plus the layer thickness (see Figure 35.1)

$$\eta = \eta_{\mathsf{b}} + h. \tag{55.84}$$

The momentum equation can be written in the form of a mechanical energy equation

$$\partial_x(u^2/2 + g\,h) = -g\,\partial_x \eta_{\mathsf{b}}. \tag{55.85}$$

We see that the mechanical energy, $u^2/2 + g\,h$, has spatial variations according to the variations in the bottom topography. Otherwise, the mechanical energy is a spatial constant.

Writing the steady state thickness equation (55.83b) in the form

$$\partial_x u = -(u/h)\,\partial_x h, \tag{55.86}$$

allows us to write the momentum equation (55.83a) as

$$(g - u^2/h)\,\partial_x h = -g\,\partial_x \eta_{\mathfrak{b}}. \tag{55.87}$$

Introducing the local *Froude number*,

$$\text{Fr} = u/\sqrt{g\,h}, \tag{55.88}$$

then leads to

$$(1 - \text{Fr}^2)\,\partial_x h = -\partial_x \eta_{\mathfrak{b}}. \tag{55.89}$$

The bottom is flat in regions away from the weir, so that $\partial_x \eta_b = 0$, in which case the left hand side of equation (55.89) must vanish. The left hand side vanishes if $\partial_x h = 0$, in which the free surface is flat, such as depicted for the region away from the weir in Figure 55.2. The left hand side also vanishes if the Froude number is unity, Fr = 1. A unit Froude number means that the particle velocity equals to the local gravity wave speed

$$u^2 = g\,h. \tag{55.90}$$

Flow moving at speeds less than the gravity wave speed is called *sub-critical*, such as flow upstream of the weir. Flow whose speed equals the gravity wave speed is said to be under *hydraulic control*, which commonly occurs near the peak of the weir in Figure 55.2. Flow that is faster than the local gravity wave speed is said to be *super-critical*, with the steady assumptions going into equation (55.89) breaking down for super-critical flow. Super-critical flow is found to exhibit a *hydraulic jump*, which is an instability with flow seemingly overtaking itself since it cannot "see" where it is going. The situation is akin to the sonic boom occuring in a compressible fluid moving at speeds greater than the acoustic wave speed.

The discussion here is rather descriptive, with more analysis required to deductively support the presentation, particularly for super-critical flow. Chapter 1 of *Pratt and Whitehead* (2008) considers this topic in more detail. The remaining chapters in *Pratt and Whitehead* (2008) consider planetary rotation, thus developing the subject of *rotating hydraulics*, which is particularly important for describing geophysical flows moving over topographic slopes.

55.6 Gravity waves in two layers

When adding more shallow water layers, how much can we use from the single layer results? To help answer that question, consider the linearized equations for two shallow water layers. The equations can be generalized to multiple layers, though with increased algebraic complexity. Indeed, even the two-layer case with rotation proves to be algebraically tedious, thus motivating us to examine just the case of gravity waves without rotation. For more general depth dependence, we find it simpler analytically to study the continuously stratified fluid in Chapter 57.

55.6.1 Linearized two-layer equations

We derived the equations for a stacked shallow water model in Section 35.4, and focused on two layers in Section 35.4.1. With reference to Figure 35.6 for notation, write the layer thicknesses in the form

$$h_1 = H_1 + h_1' = \eta_{1/2} - \eta_{3/2} = (\overline{\eta_{1/2}} - \overline{\eta_{3/2}}) + (\eta_{1/2}' - \eta_{3/2}') \tag{55.91a}$$

$$h_2 = H_2 + h_2' = \eta_{3/2} - \eta_{\mathfrak{b}} = (\overline{\eta_{3/2}} - \overline{\eta_{\mathfrak{b}}}) + (\eta_{3/2}' - \eta_{\mathfrak{b}}'), \tag{55.91b}$$

where we introduced the resting layer thicknesses

$$H_1 = \overline{\eta_{1/2}} - \overline{\eta_{3/2}} \quad \text{and} \quad H_2 = \overline{\eta_{3/2}} - \overline{\eta_{\mathfrak{b}}} \quad \text{and} \quad H = H_1 + H_2, \tag{55.92}$$

with the overbar representing the area mean, and with the half-integer labels representing interface fields. This notation leads to the linearized version of the thickness equations (35.62a) and (35.62b)

$$\partial_t h'_1 + H_1 \, \nabla \cdot \boldsymbol{u}'_1 = 0 \tag{55.93a}$$
$$\partial_t h'_2 + H_2 \, \nabla \cdot \boldsymbol{u}'_2 = 0, \tag{55.93b}$$

where $\boldsymbol{u}'_1$ and $\boldsymbol{u}'_2$ are the horizontal velocities in the two layers. Likewise, assuming a zero atmospheric pressure leads to the linearized version of velocity equations (35.77a) and (35.77b)

$$\partial_t \boldsymbol{u}'_1 + f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}'_1 = -g \nabla \eta'_{1/2} \tag{55.94a}$$
$$\partial_t \boldsymbol{u}'_2 + f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}'_2 = -g \nabla \eta'_{1/2} - g^{\mathrm{r}}_{3/2} \nabla \eta'_{3/2}. \tag{55.94b}$$

For the linearized equations, the only layer coupling occurs through undulations of the free surface impacting on the pressure felt in the lower layer.

55.6.2 Gravity wave equations

We restrict further analysis to the case with zero Coriolis acceleration so that the layer equations take the form

$$\partial_t(\eta'_{1/2} - \eta'_{3/2}) + H_1 \, \nabla \cdot \boldsymbol{u}'_1 = 0 \quad \text{and} \quad \partial_t \boldsymbol{u}'_1 = -g \, \nabla \eta'_{1/2} \tag{55.95a}$$
$$\partial_t \eta'_{3/2} + H_2 \, \nabla \cdot \boldsymbol{u}'_2 = 0 \quad \text{and} \quad \partial_t \boldsymbol{u}'_2 = -g \, \nabla \eta'_{1/2} - g^{\mathrm{r}} \, \nabla \eta'_{3/2}, \tag{55.95b}$$

where we introduced the reduced gravity for the interior layer interface

$$g^{\mathrm{r}} = g^{\mathrm{r}}_{3/2} = g \, (\rho_2 - \rho_1)/\rho_1. \tag{55.96}$$

Taking time derivatives of the thickness equations and substituting the divergence of the velocity equations leads to the matrix-vector equation

$$\begin{bmatrix} (\partial_{tt} - g \, H_1 \nabla^2) & -\partial_{tt} \\ -g \, H_2 \, \nabla^2 & (\partial_{tt} - g^{\mathrm{r}} \, H_2 \nabla^2) \end{bmatrix} \begin{bmatrix} \eta'_{1/2} \\ \eta'_{3/2} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{55.97}$$

This equation has non-trivial solutions if the determinant of the matrix vanishes, and we use that property to derive the dispersion relation.

55.6.3 Dispersion relation

To derive the dispersion relation, consider the plane wave ansatz for the free surface undulation in each layer

$$\eta'_{1/2} = \tilde{\eta}_{1/2} \, \mathrm{e}^{\mathrm{i} \, (\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t)} \quad \text{and} \quad \eta'_{3/2} = \tilde{\eta}_{3/2} \, \mathrm{e}^{\mathrm{i} \, (\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t)}. \tag{55.98}$$

Note that we assume each layer has the same wavevector and same angular frequency. However, the amplitudes, $\tilde{\eta}_{1/2}$ and $\tilde{\eta}_{3/2}$, are generally complex so that the phase of the layers can differ. The corresponding velocity for the two layers is given by

$$\boldsymbol{u}'_1 = \tilde{\boldsymbol{u}}_1 \, \mathrm{e}^{\mathrm{i} \, (\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t)} \quad \text{and} \quad \boldsymbol{u}'_2 = \tilde{\boldsymbol{u}}_2 \, \mathrm{e}^{\mathrm{i} \, (\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t)}. \tag{55.99}$$

Plugging the wave ansatz (55.98) into equation (55.97) converts the differential operators to algebraic expressions

$$\begin{bmatrix} (-\omega^2 + g\,H_1|\boldsymbol{k}|^2) & \omega^2 \\ g\,H_2\,|\boldsymbol{k}|^2 & (-\omega^2 + g^{\mathrm{r}}\,H_2\,|\boldsymbol{k}|^2) \end{bmatrix} \begin{bmatrix} \tilde{\eta}_{1/2} \\ \tilde{\eta}_{3/2} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{55.100}$$

Setting the determinant to zero leads to the quadratic equation in ω^2

$$(\omega^2 - g\,H_1\,|\boldsymbol{k}|^2)\,(\omega^2 - g^{\mathrm{r}}\,H_2\,|\boldsymbol{k}|^2) - g\,H_2\,|\boldsymbol{k}|^2\,\omega^2 = 0. \tag{55.101}$$

Solving for the squared phase speed ($C_{\mathsf{p}}^2 = \omega^2/|\boldsymbol{k}|^2$) leads to

$$2\,\omega^2/|\boldsymbol{k}|^2 = (g\,H + g^{\mathrm{r}}\,H_2) \pm \sqrt{(g\,H + g^{\mathrm{r}}\,H_2)^2 - 4\,g\,g^{\mathrm{r}}\,H_1\,H_2}. \tag{55.102}$$

Introducing the small non-dimensional parameter,

$$\epsilon = g^{\mathrm{r}}\,H_2/(g\,H) = g^{\mathrm{r}}\,H_2/c_{\mathsf{grav}}^2 \ll 1, \tag{55.103}$$

and expanding the dispersion relation (55.102) to expose the leading order behavior, yields the squared phase speeds

$$C_{\mathsf{p}}^2 \approx c_{\mathsf{grav}}^2 = g\,H \qquad \text{squared barotropic phase speed} \tag{55.104a}$$

$$C_{\mathsf{p}}^2 \approx c_{\mathsf{grav}}^2\,g^{\mathrm{r}}\,H_1\,H_2/(g\,H^2) = g^{\mathrm{r}}\,H_1\,H_2/H \qquad \text{squared baroclinic phase speed.} \tag{55.104b}$$

We motivate the names *barotropic mode* and *baroclinic mode* in the following, based on our study of vorticity in Section 40.7.2 for a Boussinesq fluid. Note that the phase speed for the barotropic mode is roughly given by the gravity wave speed for a single layer of fluid with resting thickness $H = H_1 + H_2$. This speed is much greater than that for the baroclinic mode since $g^{\mathrm{r}} \ll g$.

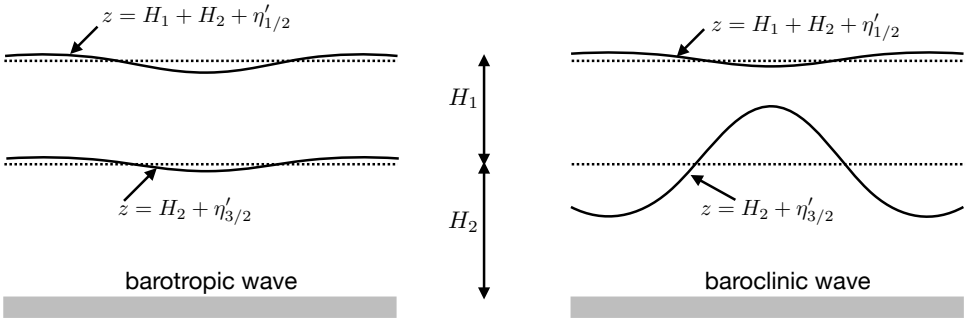

FIGURE 55.3: Illustrating the interface displacements for a two-layer shallow water gravity wave as discussed in Section 55.6.4. The left panel depicts a barotropic wave, where the undulations are both relatively small, in-phase, and on the same order of magnitude. The right panel shows a baroclinic wave, where the undulations of the free surface are small whereas those of the interior interface are much larger (order g/g^{r}) and the two undulations are π radians out of phase. For the baroclinic mode, recall that the same structure occurs for the reduced gravity model shown in Figure 35.5.

55.6.4 Structure of a plane gravity wave

In this subsection we examine the structure of a plane gravity wave by relating the wave amplitudes. To start, we relate interface height amplitudes by making use of equation (55.100) to write

$$\frac{\tilde{\eta}_{1/2}}{\tilde{\eta}_{3/2}} = \frac{\omega^2}{\omega^2 - g\,H_1\,|\boldsymbol{k}|^2} = \frac{\omega^2 - g^{\mathrm{r}}\,H_2\,|\boldsymbol{k}|^2}{g\,H_2\,|\boldsymbol{k}|^2}. \tag{55.105}$$

Since the right hand side is real, so too is the ratio of the amplitudes. Hence, the interfaces undulate either in phase or π radians out of phase. Correspondingly, we can, without loss of generality, take the interface height amplitudes to be real.

We relate the velocity amplitude to the interface amplitude by evaluating the linearized velocity equations (55.95a) and (55.95b) for plane waves, in which

$$\omega\,\tilde{\boldsymbol{u}}_1 = \boldsymbol{k}\,g\,\tilde{\eta}_{1/2} \quad \text{and} \quad \omega\,\tilde{\boldsymbol{u}}_2 = \boldsymbol{k}\,(g'\,\tilde{\eta}_{1/2} + g\,\tilde{\eta}_{3/2}). \tag{55.106}$$

Since the interface height amplitudes are real, so too are the velocity amplitudes. Evidently, the fluid particle velocity in each layer is aligned with the phase velocity, so that the gravity waves are horizontally longitudinal. Correspondingly, the ratio of the velocity amplitudes is found by taking the scalar product of equation (55.106) with the wavevector to find

$$\omega\,\tilde{\boldsymbol{u}}_1 \cdot \boldsymbol{k} = |\boldsymbol{k}|^2\,g\,\tilde{\eta}_{1/2} \quad \text{and} \quad \omega\,\tilde{\boldsymbol{u}}_2 \cdot \boldsymbol{k} = |\boldsymbol{k}|^2\,(g' + g\,H_2/H)\,\tilde{\eta}_{1/2}, \tag{55.107}$$

whose ratio is

$$\frac{\tilde{\boldsymbol{u}}_1 \cdot \boldsymbol{k}}{\tilde{\boldsymbol{u}}_2 \cdot \boldsymbol{k}} = \frac{g\,\tilde{\eta}_{1/2}}{g'\,\tilde{\eta}_{1/2} + g\,\tilde{\eta}_{3/2}}. \tag{55.108}$$

Structure of the barotropic mode

For the barotropic mode we set $\omega^2 \approx g\,H\,|\boldsymbol{k}|^2$ within equation (55.105) to render the amplitude ratio

$$\tilde{\eta}_{1/2}/\tilde{\eta}_{3/2} \approx H/H_2 > 1. \tag{55.109}$$

This inteface height ratio then leads, through equation (55.108), to the velocity amplitude

$$\frac{\tilde{\boldsymbol{u}}_1 \cdot \boldsymbol{k}}{\tilde{\boldsymbol{u}}_2 \cdot \boldsymbol{k}} \approx \tilde{\eta}_{1/2}/\tilde{\eta}_{3/2} \approx H/H_2. \tag{55.110}$$

Evidently, the two interfaces undulate in-phase and with the surface interface fluctuating more than the interior interface. Likewise, the horizontal velocities move in-phase with the interface heights, and with an amplitude ratio that concurs with the interface height ratio. We depict this wave motion in the left panel of Figure 55.3.

Structure of the baroclinic wave mode

For the baroclinic mode, setting $\omega^2 \approx g'\,H_1\,H_2\,|\boldsymbol{k}|^2/H$ within equation (55.100) leads to the amplitude ratio

$$\tilde{\eta}_{1/2}/\tilde{\eta}_{3/2} \approx -g'\,H_2/(g\,H). \tag{55.111}$$

Hence, the two interfaces undulate oppositely (i.e., π radians out of phase) and with the amplitude of the upper interface far less than the interior interface

$$|\tilde{\eta}_{1/2}/\tilde{\eta}_{3/2}| \ll 1. \tag{55.112}$$

That is, the free surface is nearly rigid relative to the interior interface, as depicted in the right panel of Figure 55.3. For the velocity amplitude, we make use of equation (55.108) along with the interface height amplitude ratio (55.111), so that

$$\frac{\tilde{\boldsymbol{u}}_1 \cdot \boldsymbol{k}}{\tilde{\boldsymbol{u}}_2 \cdot \boldsymbol{k}} \approx -\frac{g'\,H_2}{g\,H}, \tag{55.113}$$

so that the velocities are π radians out of phase and their ratio is identical to that for the interface heights.

Evidently, the baroclinic mode consists of layer velocities and interface heights that oscillate π radians out of phase, and with the velocity and surface height in the upper layer undulating much less than in the interior layer. Indeed, to leading order the upper interface is rigid and the corresponding flow stagnant. In contrast, the lower interface fluctuates as a gravity wave with the squared phase speed, $g^r\, H_1\, H_2/H$. This wave speed is far less than the $\approx \sqrt{g\, H}$ speed of the barotropic mode.

55.6.5 Energetic scaling for the waves

We here examine the relative amounts of phase averaged kinetic and available potential energies contained in the waves. From Section 36.6.3, we write the linearized layer integrated kinetic energy per area

$$\mathcal{K} = (\rho_o/2)\,(H_1\, \boldsymbol{u}_1' \cdot \boldsymbol{u}_1' + H_2\, \boldsymbol{u}_2' \cdot \boldsymbol{u}_2'), \tag{55.114}$$

whose phase average is

$$\langle \mathcal{K} \rangle = (\rho_o/4)\,(H_1\, |\tilde{\boldsymbol{u}}_1|^2 + H_2\, |\tilde{\boldsymbol{u}}_2|^2). \tag{55.115}$$

Within the gravity wave, the velocity amplitudes are related to the interface amplitudes via equation (55.106), so that the phase averaged kinetic energy per horizontal area is

$$\langle \mathcal{K} \rangle = (\rho_o/4)\,(|\boldsymbol{k}|/\omega)^2\,[H_1\,(g\,\tilde{\eta}_{1/2})^2 + H_2\,(g^r\,\tilde{\eta}_{1/2} + g\,\tilde{\eta}_{3/2})^2]. \tag{55.116}$$

For the available potential energy, we make use of the phase averaged version of equation (36.139) to write the phase averaged available potential energy per area as

$$\langle \mathcal{A} \rangle = (\rho_o/4)\,(g\,\tilde{\eta}_{1/2}^2 + g^r\,\tilde{\eta}_{3/2}^2). \tag{55.117}$$

Scaling within a barotropic gravity wave

For the barotropic gravity wave, the interface height undulations are related by equation (55.109). Hence, the phase averaged kinetic energy and available potential energy are given by the approximate expressions

$$\langle \mathcal{K} \rangle \approx \frac{\rho_o\, \tilde{\eta}_{1/2}^2}{4\, g\, H}\,[H_1\, g^2 + H_2\,(g^r + g\, H_2/H)^2] \tag{55.118a}$$

$$\langle \mathcal{A} \rangle \approx (\rho_o/4)\,\tilde{\eta}_{1/2}^2\,(g + g^r\, H_2^2/H^2), \tag{55.118b}$$

and their ratio is

$$\frac{\langle \mathcal{K} \rangle}{\langle \mathcal{A} \rangle} = \frac{1}{g\, H}\,\frac{H_1\, H^2\, g^2 + H_2\,(g^r\, H + g\, H_2)^2}{g\, H^2 + g^r\, H_2^2}. \tag{55.119}$$

This ratio is on the order of unity, with specific values determined by the layer thickness and reduced gravity. Hence, for the barotropic wave there is roughly the same amount of energy contained in the kinetic energy as in the available potential energy.

Scaling within a baroclinic gravity wave

For the baroclinic gravity wave, the interface height undulations are related by equation (55.111). Hence, the phase averaged kinetic energy and available potential energy are given by the approximate expressions

$$\langle \mathcal{K} \rangle \approx \frac{\rho_o\, \tilde{\eta}_{1/2}^2}{4\, C_{\mathsf{p}}^2}\,(H_1\, g^2 + H_2\,[g^r - (g^2\, H)/(g^r\, H_2)]^2) \approx \frac{\rho_o\, \tilde{\eta}_{1/2}^2}{4\, C_{\mathsf{p}}^2}\,\frac{g^2\, H^2}{(g^r)^2\, H_2} \tag{55.120}$$

$$\langle \mathcal{A} \rangle \approx (\rho_\circ/4)\, \tilde{\eta}_{1/2}^2\, \frac{g^2\, H^2}{g^{\mathrm{r}}\, H_2^2}. \tag{55.121}$$

Use of equation (55.104b) for the squared phase speed in the baroclinic mode leads to the energy ratio

$$\frac{\langle \mathcal{K} \rangle}{\langle \mathcal{A} \rangle} \approx \frac{1}{C_{\mathrm{p}}^2}\, \frac{g^2\, H_2}{g^{\mathrm{r}}} = \frac{g^2\, H}{(g^{\mathrm{r}})^2\, H_1} \gg 1. \tag{55.122}$$

This ratio is generally much larger than unity, indicating that the baroclinic gravity wave carries far more kinetic energy than available potential energy.

Comparing the available potential energies between the waves

Making use of the above results leads to the ratio of the available potential energies contained in the barotropic gravity wave and baroclinic gravity wave

$$\frac{\langle \mathcal{A}^{\mathrm{bt}} \rangle}{\langle \mathcal{A}^{\mathrm{bc}} \rangle} \approx \frac{g^{\mathrm{r}}\, H_2^2}{g\, H^2}\, \frac{(\tilde{\eta}_{1/2}^2)^{\mathrm{bt}}}{(\tilde{\eta}_{1/2}^2)^{\mathrm{bc}}} \approx \frac{g\, H^2}{g^{\mathrm{r}}\, H_2^2}\, \frac{(\tilde{\eta}_{3/2}^2)^{\mathrm{bt}}}{(\tilde{\eta}_{3/2}^2)^{\mathrm{bc}}}. \tag{55.123}$$

The ratio thus depends on the assumed ratio of the undulations found in the two waves. In general we expect that

$$\frac{(\tilde{\eta}_{1/2}^2)^{\mathrm{bt}}}{(\tilde{\eta}_{1/2}^2)^{\mathrm{bc}}} \gg 1 \quad \text{and} \quad \frac{(\tilde{\eta}_{3/2}^2)^{\mathrm{bt}}}{(\tilde{\eta}_{3/2}^2)^{\mathrm{bc}}} \ll 1. \tag{55.124}$$

Even so, we cannot make any general statements about the ratio of available potential energies without further information. That is, we cannot *a priori* state that the barotropic wave requires more or less available potential energy than the baroclinic wave. Whereas the baroclinic wave involves large undulations of the interior interface, these undulations are coupled to the relatively small reduced gravity ($g^{\mathrm{r}} \ll g$), thus ameliorating the available potential energy cost. In contrast, the barotropic wave involves a relatively small undulation of the interior interface and somewhat larger free surface undulation (larger than for the baroclinic mode). The free surface motion is coupled to the relatively large buoyancy through $g \gg g^{\mathrm{r}}$, thus enhancing the potential energy cost for the free surface undulation, making the barotropic wave available potential energy comparable to that of the baroclinic wave.

55.6.6 The depth averaged velocity and the velocity difference

There are occasions in which it is useful to combine the layer velocity equations in a manner that directly approximates the barotropic and baroclinic motions. For this purpose we introduce the depth averaged velocity[5]

$$H\, \overline{\boldsymbol{u}} = H_1\, \boldsymbol{u}_1' + H_2\, \boldsymbol{u}_2', \tag{55.125}$$

with $H = H_1 + H_2$, along with the layer deviations from the depth average

$$\boldsymbol{u}_{1\mathrm{b}} = \boldsymbol{u}_1' - \overline{\boldsymbol{u}} \quad \text{and} \quad \boldsymbol{u}_{2\mathrm{b}} = \boldsymbol{u}_2' - \overline{\boldsymbol{u}}. \tag{55.126}$$

Making use of the linearized equations (55.94a) and (55.94b) (here returning to the case with rotation) leads to the equations of motion (see Exercise 55.3)

$$\partial_t \overline{\boldsymbol{u}} + f\, \hat{\boldsymbol{z}} \times \overline{\boldsymbol{u}} = -g\, \nabla \eta_{1/2}' - (H_2\, g^{\mathrm{r}}/H)\, \nabla \eta_{3/2}' \tag{55.127a}$$

$$\partial_t \boldsymbol{u}_{1\mathrm{b}} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{1b} = (g^{\mathrm{r}}\, H_2/H)\, \nabla \eta_{3/2}' \tag{55.127b}$$

$$\partial_t \boldsymbol{u}_{2\mathrm{b}} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{2b} = -(g^{\mathrm{r}}\, H_1/H)\, \nabla \eta_{3/2}'. \tag{55.127c}$$

[5]We study vorticity of the depth averaged velocity for a continuous fluid in Section 40.9.7.

Notice that the two deviation velocities, $\boldsymbol{u}_{1\mathrm{b}}$ and $\boldsymbol{u}_{2\mathrm{b}}$, are independent of the free surface fluctuations. Furthermore, a layer integration of these two velocities vanishes

$$H_1 \, \boldsymbol{u}_{1\mathrm{b}} + H_2 \, \boldsymbol{u}_{2\mathrm{b}} = 0, \tag{55.128}$$

which is consistent with a vanishing integral for their equations of motion

$$H_1(\partial_t \boldsymbol{u}_{1\mathrm{b}} + f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{1\mathrm{b}}) + H_2(\partial_t \boldsymbol{u}_{2\mathrm{b}} + f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{2\mathrm{b}}) = 0. \tag{55.129}$$

Finally, introduce the vertical shear velocity

$$\boldsymbol{u}_{\mathrm{s}} = \boldsymbol{u}_1 - \boldsymbol{u}_2 = \boldsymbol{u}_{1\mathrm{b}} - \boldsymbol{u}_{2\mathrm{b}} \tag{55.130}$$

whose equation of motion is

$$\partial_t \boldsymbol{u}_{\mathrm{s}} + f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{s}} = g^{\mathrm{r}} \nabla \eta'_{3/2}. \tag{55.131}$$

For the barotropic wave, whereby both layer interfaces undulate in phase and with a relatively small amplitude (Figure 55.3), then the shear velocity is nearly zero since the pressure gradient, $g^{\mathrm{r}} \nabla \eta'_{3/2}$ in equation (55.131) is small for the barotropic wave. In contrast, the depth averaged velocity described by equation (55.127a) is dominated by the larger (in magnitude) pressure gradient arising from free surface height undulations, $-g \nabla \eta'_{1/2}$. For the baroclinic wave, the depth averaged velocity is far smaller in magnitude than found in the barotropic wave, and the pressure gradient is dominated by interior interface undulations via $g^{\mathrm{r}} \nabla \eta'_{3/2}$. These behaviors motivate the oceanographic colloquial terminology whereby the depth averaged velocity is referred to as the *barotropic velocity* and the shear velocity is referred to as the *baroclinic velocity*.

55.6.7 Comments

As noted at the start of this section, the addition of further layers greatly increases the algebraic complexity of the analysis, thus motivating the use of numerical models for studies with $N > 2$ layers. One generally finds that each layer adds another wave mode, with N layers realizing N modes (one barotropic mode and $N - 1$ baroclinic modes). We further the study of gravity waves in Chapter 57 by studying internal gravity waves, with such waves corresponding here to a continuum of baroclinic modes.

55.7 Kelvin waves

The Kelvin wave is a non-dispersive gravity wave. It arises from the combined presence of a boundary and the Coriolis acceleration. The boundary considered here is a solid vertical wall. Additionally, Kelvin waves occur along the equator, with the equator acting as a boundary due to the change in sign of the Coriolis parameter, f.

55.7.1 Wave solutions with a southern boundary

To expose the key points about the shallow water Kelvin wave, it is sufficient to orient the f-plane with a boundary at $y = y_0$ and to consider flow in the region $y > y_0$. The meridional velocity component must vanish at $y = y_0$ to satisfy the no-normal flow condition. We are thus motivated to seek nontrivial solutions with $v' = 0$ everywhere, in which case the linearized

f-plane thickness and velocity equations are

$$\partial_t \eta' = -H\, \partial_x u' \tag{55.132a}$$
$$\partial_t u' = -g\, \partial_x \eta' \tag{55.132b}$$
$$f\, u' = -g\, \partial_y \eta'. \tag{55.132c}$$

It is notable that the meridional velocity equation (55.132c) expresses geostrophic balance between the Coriolis acceleration, $f\, u'$, and meridional pressure gradient, $-g\, \partial_y \eta'$.

Taking the time derivative of the zonal velocity equation (55.132b) and making use of the free surface equation (55.132a) leads to the one-dimensional wave equation for the zonal velocity

$$(\partial_{tt} - c_{\text{grav}}^2\, \partial_{xx})\, u' = 0, \tag{55.133}$$

where

$$c_{\text{grav}} = \sqrt{g\, H} \tag{55.134}$$

is the shallow water gravity wave speed. Likewise, a time derivative of the free surface equation (55.132a) and substitution of zonal velocity equation (55.132b) recovers the same wave equation satisfied by the free surface

$$(\partial_{tt} - c_{\text{grav}}^2\, \partial_{xx})\, \eta' = 0. \tag{55.135}$$

55.7.2 Kelvin wave solutions

In Section 6.7 we studied how to solve the wave equations (55.133) and (55.135), in which we write the general solutions in the form

$$u'(x, y, t) = F_1(x^{\text{L}}(t), y) + F_2(x^{\text{R}}(t), y), \tag{55.136a}$$
$$\eta'(x, y, t) = E_1(x^{\text{L}}(t), y) + E_2(x^{\text{R}}(t), y). \tag{55.136b}$$

In these expressions, F_1, E_1, F_2, E_2 are functions of space that are specified by the initial conditions, and

$$x^{\text{L}}(t) = x + c_{\text{grav}}\, t \quad \text{and} \quad x^{\text{R}}(t) = x - c_{\text{grav}}\, t \tag{55.137}$$

are points along the x-axis that, as time increases, move to the left and right, respectively, at the gravity wave speed. Evidently, the wave signal transmits, without distortion, the F_1 and E_1 patterns in the negative $\hat{\boldsymbol{x}}$-direction, and the F_2 and E_2 patterns propagate in the positive $\hat{\boldsymbol{x}}$-direction.

The free surface height and zonal velocity are coupled via the equations of motion (55.132a)–(55.132c), so that the functions F_1, F_2 are related to E_1, E_2. To determine this relation we use the velocity equation (55.132b) along with the chain rule

$$\frac{\partial F_1}{\partial t} = \frac{\partial F_1(x^{\text{L}}, y)}{\partial x^{\text{L}}} \frac{\mathrm{d}x^{\text{L}}}{\mathrm{d}t} = \frac{\partial F_1(x^{\text{L}}, y)}{\partial x^{\text{L}}}\, c_{\text{grav}} \tag{55.138a}$$
$$\frac{\partial F_2}{\partial t} = \frac{\partial F_2(x^{\text{R}}, y)}{\partial x^{\text{R}}} \frac{\mathrm{d}x^{\text{R}}}{\mathrm{d}t} = -\frac{\partial F_2(x^{\text{R}}, y)}{\partial x^{\text{R}}}\, c_{\text{grav}}, \tag{55.138b}$$

in which case

$$\partial_t u' = c_{\text{grav}}\, (\partial F_1 / \partial x^{\text{L}} - \partial F_2 / \partial x^{\text{R}}) = -g\, \partial_x \eta' = -g\, (\partial E_1 / \partial x^{\text{L}} - \partial E_2 / \partial x^{\text{R}}), \tag{55.139}$$

so that

$$\eta'(x, y, t) = (c_{\text{grav}}/g)\, \big[-F_1(x + c_{\text{grav}}\, t, y) + F_2(x - c_{\text{grav}}\, t, y)\big]. \tag{55.140}$$

To determine the meridional dependence to the wave solutions requires the geostrophic

balance (55.132c), with the free surface equation (55.140) and zonal velocity equation (55.136a) leading to

$$\partial_y F_1 = f\, F_1 / c_{\text{grav}} \quad \text{and} \quad \partial_y F_2 = -f\, F_2 / c_{\text{grav}}, \tag{55.141}$$

whose solutions take the form

$$F_1 = F(x + c_{\text{grav}}\, t)\, \mathrm{e}^{(y-y_0)/L_{\text{d}}} \quad \text{and} \quad F_2 = G(x - c_{\text{grav}}\, t)\, \mathrm{e}^{-(y-y_0)/L_{\text{d}}}, \tag{55.142}$$

where

$$L_{\text{d}} = c_{\text{grav}} / f \tag{55.143}$$

is the shallow water deformation radius defined in equation (43.31) (and used in Section 55.4.6). We also introduced the functions F and G, which are functions of a single space coordinate. To ensure boundedness in the region $y > y_0$, where the fluid is assumed to exist, we drop the F_1 solution, thus leaving the free surface

$$\eta' = (H/g)^{1/2}\, \mathrm{e}^{-(y-y_0)/L_{\text{d}}}\, G(x - c_{\text{grav}}\, t), \tag{55.144}$$

and the horizontal velocity components

$$u' = \mathrm{e}^{-(y-y_0)/L_{\text{d}}}\, G(x - c_{\text{grav}}\, t) \quad \text{and} \quad v' = 0. \tag{55.145}$$

For the vertical velocity component we return to equation (55.26) to write

$$w'(z) = w'(z = -H) - (z + H)\, \partial_x u' \tag{55.146a}$$

$$= w'(z = -H) + H^{-1}\, (z + H)\, \partial_t \eta' \tag{55.146b}$$

$$= w'(z = -H) - (z + H)\, \mathrm{e}^{-(y-y_0)/L_{\text{d}}}\, \frac{\mathrm{d}G(x^{\text{R}})}{\mathrm{d}x^{\text{R}}}, \tag{55.146c}$$

where the second equality used the linearized thickness equation (55.132a), and the third equality used the chain rule.

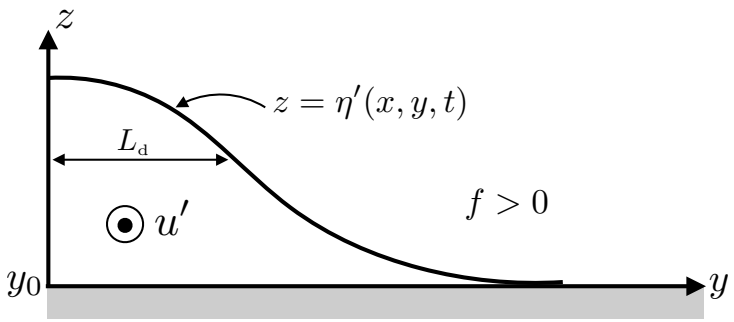

FIGURE 55.4: Illustrating free surface and zonal velocity for a northern hemisphere Kelvin wave with a solid boundary on the south. The free surface exponentially decays away from the boundary with a decay scale set by the deformation radius, L_{d}. With $f > 0$ the Kelvin wave propagates with the boundary on the right, so that for this orientation the wave phase velocity is coming out of the page.

These non-dispersive gravity wave signals propagate in the positive $\hat{\boldsymbol{x}}$ direction, in which case the boundary $y = y_0$ is on the right. This orientation holds for any boundary orientation in the northern hemisphere, whereby Kelvin waves propagate with the solid boundary on the right when looking in the direction of wave phase velocity. For the southern hemisphere, Kelvin waves propagate with the boundary to the left of the wave motion. Hence, Kelvin waves propagate cyclonically around a closed basin. In Figure 55.4 we illustrate the free surface and velocity for the Kelvin wave solution just derived.

55.8 Inertia-gravity waves

In this section we set the Coriolis parameter, f, to a nonzero constant while retaining a flat bottom and removing all side boundaries. We also retain a nonzero gravity, which is consistent with the shallow water being in hydrostatic balance. The linearized thickness equation (55.13), velocity equation (55.15), and potential vorticity equation (55.23) take the form

$$\partial_t \eta' = -H \nabla \cdot \boldsymbol{u}' \tag{55.147a}$$

$$\partial_t \boldsymbol{u}' + f \hat{\boldsymbol{z}} \times \boldsymbol{u}' = -g \nabla \eta' \tag{55.147b}$$

$$\partial_t Q' = 0, \tag{55.147c}$$

where the linear flat bottom f-plane shallow water potential vorticity is given from equation (55.22)

$$Q' = \zeta'/H - f \eta'/H^2, \tag{55.148}$$

where we dropped the constant f since it plays no dynamical role.

55.8.1 Forced oscillator equation for horizontal velocity

Taking a time derivative of the horizontal velocity equation (55.147b), and then back-substituting the velocity equation, leads to

$$(\partial_{tt} + f^2)\boldsymbol{u}' = -g\,(\partial_t \nabla \eta' - f \hat{\boldsymbol{z}} \times \nabla \eta'). \tag{55.149}$$

This equation for the horizontal velocity is in the form of a forced oscillator, with forcing from gradients in the free surface. We make use of this equation when developing the mathematical expressions for plane inertia-gravity waves in Section 55.8.9.

55.8.2 Free wave equation and potential vorticity

For the case of a flat bottom on an f-plane, we can write the wave equation (55.31) as

$$(\partial_{tt} - c_{\text{grav}}^2 \nabla^2)\eta' = -H f \zeta'. \tag{55.150}$$

This equation describes a forced shallow water gravity wave with forcing from relative vorticity coupled to the Coriolis parameter. Recall that this coupling between Coriolis and relative vorticity is fundamental to the inertial waves studied in Chapter 53. We can now use the vorticity equation as in Section 55.4.2 to eliminate ζ' to reveal a free wave equation. Equivalently, in equation (55.38) we set f to a constant and the bottom to be flat, thus leading to

$$\partial_t \left[\partial_{tt}\eta' + f^2 \eta' - c_{\text{grav}}^2 \nabla^2 \eta'\right] = 0. \tag{55.151}$$

The linear fluctuations described by this equation are known as shallow water *inertia-gravity* or *Poincaré waves*. The name "inertia-gravity" is due to the presence of both the Coriolis frequency, f, and gravitational acceleration, g, with both playing a role as restoring forces to support the waves.

The wave equation (55.151) is in the form of a local conservation law where the term in square brackets is static. We already know about another static field, namely the potential vorticity, Q', given by equation (55.148). We here show that the wave equation (55.151) is indeed identical to the potential vorticity equation (55.147c). For this purpose, substitute the expression (55.148) for the potential vorticity into the forced wave equation (55.150), which readily yields

$$f H^2 Q' = -(\partial_{tt} + f^2 - c_{\text{grav}}^2 \nabla^2)\,\eta'. \tag{55.152}$$

We thus find that

$$\partial_t Q' = 0 \Longrightarrow \partial_t \left[\partial_{tt} \eta' + f^2 \, \eta' - c_{\text{grav}}^2 \nabla^2 \eta' \right] = 0, \tag{55.153}$$

so that the wave equation (55.151) for inertia-gravity waves is identical to the conservation equation for linear shallow water potential vorticity. We saw a similar connection between potential vorticity conservation and waves in our study of Rossby waves in Section 54.3 for the horizontally non-divergent barotropic fluid, and will see the connection yet again for shallow water Rossby waves in Section 55.9.

55.8.3 Dispersion relation

Substituting the wave ansatz (55.24) into equations (55.147a)-(55.147b) renders the homogeneous matrix-vector equation

$$\begin{bmatrix} -\mathrm{i}\,\omega & -f & \mathrm{i}\,g\,k_x \\ f & -\mathrm{i}\,\omega & \mathrm{i}\,g\,k_y \\ \mathrm{i}\,H\,k_x & \mathrm{i}\,H\,k_y & -\mathrm{i}\,\omega \end{bmatrix} \begin{bmatrix} \tilde{u} \\ \tilde{v} \\ \tilde{\eta} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}. \tag{55.154}$$

This equation has a nontrivial solution only when the determinant of the matrix vanishes. The real part of the determinant cancels exactly, thus leaving just the imaginary part. Setting the imaginary part to zero yields the dispersion relation

$$\omega \left[\omega^2 - f^2 - g\,H\,|\boldsymbol{k}|^2 \right] = 0. \tag{55.155}$$

We can derive the same dispersion relation by substituting the wave ansatz into the wave equation (55.153). There are three solutions to this cubic equation described in the following subsections.

55.8.4 Zero frequency geostrophic mode

The zero frequency solution to the dispersion relation (55.155) corresponds to f-plane geostrophic motion. Such motion is static so that the linearized continuity equation (55.147a) means that the flow is horizontally non-divergent, $\nabla \cdot \boldsymbol{u}' = 0$. Furthermore, the geostrophic solution corresponds to a static yet non-zero potential vorticity

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}' = -g\,\nabla\eta' \Longrightarrow (f/g)\,Q' = (\nabla^2 - L_{\mathsf{d}}^{-2})\,\eta' \neq 0, \tag{55.156}$$

where we introduced the deformation radius, $L_{\mathsf{d}} = c_{\text{grav}}/f$, from equation (55.54). Turning equation (55.156) around, we see that if the potential vorticity is known, then the geostrophically balanced free surface can be found by inverting the elliptic operator, $\nabla^2 - L_{\mathsf{d}}^{-2}$.

The static geostrophic mode with nonzero potential vorticity is decoupled, in the linear theory, from the ageostrophic inertia-gravity wave whose potential vorticity is identically zero and yet whose relative vorticity and free surface are time dependent. For this reason we can separately study the two linear modes without concern for interactions.

55.8.5 Inertia-gravity wave modes

The $\omega \neq 0$ solution to the dispersion relation (55.155) satisfies the dispersion relation

$$\omega^2 = f^2\,(1 + L_{\mathsf{d}}^2\,|\boldsymbol{k}|^2). \tag{55.157}$$

Recall from Section 49.2 that we consider the angular frequency of waves to be non-negative. Hence, we only take the positive root

$$\omega = |f| \sqrt{1 + L_\mathsf{d}^2 \, |\boldsymbol{k}|^2}, \tag{55.158}$$

with Figure 55.5 depicting this relation.

The $\omega > 0$ modes satisfying the dispersion relation (55.158) are inertia-gravity waves. These waves have an angular frequency greater than or equal to the inertial frequency

$$\omega \geq |f|, \tag{55.159}$$

and are thus said to be *super-inertial waves*.[6] Furthermore, they carry zero potential vorticity (equation (55.152))

$$f \, H^2 \, Q' = -(\partial_{tt} + f^2 - c_\mathsf{grav}^2 \, \nabla^2) \, \eta' = 0, \tag{55.160}$$

where we verify this property holds for plane inertia-gravity waves in Exercise 55.5. With $Q' = 0$, equation (55.148) for the potential vorticity shows that the inertia-gravity waves carry a relative vorticity given by

$$\zeta' = f \, \eta' / H. \tag{55.161}$$

Since $|\eta'|/H \ll 1$, we see that the relative vorticity carried by shallow water inertia-gravity waves is small relative to the planetary vorticity

$$|\zeta'| \ll |f|. \tag{55.162}$$

55.8.6 Group velocity

Taking the $\boldsymbol{k}$-space gradient of the dispersion relation (55.158) leads to the group velocity for the shallow water inertia-gravity waves

$$\boldsymbol{c}_\mathsf{g} = \nabla_{\boldsymbol{k}} \varpi(\boldsymbol{k}) = \frac{c_\mathsf{grav}^2 \, \boldsymbol{k}}{\omega} = \frac{\boldsymbol{c}_\mathsf{p} \, c_\mathsf{grav}^2}{|\boldsymbol{c}_\mathsf{p}|^2} = \frac{\boldsymbol{c}_\mathsf{p}}{1 + (L_\mathsf{d} \, |\boldsymbol{k}|)^{-2}}, \tag{55.163}$$

where the phase velocity is $\boldsymbol{c}_\mathsf{p} = (\omega / |\boldsymbol{k}|) \, \hat{\boldsymbol{k}}$. Evidently, the group velocity is parallel to the phase velocity and the ratio of their magnitudes is given by

$$\frac{|\boldsymbol{c}_\mathsf{g}|}{|\boldsymbol{c}_\mathsf{p}|} = \frac{c_\mathsf{grav}^2}{|\boldsymbol{c}_\mathsf{p}|^2} = \frac{1}{1 + (L_\mathsf{d} \, |\boldsymbol{k}|)^{-2}}. \tag{55.164}$$

In the non-rotating case, where $f = 0$ so that $L_\mathsf{d}^{-2} = (c_\mathsf{grav}/f)^{-2} = 0$, the group and phase velocities are equal, which we expect since the non-rotating shallow water gravity waves from Section 55.5 are non-dispersive. The inertia-gravity waves approach the non-dispersive limit for wavelengths much smaller than the deformation radius, in which the waves are too small to feel the effects from the Coriolis acceleration (we further discuss the shortwave limit in Section 55.8.7). But for the general case with dispersion, the Coriolis acceleration causes the group velocity to be smaller in magnitude than the phase velocity. Hence, the wave energy, which is carried by the group velocity (see Section 55.8.10 on energetics), is more slowly transmitted than the phase.

[6] The inertial waves considered in Chapter 53, which we studied in a homogeneous fluid, have their angular frequency bounded by $\omega^2 < f^2$. These are *sub-inertial* waves. They are again encountered in Section 57.9.1 as a special case of a rotating internal gravity wave in the limit where the reference fluid state is homogeneous. They are distinct from the shallow water inertial waves since the shallow water fluid is hydrostatic whereas the inertial waves in Chapter 53 rely on non-hydrostatic pressure.

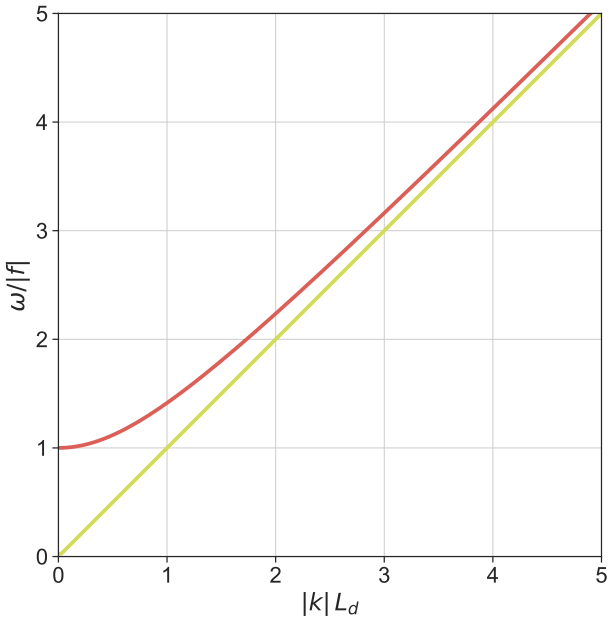

FIGURE 55.5: Illustrating the dispersion relation for shallow water inertia-gravity waves. The red hyperbolic curve is the dispersion relation (55.157), which asymptotes at high wavenumber (small wavelength) to the straight line for the non-rotating case. The angular frequency, ω, is scaled by the magnitude of the Coriolis frequency, $|f|$, and the horizontal wavenumber, $|\boldsymbol{k}|$, is multiplied by the deformation radius $L_{\text{d}} = \sqrt{gH}/f = c_{\text{grav}}/f$. For small wave numbers ($|\boldsymbol{k}|\, L_{\text{d}} \ll 1$ or $\Lambda \gg 2\,\pi\, L_{\text{d}}$), the inertial-gravity wave frequency approaches the inertia frequency, f, with this behavior seen at the minimum of the dispersion curve. We expect this result since waves large relative to the deformation radius feel the Coriolis acceleration. At the opposite extreme of high wave numbers ($\Lambda \ll 2\,\pi\, L_{\text{d}}$), the wave frequency approaches the non-rotating gravity wave frequency, shown here by the linear dispersion relation $\omega = |\boldsymbol{k}|\,\sqrt{g\,H} = |\boldsymbol{k}| c_{\text{grav}}$. Waves small relative to the deformation radius do not feel the Coriolis acceleration and thus converge to non-rotating gravity waves. Since all shallow water inertia-gravity waves satisfy $\omega^2 \geq f^2$, they are said to be *super-inertial* waves; i.e., waves whose frequency is larger in magnitude than the inertial frequency.

55.8.7 Shortwave limit for inertia-gravity waves

The shortwave limit is in the regime where

$$|\boldsymbol{k}|^2\, L_{\text{d}}^2 \gg 1, \tag{55.165}$$

so that the shortwave limit occurs when the wavelength is much shorter than the deformation radius, in which case the waves do not feel the effects from the Coriolis acceleration. For example, consider a middle latitude shallow water gravity wave in a layer with $H = 10^3$ m and $f = 10^{-4}$ s^{-1}, in which case the shallow water deformation radius is $L_{\text{d}} = \sqrt{g\,H}/f = 10^3$ km. Maintaining the constraint (55.165) means that the wavelength of the gravity wave, $\Lambda = 2\pi/|\boldsymbol{k}|$, must satisfy

$$\Lambda \ll 2\pi\, L_{\text{d}}. \tag{55.166}$$

Within the shortwave limit, however, the wavelength cannot be too small since the flow must retain the hydrostatic balance as per a shallow water model. As discussed in Section 27.2, maintaining the hydrostatic balance means that the flow retains a small vertical to horizontal aspect ratio. In terms of the wavenumber for gravity waves, the hydrostatic balance implies

$$|\boldsymbol{k}|\, H \ll 1 \quad \Longleftarrow \text{hydrostatic balance.} \tag{55.167}$$

We conclude that the shortwave limit for shallow water gravity waves is given by the regime

$$L_{\text{d}}^{-1} \ll |\boldsymbol{k}| \ll H^{-1} \Longleftrightarrow 2\pi\, H \ll \Lambda \ll 2\pi\, L_{\text{d}}. \tag{55.168}$$

Although considered short from the perspective of the shallow water model, these waves are hydrostatic and thus considered long gravity waves from the perspective of the surface gravity waves studied in Chapter 52.

Finally, for the shortwave limit, the dispersion relation (55.157) reduces to the dispersion relation (55.81)

$$\omega \approx |\boldsymbol{k}|\, c_{\text{grav}}. \tag{55.169}$$

Such waves are only weakly affected by the Coriolis acceleration so that their dispersion relation reduces to linear and non-dispersive gravity waves of Section 55.5.

55.8.8 Longwave limit for inertia-gravity waves

The longwave limit occurs when

$$|\boldsymbol{k}|^2\, L_{\text{d}}^2 \ll 1, \tag{55.170}$$

so the waves are much longer than the deformation radius. In this limit the wave is strongly affected by the Coriolis acceleration. Indeed, the wave dispersion relation becomes

$$\omega^2 = f^2, \tag{55.171}$$

in which fluid particles exhibit inertial oscillations (Sections 55.8.9 and 14.4).

55.8.9 Polarization relations for a plane inertia-gravity wave

As for the gravity waves in Section 55.5, we study the behavior of the traveling plane wave ansatz (55.24). In contrast to the case with $f = 0$, here we require the complex nature of the wave amplitudes $(\tilde{u}, \tilde{v}, \tilde{\eta})$ in order to realize nontrivial inertia-gravity wave solutions. Such complex amplitudes mean there are differences in phase between the velocity and free surface, with phase differences arising from the Coriolis parameter.

Polarization relations for the wave

Substituting the traveling plane wave ansatz (55.24) into the forced oscillator equation (55.149) leads to the amplitude relation

$$(-\omega^2 + f^2)\, \tilde{\boldsymbol{u}} = -g\, (\omega\, \boldsymbol{k} - \mathrm{i}\, f\, \hat{\boldsymbol{z}} \times \boldsymbol{k})\, \tilde{\eta}. \tag{55.172}$$

Without loss of generality, we assume the free surface amplitude, $\tilde{\eta}$, is real, which then leads to the free surface height

$$\eta' = \tilde{\eta} \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t), \tag{55.173}$$

and the fluid velocity within a plane wave

$$\boldsymbol{u}' = \frac{g\, |\boldsymbol{k}|\, \tilde{\eta}}{\omega^2 - f^2} \left[\underbrace{\omega\, \hat{\boldsymbol{k}} \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}_{\text{horizontally longitudinal}} + \underbrace{f\, (\hat{\boldsymbol{z}} \times \hat{\boldsymbol{k}}) \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}_{\text{horizontally transverse}} \right] \tag{55.174a}$$

$$= \frac{\tilde{\eta}}{|\boldsymbol{k}|\, H} \left[\underbrace{\omega\, \hat{\boldsymbol{k}} \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}_{\text{horizontally longitudinal}} + \underbrace{f\, (\hat{\boldsymbol{z}} \times \hat{\boldsymbol{k}}) \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}_{\text{horizontally transverse}} \right], \tag{55.174b}$$

where the unit vector

$$\hat{\boldsymbol{k}} = \boldsymbol{k}/|\boldsymbol{k}| \tag{55.175}$$

points in the direction of the wave, and equation (55.174b) follows from use of the dispersion relation (55.157) in equation (55.174a). The vanishing potential vorticity in these waves means

that they carry a nonzero relative vorticity as given by equation (55.161), so that

$$\zeta' = f\,\eta'/H = (f\,\tilde{\eta}/H)\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t). \tag{55.176}$$

Hence, in the northern hemisphere the relative vorticity is in-phase with the free surface, whereas in the southern hemisphere it is π radians out of phase.

These mathematical expressions for the fields within a wave are sometimes referred to as *polarization relations*. Observe that the horizontally transverse component of the velocity vector is $\pi/2$ out of phase from the horizontally longitudinal component. Furthermore, the transverse component corresponds to fluid particle motion that is perpendicular to the wavevector, in which case we say that the transverse component is *polarized* perpendicular to the wavevector.

Drawing the polarization relations

To draw the free surface (55.173), vorticity (55.176), and velocity (55.174b) we assume that $f > 0$ for the northern hemisphere, and recall that $\omega^2 \geq f^2$ since shallow water inertia-gravity waves are super-inertial. We also find it convenient to write the velocity as

$$\frac{\boldsymbol{u}'\,|\boldsymbol{k}|\,H}{\tilde{\eta}\,f} = (\omega/f)\,\hat{\boldsymbol{k}}\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) + (\hat{\boldsymbol{z}}\times\hat{\boldsymbol{k}})\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t). \tag{55.177}$$

Consider a point fixed in space and let time progress so that the phase,

$$\mathcal{P} = \boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t, \tag{55.178}$$

decreases. Consequently, the velocity vector rotates in a clockwise direction, forming an ellipse with the major axis along the longitudinal direction, $\hat{\boldsymbol{k}}$, and minor axis along the transverse direction, $(\hat{\boldsymbol{z}}\times\hat{\boldsymbol{k}})$. This motion corresponds to the inertial oscillations studied in Section 14.4 (where $\omega^2 = f^2$). Now consider a fixed time and sample the velocity field in the direction of the wave. In this case the phase increases as we move in the wave direction, so that the sampled velocity progresses counter-clockwise around the ellipse. Figure 55.6 offers three depictions of the wave field.

55.8.10 Energetics

In Section 55.3.2 we considered the general form of energy balances for the linearized shallow water equations integrated over the shallow water layer. For the special case of a flat bottom domain (with $\eta_\mathrm{b} = 0$ for simplicity), these equations take the form

$$\partial_t(\mathcal{K}^{\mathrm{sw}} + \mathcal{P}^{\mathrm{sw}}) = -g\,\rho\,H\,\nabla\cdot[(\overline{\eta} + \eta')\,\boldsymbol{u}'] \tag{55.179a}$$

$$\mathcal{P}^{\mathrm{sw}} = (\rho/2)\,g\,\eta^2 \tag{55.179b}$$

$$\mathcal{K}^{\mathrm{sw}} = (\rho/2)\,H\,\boldsymbol{u}'\cdot\boldsymbol{u}'. \tag{55.179c}$$

Here we consider the energy carried by a plane inertia-gravity wave, and focus on the phase averaged energetics. Note that since the waves are present throughout space (as per the plane wave assumption), we do not expect to have energy accumulate in any particular region when phase averaged. Instead, we expect the phase averaged energy to remain constant. So our question then concerns how that energy is partitioned according to kinetic energy and potential energy, and how the energy moves or is fluxed.

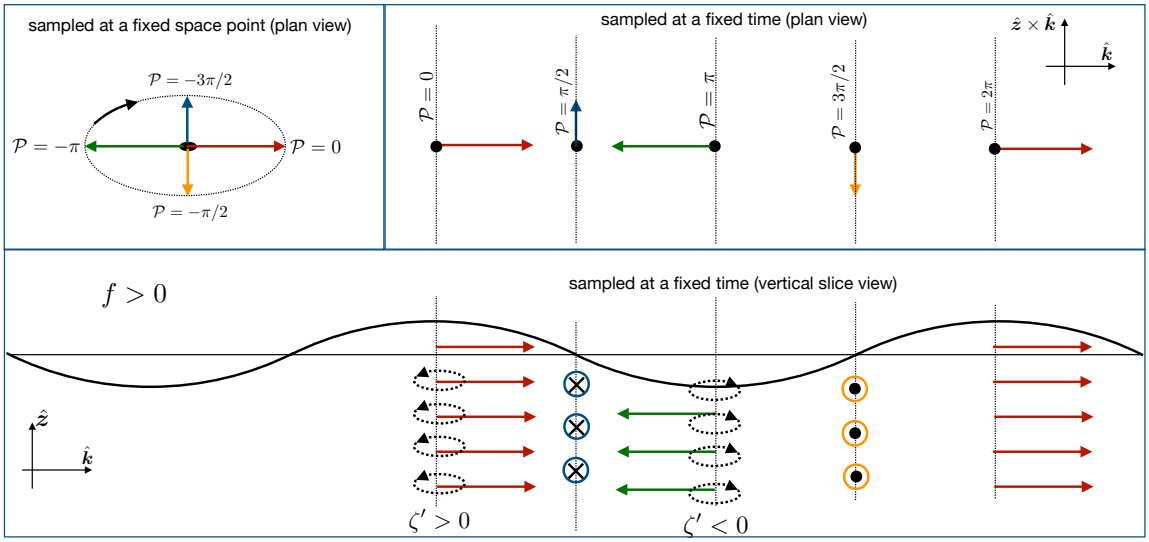

FIGURE 55.6: Illustrating the shallow water inertia gravity wave from three perspectives, with $\mathcal{P} = \boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t$ the phase and $f > 0$. The upper left panel shows the horizontal velocity vector at a fixed point in space as time increases and so the phase decreases (becomes more negative). The resulting velocity vector rotates clockwise and exhibits inertial oscillations. The upper right panel shows the horizontal velocity vector sampled along the wave direction, $\hat{\boldsymbol{k}}$, at a fixed time from a plan (horizontal) view, in which case the phase increases moving in the $\hat{\boldsymbol{k}}$ direction. The lower panel shows the horizontal velocity, relative vorticity, and free surface as viewed from a vertical slice aligned with the wavevector direction. Note that the relative vorticity is the vertical component, ζ', so that the arrowed ellipses on the lower panel are in the horizontal plane.

Kinetic and potential energies contained in a plane wave

Writing the free surface as in equation (55.173) and the horizontal velocity as in equations (55.174a) and (55.174b) leads to the potential energy and kinetic energy carried by the wave field

$$\mathscr{P}^{\text{sw}} = \frac{\rho\, g\, \tilde{\eta}^2}{2} \cos^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) \tag{55.180a}$$

$$\mathscr{K}^{\text{sw}} = \frac{\rho\, \tilde{\eta}^2}{|\boldsymbol{k}|^2\, H^2} \left[\omega^2 \cos^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) + f^2 \sin^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)\right], \tag{55.180b}$$

with a corresponding phase average given by

$$\langle \mathscr{P}^{\text{sw}} \rangle = \frac{\rho\, g\, \tilde{\eta}^2}{4} \tag{55.181a}$$

$$\langle \mathscr{K}^{\text{sw}} \rangle = \frac{\rho\, \tilde{\eta}^2\, (\omega^2 + f^2)}{2\, |\boldsymbol{k}|^2\, H^2} = \frac{\rho\, g\, \tilde{\eta}^2}{4} \frac{\omega^2 + f^2}{\omega^2 - f^2}. \tag{55.181b}$$

Evidently, for non-rotating shallow water gravity waves, $f = 0$, there is an equipartition between phase averaged potential and kinetic energy. However, for the general case with rotation, the phase averaged kinetic energy is larger than the potential energy

$$\frac{\langle \mathscr{K}^{\text{sw}} \rangle}{\langle \mathscr{P}^{\text{sw}} \rangle} = \frac{\omega^2 + f^2}{\omega^2 - f^2} = 1 + 2\, (L_{\text{d}}\, |\boldsymbol{k}|)^{-2}, \tag{55.182}$$

with equipartition approached only for wave lengths smaller than the deformation radius (high wave numbers).

Mechanical energy and energy flux contained in a plane wave

The phase averaged mechanical energy contained in a plane wave is given by

$$\langle \mathscr{P}^{\text{sw}} \rangle + \langle \mathscr{K}^{\text{sw}} \rangle = \langle \mathscr{P}^{\text{sw}} \rangle \left[1 + \frac{\omega^2}{\omega^2 - f^2} \right] = 2 \langle \mathscr{P}^{\text{sw}} \rangle \frac{|\boldsymbol{c}_{\text{p}}|^2}{c_{\text{grav}}^2} = \frac{\rho\, g\, \tilde{\eta}^2}{2} \frac{|\boldsymbol{c}_{\text{p}}|}{|\boldsymbol{c}_{\text{g}}|}, \tag{55.183}$$

where we made use of equation (55.164) for the ratio of the group velocity magnitude to the phase velocity magnitude. For the flux of energy contained in the wave, we return to the energy equation (55.179a) and only consider the phase averaged flux, which takes the form

$$g\, \rho\, H\, \langle \eta'\, \boldsymbol{u}' \rangle = \frac{g\, \rho\, \tilde{\eta}^2\, \omega\, \boldsymbol{k}}{2\, |\boldsymbol{k}|^2} = \frac{g\, \rho\, \tilde{\eta}^2\, \boldsymbol{c}_{\text{p}}}{2} = \frac{g\, \rho\, \tilde{\eta}^2\, \boldsymbol{c}_{\text{g}}}{2} \frac{|\boldsymbol{c}_{\text{p}}|}{|\boldsymbol{c}_{\text{g}}|} = \boldsymbol{c}_{\text{g}} \left(\langle \mathscr{P}^{\text{sw}} \rangle + \langle \mathscr{K}^{\text{sw}} \rangle \right). \tag{55.184}$$

Hence, the phase averaged mechanical energy flux contained in the plane wave is given by the group velocity times the phase averaged mechanical energy. This is a standard result that we have seen before in the study of other linear waves.

55.9 Rossby waves

We now focus on the sub-inertial wave equation (55.62) derived in Section (55.4.6)

$$\partial_t \left[(L_{\text{d}}^{-2} - \nabla^2)\, \eta' \right] = H\, \hat{\boldsymbol{z}} \cdot (\nabla \eta' \times \nabla Q_{\text{r}}), \tag{55.185}$$

where

$$Q_{\text{r}} = f / H_{\text{r}} \tag{55.186}$$

is the potential vorticity in the resting fluid. Equation (55.185) describes shallow water *Rossby waves*.

55.9.1 Dispersion relation

Making use of the plane wave ansatz (55.24) in the wave equation (55.185) readily leads to the shallow water Rossby wave dispersion relation

$$\omega = \frac{H\, (\boldsymbol{k} \times \hat{\boldsymbol{z}}) \cdot \nabla Q_{\text{r}}}{k_{\text{d}}^2 + |\boldsymbol{k}|^2} \tag{55.187}$$

For the angular frequency to be independent of space, ∇Q_{r} must be spatially independent. We can ensure this property by assuming a β-plane along with linear and gently varying topography

$$\nabla H_{\text{r}}^{-1} = -H_{\text{r}}^{-2}\, \nabla H_{\text{r}} = H_{\text{r}}^{-2}\, \nabla \eta_{\text{b}}' \approx H^{-2}\, \nabla \eta_{\text{b}}', \tag{55.188}$$

where $\nabla \eta_{\text{b}}'$ is spatially independent with linear topography. More general (but gently varying) bottom topography requires the asymptotic methods from Chapter 50.

The dispersion relation (55.187) compares directly to equation (54.32) for Rossby waves in the horizontally non-divergent barotropic model. The sole difference concerns the presence of the deformation radius, L_{d} from equation (55.54), and its associated wavenumber

$$k_{\text{d}} = L_{\text{d}}^{-1} = f / c_{\text{grav}}, \tag{55.189}$$

which is present in the shallow water dispersion relatio. This term is missing from the non-divergent barotropic model since c_{grav} is formally infinite (there are no gravity waves in that model), in which case $L_{\text{d}}^{-2} = k_{\text{d}}^2 = 0$.

55.9.2 Connecting to quasi-geostrophic potential vorticity

When deriving the sub-inertial equations in Section 55.4.6, we noted that the assumptions made in that derivation are identical to the assumptions made when deriving shallow water quasi-geostrophy in Section 43.5. Indeed, the Rossby wave equation (55.185) is the linearized equation for the material evolution of shallow water quasi-geostrophic potential vorticity. We see this equality by recalling the discussion in Section (43.6.3), where we derived equation (43.90)

$$(f_\circ/g)\,\mathrm{D}q/\mathrm{D}t = \partial_t\left[(L_\mathrm{d}^{-2} - \nabla^2)\,\eta'\right] - H\,\hat{\boldsymbol{z}}\cdot(\nabla\eta'\times\nabla Q_\mathrm{r}) - (g/f_\circ)\,\hat{\boldsymbol{z}}\cdot[\nabla\eta'\times\nabla(\nabla^2\eta')], \quad (55.190)$$

where q is the quasi-geostrophic potential vorticity. For an inviscid fluid, $\mathrm{D}q/\mathrm{D}t = 0$, and for small amplitude fluctuations the nonlinear term in equation (55.190) (final term on the right hand side) is neglected. In this case we see that the linearized equation for material evolution of quasi-geostrophic potential vorticity is identical to the Rossby wave equation (55.185).

The nonlinear term in equation (55.190) arises from the geostrophic advection of geostrophic relative vorticity. Although it is small for small amplitude fluctuations, and thus commonly dropped when deriving the dispersion relation, we note that it vanishes identically for a plane wave. It does so in precisely the same way as it vanishes for the non-divergent barotropic vorticity equation in Section 54.2.3. Namely, this result follows since for a plane wave, $\nabla(\nabla^2\eta') = -|\boldsymbol{k}|^2\nabla\eta'$, so that it follows immediately that $\nabla\eta'\times\nabla(\nabla^2\eta') = 0$. Hence, a plane Rossby wave is an exact solution to the shallow water quasi-geostrophic potential vorticity equation in an inviscid fluid.

55.9.3 Vorticity mechanism

In Section 54.3 we studied Rossby waves in the horizontally non-divergent barotropic model, with a vorticity mechanism for the waves presented in Figure 54.3. This mechanism follows from the material evolution of absolute vorticity in the horizontally non-divergent barotropic model. The identical mechanism holds for the shallow water fluid yet with quasi-geostrophic potential vorticity replacing absolute vorticity. Hence, all conceptual points from Figure 54.3 also hold for the shallow water fluid.

55.9.4 Dispersion circle for planetary Rossby waves

In Section 54.4.2 we described a geometric method to help interpret the dispersion relation for planetary Rossby waves in the horizontally non-divergent barotropic model. That method also proved useful in Section 54.4.3 for describing the reflection of Rossby waves from a smooth and flat wall. Here we extend the geometric method to shallow water planetary Rossby waves, in which the dispersion relation is given by the β portion of the general dispersion relation (55.187)

$$\varpi_\beta = -\frac{\beta\,k_x}{k_\mathrm{d}^2 + |\boldsymbol{k}|^2}. \quad (55.191)$$

This equation compares to the β portion of the dispersion relation (54.32) holding for the non-divergent barotropic model. Again, the sole distinction is that the shallow water Rossby wave dispersion has a nonzero deformation wavenumber, $k_\mathrm{d} \neq 0$.

Dispersion circle

Following the geometric approach from Section 54.4, we write the dispersion relation (55.191) as the equation of a circle in wavevector space

$$(k_x + \beta/2\omega)^2 + k_y^2 = (\beta/2\omega)^2 - k_\mathrm{d}^2. \quad (55.192)$$

As written, the angular frequency, ω, is a parameter for the circle whose center is

$$\boldsymbol{k}_{\text{center}} = -(\beta/2\omega)\,\hat{\boldsymbol{x}} \tag{55.193}$$

and squared radius is $(\beta/2\omega)^2 - k_{\mathsf{d}}^2$. The deformation wavenumber appearing on the right hand side of the circle equation (55.192) places an upper bound on the angular frequency allowed for propagating Rossby waves

$$\omega \leq \omega_{\max} = \beta/(2\,k_{\mathsf{d}}) = \beta\,L_{\mathsf{d}}/2. \tag{55.194}$$

The shallow water model supports gravity waves that render $k_{\mathsf{d}} \neq 0$, thus imposing an upper bound on the shallow water Rossby wave angular frequency. In contrast, for the horizontally non-divergent barotropic model, $k_{\mathsf{d}} = 0$ since there are no gravity waves, in which case there is no maximum frequency for Rossby waves. Note that for the β-plane scaling used to derive the Rossby waves,

$$\omega_{\max}/f_{\mathsf{o}} = \beta\,L_{\mathsf{d}}/(2\,f_{\mathsf{o}}) \ll 1, \tag{55.195}$$

thus confirming that the shallow water Rossby waves are strictly sub-inertial.

Group velocity

The group velocity, $\boldsymbol{c}_{\mathsf{g}} = \nabla_{\boldsymbol{k}}\varpi$, is given by

$$\boldsymbol{c}_{\mathsf{g}} = \frac{\beta\,[(k_x^2 - k_y^2 - k_{\mathsf{d}}^2)\,\hat{\boldsymbol{x}} + 2\,k_x\,k_y\,\hat{\boldsymbol{y}}]}{(|\boldsymbol{k}|^2 + k_{\mathsf{d}}^2)^2} = -\frac{2\,\omega\,\boldsymbol{R}}{|\boldsymbol{k}|^2 + k_{\mathsf{d}}^2}, \tag{55.196}$$

where we introduced the group velocity orientation vector

$$\boldsymbol{R} = -\boldsymbol{k} - \beta/(2\,\omega)\,\hat{\boldsymbol{x}} = -[k_x + \beta/(2\,\omega)]\,\hat{\boldsymbol{x}} - k_y\,\hat{\boldsymbol{y}} \quad \text{with} \quad |\boldsymbol{R}|^2 = (\beta/2\omega)^2 - k_{\mathsf{d}}^2. \tag{55.197}$$

As for the orientation vector (54.62) in the horizontally non-divergent barotropic model, the vector $\boldsymbol{R}$ points from the perimeter of the dispersion circle to the center (its magnitude equals to the radius of the circle). We thus conclude that the dispersion geometry for shallow water planetary waves directly carries over from the horizontally non-divergent barotropic model detailed in Section 54.4.2. We illustrate the dispersion geometry for shallow water Rossby waves in Figure 55.7, with many details provided in the figure and its caption.

55.9.5 Comments

A more streamlined approach to deriving the Rossby wave dispersion relation starts directly from the quasi-geostrophic potential vorticity equation. That approach makes use of the quasi-geostrophic theory derived in in Section 43.5. Even so, the longer approach taken in the current section benefits by exposing the direct connection to other shallow water waves through the unified shallow water equation (55.42).

In Chapter 62 we study waves in a continuous quasi-geostrophic fluid, thus returning to some of the material in this section while extending it to continuous stratification.

55.10 Exercises

EXERCISE 55.1: STEPS IN DERIVING THE LINEAR PV EQUATION
Fill in the mathematical details needed to derive the linearized potential vorticity equation (55.23). Hint: form the linearized relative vorticity equation as an intermediate step.

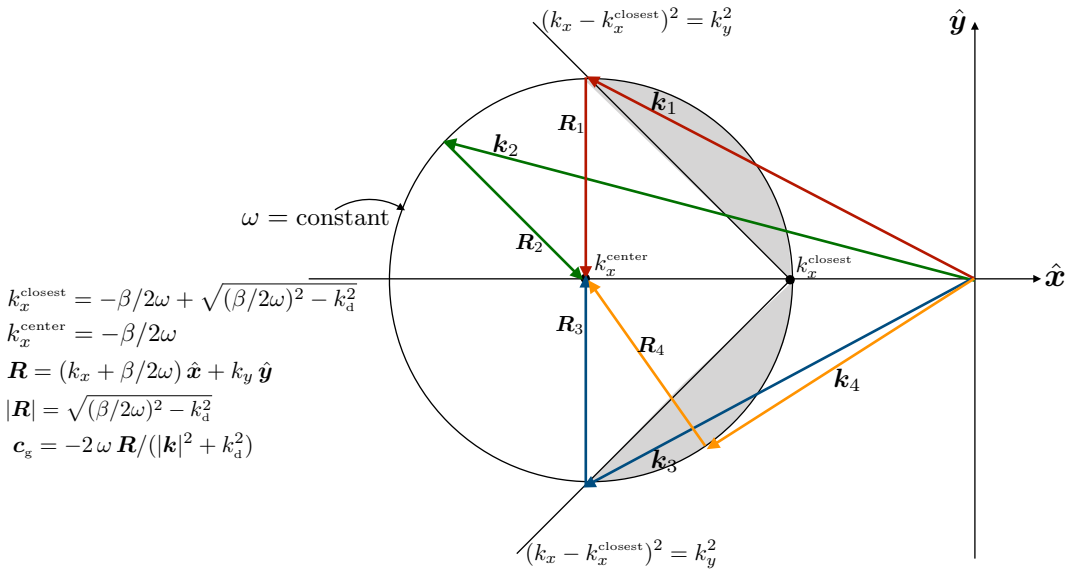

FIGURE 55.7: Dispersion circle for shallow water planetary Rossby waves as depicted by a circle in wavevector space, (k_x, k_y), parameterized by the angular frequency, ω. The center of the circle is at $\boldsymbol{k}_{\text{center}} = -(\beta/2\omega)\,\hat{\boldsymbol{x}}$ and the squared radius is $(\beta/2\omega)^2 - k_d^2$. A positive radius requires the angular frequency to be less than the maximum, $\omega_{\text{max}} = \beta/(2\,k_d)$. We depict four sample wavevectors, $\boldsymbol{k} = k_x\,\hat{\boldsymbol{x}} + k_y\,\hat{\boldsymbol{y}}$, that orient the phase velocity, $\boldsymbol{c}_p = \hat{\boldsymbol{k}}\,\omega/|\boldsymbol{k}|$. Each wavevector extends from the origin to a point on the circle. Each wavevector has an associated group velocity orientation vector, $\boldsymbol{R} = -\boldsymbol{k} - \beta/(2\,\omega)\,\hat{\boldsymbol{x}}$, that points from the circle perimeter to the circle center. The group velocity is westward for those wavevectors that intersect the circle perimeter within the gray-shaded region, which generally includes Rossby waves with low zonal wavenumbers. The group velocity is eastward for wavevectors outside the gray region, with the lines $(k_x - k_x^{\text{closest}})^2 = k_y^2$ separating these regions where the group velocity is westward or eastward. In particular, the group velocity for wavevector $\boldsymbol{k}_1$ is southward; for $\boldsymbol{k}_2$ it is southeastward; for $\boldsymbol{k}_3$ it is northward, and for $\boldsymbol{k}_4$ it is northwestward. This dispersion circle directly compares to Figure 54.5 constructed for the horizontally non-divergent barotropic model, with the key difference being $k_d \neq 0$ for the shallow water so that the dispersion circle does not touch the origin at $\boldsymbol{k} = 0$.

EXERCISE 55.2: STEPS IN DERIVING EQUATION (55.40)
Derive equation (55.40) from the linearized velocity equation (55.15).

EXERCISE 55.3: EQUATIONS FOR BAROTROPIC AND BAROCLINIC VELOCITIES
Fill in the details for deriving the equations (55.127a)-(55.127c) for the depth averaged and depth-deviation velocities.

EXERCISE 55.4: GRAVITY WAVES ON A CONSTANT REFERENCE FLOW
Consider a one-dimensional shallow water layer moving with a constant zonal speed, $U > 0$, over a flat bottom and in a non-rotating reference frame. We here examine the linear gravity wave disturbances on this constant background flow, thus generalizing the case from Section 55.5 for gravity waves propagating on a stationary background.

(a) Determine a general expression for the free surface wave fluctuation. Hint: perform a Galilean transformation (Section 17.5) to a reference frame moving with the constant background flow.

(b) Determine a general expression for the zonal velocity wave fluctuation.

(c) Making use of the ideas from hydraulic control in Section 55.5.4, discuss the cases where $U < c_{\text{grav}}$ (subcritical flow), $U > c_{\text{grav}}$ (supercritical flow), and $U = c_{\text{grav}}$ (critical flow).

EXERCISE 55.5: VANISHING POTENTIAL VORTICITY FOR INERTIA-GRAVITY WAVES
Verify that the linearized potential vorticity, $H\,Q' = \zeta' - f\,\eta'/H$, vanishes for the plane shallow water inertia-gravity waves (f-plane) given by the polarization relations in Section 55.8.9.

Chapter 56

SHALLOW WATER WAVES: CASE STUDIES

In this chapter we examine some case studies in shallow waves, thus furthering our study of shallow water wave mechanics.

READER'S GUIDE TO THIS CHAPTER

This chapter is a direct extension of the shallow water wave theory studied in Chapter 55.

56.1 Loose threads

- WKBJ approximation for shallow water gravity waves so to compute the change in the amplitude of the wave. Need to reinterpret the acoustic amplitude equation 50.37c for shallow water.

- Salmon class notes Chapter 9 on shallow water waves induced by an earthquake: solving the initial value problem.

- String function discussion from *Tyler and Käse* (2000) and *Tyler and Käse* (2001).

- non-Doppler for long Rossby waves as on page 14 of Liu's notes.

56.2 Waves excited by flow over topography

Consider the f-plane flow of a single layer of shallow water fluid with a static and prescribed reference flow, $\boldsymbol{u}_{\text{R}}$, and let this flow pass over a non-flat bottom with vertical position

$$\eta_{\text{b}}(x, y) = \overline{\eta_{\text{b}}} + \eta'_{\text{b}}(x, y). \tag{56.1}$$

If the topographic amplitude is much smaller than the resting layer thickness, $|\eta'_{\text{b}}| \ll H$, then the motion consists of linear waves, and with the principle of superposition allowing Fourier analysis to construct the linear wave fields generated by arbitrary (small amplitude) topography. Additionally, the linearized form of shallow water potential vorticity conservation constrains the waves. Indeed, it provides the wave equation. This section works through many elements of the kinematics and dynamics encountered in a variety of forced wave problems, here with the special restrictions imposed by the vertically columnar motion of a shallow water layer.[1]

56.2.1 Linearized governing equations

Following the linearization process detailed in Section 55.3, here with a nonzero reference flow, leads to the thickness and velocity decomposition

$$h = H + \eta' - \eta'_{\text{b}} = H + h' \quad \text{and} \quad \boldsymbol{u} = \boldsymbol{u}_{\text{R}} + \boldsymbol{u}'. \tag{56.2}$$

The reference flow is assumed to be in geostrophic balance with a prescribed pressure gradient generated by a static free surface,

$$f_{\circ}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{R}} = -g\, \nabla \eta_{\text{R}}. \tag{56.3}$$

Making use of equations (56.2) and (56.3) in the shallow water equations (55.1a) and (55.1b) leads to the linearized governing equations

$$[\partial_t + \gamma + (\boldsymbol{u}_{\text{R}} \cdot \nabla)]\boldsymbol{u}' + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}' = -g\, \nabla \eta' \tag{56.4a}$$

$$(\partial_t + \boldsymbol{u}_{\text{R}} \cdot \nabla) h' = -H\, \nabla \cdot \boldsymbol{u}'. \tag{56.4b}$$

The constant, $\gamma \geq 0$, is the inverse time scale for a Rayleigh drag (Section 25.8.5). We include Rayleigh drag since in many wave problems it is used to retain a finite solution in the presence of resonances. Even so, we drop it when examining the structure of the waves generated in the presence of flow over topography.

Taking the curl of the velocity equation (56.4a) and then making use of the thickness equation (56.4b) leads to the linearized version of the potential vorticity equation

$$(\partial_t + \boldsymbol{u}_{\text{R}} \cdot \nabla) Q' = -\gamma\, \zeta'/H, \tag{56.5}$$

where $\zeta' = \partial_x v' - \partial_y u'$ is the relative vorticity of the perturbation, and

$$Q' = f/H + \zeta'/H - f\, h'/H^2 \tag{56.6}$$

is the linearized potential vorticity (equation (55.22)), with f/H a constant for the f-plane examined here. Equation (56.5) reveals that the linearized potential vorticity locally evolves according to dissipation from Rayleigh drag acting on the relative vorticity.

[1] The setup is analogous to that considered for inertial waves in Section 53.5.2, which considered inertial waves generated in a resting flow forced by moving topography.

56.2.2 Galilean transformation to the frame of the reference flow

The reference flow is constant in space and time, so that a Galilean transformation to the frame moving with this flow acts to remove advection from the equations of motion (56.4a)-(56.4b). For this purpose, consider the Galilean transformation

$$\bar{t} = t \qquad \text{and} \qquad \overline{\boldsymbol{x}} = \boldsymbol{x} - \boldsymbol{u}_{\mathsf{R}}\, t. \tag{56.7}$$

Following our discussion of Galilean transformations in Section 17.5, we know that the derivative operators transform according to

$$\partial_{\bar{t}} = \partial_t + \boldsymbol{u}_{\mathsf{R}} \cdot \nabla \quad \text{and} \quad \partial_{\overline{x}} = \partial_x \quad \text{and} \quad \partial_{\overline{y}} = \partial_y, \tag{56.8}$$

which then brings the linear equations (56.4a), (56.4b), and (56.5) to

$$(\partial_{\bar{t}} + \gamma)\boldsymbol{u}' + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}' = -g\,\nabla\eta' \tag{56.9a}$$

$$\partial_{\bar{t}} h' = -H\,\nabla \cdot \boldsymbol{u}' \tag{56.9b}$$

$$\partial_{\bar{t}} Q' = -\gamma\,\zeta'/H. \tag{56.9c}$$

Whereas the reference flow moves with the velocity $\boldsymbol{u}_{\mathsf{R}}$ relative to the topography, the topography moves with a velocity $-\boldsymbol{u}_{\mathsf{R}}$ relative to the reference flow. Correspondingly, by moving to the boosted frame of the reference flow, the topography, which is independent of the rest frame time, t, is a function of time as measured in the boosted frame, $\bar{t}$.

56.2.3 Forced wave equation and potential vorticity

To derive a wave equation, take $\partial_{\bar{t}}$ of the thickness equation (56.9b) to render

$$\partial_{\bar{t}\bar{t}} h' = -H\,\nabla \cdot \partial_{\bar{t}}\boldsymbol{u}'. \tag{56.10}$$

Replacing $\partial_{\bar{t}}\boldsymbol{u}'$ using the linearized velocity equation (56.9a) leads to the forced wave equation

$$\partial_{\bar{t}}\left[(\partial_{\bar{t}} + \gamma)\, h'\right] - c_{\mathsf{grav}}^2\,\nabla^2\eta' = -f\,H\,\zeta', \tag{56.11}$$

where we introduced the squared shallow water gravity wave speed

$$c_{\mathsf{grav}}^2 = g\,H. \tag{56.12}$$

Following the approach in Section 55.8.2, make use of the linearized potential vorticity, Q' (equation (56.6)) to replace ζ', in which

$$f\,H^2\,Q' = -(\partial_{\bar{t}\bar{t}} + \gamma\,\partial_{\bar{t}} + f^2)h' + c_{\mathsf{grav}}^2\,\nabla^2\eta', \tag{56.13}$$

which agrees with equation (55.152) for the case with $\boldsymbol{u}_{\mathsf{R}} = 0$, $\gamma = 0$, and $\eta'_{\mathsf{b}} = 0$. Equation (56.13) brings the potential vorticity evolution equation (56.9c) to the form

$$\partial_{\bar{t}}[(\partial_{\bar{t}\bar{t}} + \gamma\,\partial_{\bar{t}} + f^2)h' - c_{\mathsf{grav}}^2\,\nabla^2\eta'] = f\,H\,\gamma\,\zeta', \tag{56.14}$$

which can be rewritten to isolate a forced wave equation for η'

$$\partial_{\bar{t}}[(\partial_{\bar{t}\bar{t}} + f^2)\eta' - c_{\mathsf{grav}}^2\,\nabla^2\eta'] = \gamma\,[f\,H\,\zeta' - \partial_{\bar{t}\bar{t}}(\eta' - \eta'_{\mathsf{b}})] + \partial_{\bar{t}}[(\partial_{\bar{t}\bar{t}} + f^2)\eta'_{\mathsf{b}}]. \tag{56.15}$$

In the absence of dissipation ($\gamma = 0$) and for a flat bottom ($\eta'_{\mathsf{b}} = 0$), this equation has solutions given by the free inertia-gravity wave modes discussed in Section 55.8.

For the remainder of this section we set $\gamma = 0$ to focus on responses of a non-dissipative flow moving over small amplitude topography. In this case equation (56.15) simplifies to

$$\partial_{\bar{t}}[(\partial_{\bar{t}\bar{t}} + f^2)\eta' - c_{\text{grav}}^2 \nabla^2 \eta'] = \partial_{\bar{t}}[(\partial_{\bar{t}\bar{t}} + f^2)\eta'_{\text{b}}]. \tag{56.16}$$

Furthermore, consistent with our treatment of free inertia-gravity waves in Section 55.8, we focus on wave solutions with zero potential vorticity, which leads to the forced linear wave equation

$$(\partial_{\bar{t}\bar{t}} + f^2)\eta' - c_{\text{grav}}^2 \nabla^2 \eta' = (\partial_{\bar{t}\bar{t}} + f^2)\eta'_{\text{b}}. \tag{56.17}$$

Finally, since the bottom topography is independent of time, t, the source on the right hand side takes the form

$$(\partial_{\bar{t}\bar{t}} + f^2)\eta' - c_{\text{grav}}^2 \nabla^2 \eta' = [(\boldsymbol{u}_{\text{R}} \cdot \nabla)^2 + f^2]\eta'_{\text{b}}. \tag{56.18}$$

This is a forced linear wave equation for a shallow water layer moving in a uniform background flow over topography.

56.2.4 Monochromatic topography

We consider bottom topography in the form of a monochromatic wave

$$\eta'_{\text{b}} = \eta_{\text{o}}\, \mathrm{e}^{\mathrm{i}\boldsymbol{k}_{\text{b}} \cdot \boldsymbol{x}} = \eta_{\text{o}}\, \mathrm{e}^{\mathrm{i}\boldsymbol{k}_{\text{b}} \cdot (\bar{\boldsymbol{x}} + \boldsymbol{u}_{\text{R}}\, \bar{t})} = \eta_{\text{o}}\, \mathrm{e}^{\mathrm{i}(\boldsymbol{k}_{\text{b}} \cdot \bar{\boldsymbol{x}} - \omega_{\text{R}}\, \bar{t})}, \tag{56.19}$$

where η_{o} is a constant real amplitude, $\boldsymbol{k}_{\text{b}}$ is the topography wavevector, and

$$\omega_{\text{R}} = -\boldsymbol{k}_{\text{b}} \cdot \boldsymbol{u}_{\text{R}} > 0 \tag{56.20}$$

is the angular frequency implied by the reference flow that moves over the topography. Since the wave response is assumed to be linear, the response to more complex topography can be built using Fourier analysis.[2]

The topography (56.19) is stationary in the rest frame, but it moves in the direction opposite to the reference flow when viewed in the boosted frame. This direction swap is reflected in the choice $\boldsymbol{k}_{\text{b}} \cdot \boldsymbol{u}_{\text{R}} < 0$, which orients the topography wavevector, $\boldsymbol{k}_{\text{b}}$, according to the reference flow, $\boldsymbol{u}_{\text{R}}$. For example, a zonal referential flow, $\boldsymbol{u}_{\text{R}} = U\, \hat{\boldsymbol{x}}$, with $U > 0$, has a topography wavevector $\boldsymbol{k}_{\text{b}} = -|\boldsymbol{k}_{\text{b}}|\, \hat{\boldsymbol{x}}$, in which case the topography (56.19) takes the form

$$\eta'_{\text{b}} = \eta_{\text{o}}\, \mathrm{e}^{-\mathrm{i}|\boldsymbol{k}_{\text{b}}| x} = \eta_{\text{o}}\, \mathrm{e}^{-\mathrm{i}|\boldsymbol{k}_{\text{b}}|\, (\bar{x} + U\, \bar{t})}. \tag{56.21}$$

Evidently, a boosted frame observer rides along with the reference flow while the topography moves as a plane wave in the $-\hat{\boldsymbol{x}}$ direction. Conversely, a rest frame observer sees static topography with the reference flow moving in the $+\hat{\boldsymbol{x}}$ direction.

56.2.5 Stationary waves and causality

Before considering the non-stationary (or non-steady) wave response in Section 56.2.7, we determine the stationary response from a uniform flow moving over the monochromatic topography (56.21). Notably, stationary flow (also steady flow) refers to stationary in the rest frame of the topography, so that

$$\partial_t = 0 \Longrightarrow \partial_{\bar{t}} = \boldsymbol{u}_{\text{R}} \cdot \nabla. \tag{56.22}$$

In effect, we assume all transient (traveling) waves have propagated far away from the region of interest, leaving just the stationary wave response to the forcing. For flow over topography, the

[2] We illustrate the Fourier analysis approach in Section 58.3 for stationary internal gravity waves generaged by flow over a single mountain.

forcing angular frequency is $\omega_\mathsf{R} = -\boldsymbol{u}_\mathsf{R} \cdot \boldsymbol{k}_\mathsf{b} > 0$, whereas this frequency might have a different origin in other systems, such as the frequency of a piston in a laboratory experiment.

Causality and the non-negative forcing frequency

Stationary waves are generally simpler to mathematically determine than their transient cousins. Furthermore, stationary waves are often of primary physical interest when concerned with long term wave responses. However, there are subtleties related to *causality* that must be kept in mind when studying stationary solutions. Namely, the stationary equations have time symmetry merely because all fields are time independent (in the rest frame). However, stationary waves result from equilibration of transients that arise from a particular forcing. For example, with flow over topography the stationary wave solution knows about the direction of the reference flow, thus respecting causality (e.g., waves are swept downstream not upstream). So although there are no time derivatives in the stationary equations, we build in causality through specifying the forcing frequency, $\omega_\mathsf{R} = -\boldsymbol{u}_\mathsf{R} \cdot \boldsymbol{k}_\mathsf{b} > 0$ (equation (56.20)). Our choice to insist on a positive forcing angular frequency provides a robust means to maintain causality. It also accords with our choice in this book to only consider non-negative angular frequencies (see Section 49.2.3).

Free surface and velocity for the stationary flow

We insert the topography Fourier mode (56.19) into the potential vorticity equation (56.16), and take a plane wave ansatz for the free surface

$$\eta' = \widetilde{\eta}\, \mathrm{e}^{\mathrm{i}(\boldsymbol{k}\cdot\overline{\boldsymbol{x}} - \overline{\omega}\,\overline{t})}, \tag{56.23}$$

where $\overline{\omega}$ is the angular frequency seen in the boosted reference frame. This substitution yields

$$\overline{\omega}\,(-\overline{\omega}^2 + f^2 + c_\mathsf{grav}^2\,|\boldsymbol{k}|^2)\,\widetilde{\eta}\,\mathrm{e}^{\mathrm{i}(\boldsymbol{k}\cdot\overline{\boldsymbol{x}} - \overline{\omega}\,\overline{t})} = \omega_\mathsf{R}\,(-\omega_\mathsf{R}^2 + f^2)\,\eta_\circ\,\mathrm{e}^{\mathrm{i}(\boldsymbol{k}_\mathsf{b}\cdot\overline{\boldsymbol{x}} - \omega_\mathsf{R}\,\overline{t})}. \tag{56.24}$$

Since the fluctuations are assumed to be linear, we expect the reference flow over the topography to excite linear waves. Furthermore, in the steady state we expect the wavevector and angular frequency to be set by the flow and topography

$$\overline{\omega}^2 = \omega_\mathsf{R}^2 = (\boldsymbol{k}_\mathsf{b} \cdot \boldsymbol{u}_\mathsf{R})^2 \quad \text{and} \quad |\boldsymbol{k}|^2 = |\boldsymbol{k}_\mathsf{b}|^2, \tag{56.25}$$

in which case equation (56.24) yields the amplitude ratio

$$\frac{\widetilde{\eta}}{\eta_\circ} = \frac{\omega_\mathsf{R}^2 - f^2}{\omega_\mathsf{R}^2 - f^2 - c_\mathsf{grav}^2\,|\boldsymbol{k}_\mathsf{b}|^2}, \tag{56.26}$$

and the corresponding free surface wave form

$$\eta' = \widetilde{\eta}\,\mathrm{e}^{\mathrm{i}\boldsymbol{k}_\mathsf{b}\cdot\boldsymbol{x}} = \frac{(\omega_\mathsf{R}^2 - f^2)\;\eta_\circ\,\mathrm{e}^{\mathrm{i}\boldsymbol{k}_\mathsf{b}\cdot\boldsymbol{x}}}{\omega_\mathsf{R}^2 - f^2 - c_\mathsf{grav}^2\,|\boldsymbol{k}_\mathsf{b}|^2} = \left[\frac{\omega_\mathsf{R}^2 - f^2}{\omega_\mathsf{R}^2 - f^2 - c_\mathsf{grav}^2\,|\boldsymbol{k}_\mathsf{b}|^2}\right] \eta'_\mathsf{b}, \tag{56.27}$$

with an example given by Figure 56.1. Evidently, the stationary solution has a free surface and bottom topography that are either in-phase (same sign) or π radians out of phase (opposite sign), depending on properties of the reference flow, the topography, the gravity wave speed, and the Coriolis parameter. The stationary velocity field can be found just like for the free inertia-gravity waves in Section 55.8.9 through use of the linear velocity equation (56.9a) (with the Rayleigh drag, $\gamma = 0$), in which

$$\boldsymbol{u}' = \widetilde{\boldsymbol{u}}\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}_\mathsf{b}\cdot\boldsymbol{x}} \tag{56.28}$$

with the complex amplitude

$$\widetilde{\boldsymbol{u}} = \frac{g\,\widetilde{\eta}\,(-\boldsymbol{k}_\mathsf{b}\,\omega_\mathsf{R} - \mathrm{i}\,f\,\hat{\boldsymbol{z}}\times\boldsymbol{k}_\mathsf{b})}{\omega_\mathsf{R}^2 - f^2} = \frac{g\,\eta_\circ\,(-\boldsymbol{k}_\mathsf{b}\,\omega_\mathsf{R} - \mathrm{i}\,f\,\hat{\boldsymbol{z}}\times\boldsymbol{k}_\mathsf{b})}{\omega_\mathsf{R}^2 - f^2 - c_\mathsf{grav}^2\,|\boldsymbol{k}_\mathsf{b}|^2}. \tag{56.29}$$

These waves are not the free inertia-gravity waves studied in Section 55.8 since $\omega_\mathsf{R}^2 \neq f^2\,(1 + L_\mathsf{d}^2\,|\boldsymbol{k}_\mathsf{b}|^2)$. Rather, they are stationary waves forced by the motion of the shallow water fluid over the sinusoidal topography. Even so, they share many properties with inertia-gravity waves, including the polarization relation exhibited by equation (56.29), which directly compares to the free inertia-gravity wave in equation (55.174b).

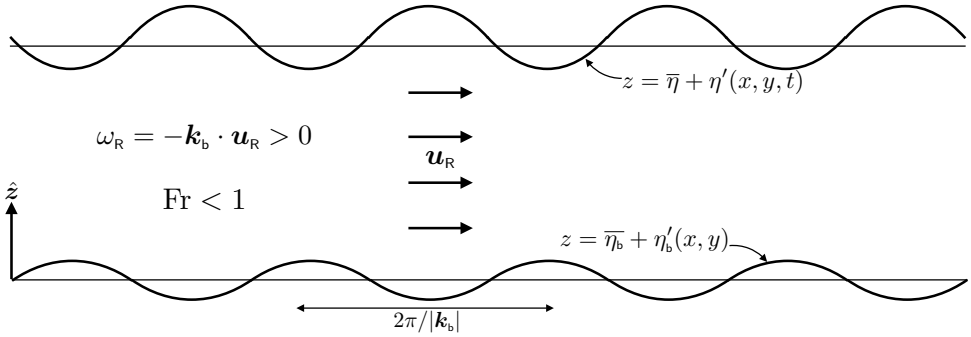

FIGURE 56.1: A shallow water fluid layer with reference flow that moves over a sinusoidal bottom topography for the sub-critical case ($\mathrm{Fr} < 1$) from equation (56.33) with $f = 0$. The stationary gravity waves have amplitude, $\widetilde{\eta} = -\eta_\circ\,\mathrm{Fr}^2/(1-\mathrm{Fr}^2)$, that is opposite to that of the topography. Note that the specification, $\boldsymbol{k}_\mathsf{b}\cdot\boldsymbol{u}_\mathsf{R} < 0$, orients the topography wavevector, $\boldsymbol{k}_\mathsf{b}$, according to the reference flow, $\boldsymbol{u}_\mathsf{R}$. This orientation ensures that the topography observed in the boosted frame moves in the opposite direction to the reference flow as viewed in the rest frame. It also builds in causality as discussed in Section 56.2.5.

Flow regimes and free surface deflections

To help understand the amplitude ratio (56.26), consider the special case of zonal reference flow with $\boldsymbol{u}_\mathsf{R} = U\,\hat{\boldsymbol{x}}$, so that the squared frequency is

$$\omega_\mathsf{R}^2 = U^2\,|\boldsymbol{k}_\mathsf{b}|^2. \tag{56.30}$$

We also find it useful to introduce the Froude number, shallow water deformation radius, and period of an inertial oscillation

$$\mathrm{Fr} = U/c_\mathsf{grav} \quad \text{and} \quad L_\mathsf{d} = c_\mathsf{grav}/f \quad \text{and} \quad T_\mathsf{inertial} = 2\pi/f. \tag{56.31}$$

We can thus write the amplitude ratio (56.26) in the equivalent forms

$$\frac{\widetilde{\eta}}{\eta_\circ} = \frac{\omega_\mathsf{R}^2 - f^2}{\omega_\mathsf{R}^2 - f^2 - c_\mathsf{grav}^2\,|\boldsymbol{k}_\mathsf{b}|^2} = \frac{U^2 - f^2\,|\boldsymbol{k}_\mathsf{b}|^{-2}}{U^2 - f^2\,|\boldsymbol{k}_\mathsf{b}|^{-2} - c_\mathsf{grav}^2} = \frac{\mathrm{Fr}^2 - (L_\mathsf{d}\,|\boldsymbol{k}_\mathsf{b}|)^{-2}}{\mathrm{Fr}^2 - (L_\mathsf{d}\,|\boldsymbol{k}_\mathsf{b}|)^{-2} - 1}, \tag{56.32}$$

with the first a ratio of angular frequencies, the second a ratio of speeds, and the third a ratio of non-dimensional numbers.

There are three regimes for the amplitude as determined by

$$\frac{\widetilde{\eta}}{\eta_\circ} = \begin{cases} > 0 & \text{if} \quad \omega_\mathsf{R}^2 > f^2 + c_\mathsf{grav}^2\,|\boldsymbol{k}_\mathsf{b}|^2 \\ < 0 & \text{if} \quad f^2 < \omega_\mathsf{R}^2 < f^2 + c_\mathsf{grav}^2\,|\boldsymbol{k}_\mathsf{b}|^2 \\ > 0 & \text{if} \quad \omega_\mathsf{R}^2 < f^2, \end{cases} \tag{56.33}$$

as well as their equivalent forms in terms of speeds and non-dimensional numbers. Actually, it is simplest to start by considering the $f = 0$ case, in which there are just two regimes as determined by

$$\left[\frac{\widetilde{\eta}}{\eta_\circ}\right]_{\text{non-rotating}} = \begin{cases} > 0 & \text{if} \quad \text{Fr} > 1 \\ < 0 & \text{if} \quad \text{Fr} < 1. \end{cases} \tag{56.34}$$

With $\text{Fr} > 1$, the free surface is in-phase with the topography, so that the free surface rises when the bottom rises, and vice versa. As discussed in Section 55.5.4, the $\text{Fr} > 1$ flow is a state of hydraulic control and is generally unstable (the fluid particle speed is greater than the gravity wave speed, and the flow generally breaks down into turbulence). For the sub-critical flow with $\text{Fr} < 1$, the free surface falls when the topography rises, and vice versa. Equation (56.33) shows that the addition of a non-zero Coriolis parameter, and thus a finite deformation radius and finite inertial oscillation period, introduces a third regime for in-phase free surface and topography, while it modifies the sub-critical and super-critical regimes.

56.2.6 Free stationary inertia-gravity waves

Consider the special case of

$$\omega_{\mathsf{R}}^2 = (\boldsymbol{k}_{\mathsf{b}} \cdot \boldsymbol{u}_{\mathsf{R}})^2 = f^2, \tag{56.35}$$

in which case the topographic forcing vanishes on the right hand side of the potential vorticity equation (56.24). This case allows for any free inertia-gravity wave to fit within the domain so that

$$\omega^2 = f^2 \, (1 + L_{\mathsf{d}}^2 \, |\boldsymbol{k}|^2). \tag{56.36}$$

That is, the free inertia-gravity wave can exist just as in the case of the flat bottom domain examined in Section 55.8. Transforming the free surface back to the rest frame yields

$$\eta' = \widetilde{\eta} \, \mathrm{e}^{\mathrm{i}(\boldsymbol{k} \cdot \overline{\boldsymbol{x}} - \overline{\omega} \, \overline{t})} = \widetilde{\eta} \, \mathrm{e}^{\mathrm{i}[\boldsymbol{k} \cdot \boldsymbol{x} - (\boldsymbol{k} \cdot \boldsymbol{u}_{\mathsf{R}} + \overline{\omega}) \, t]} = \widetilde{\eta} \, \mathrm{e}^{\mathrm{i}(\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t)}, \tag{56.37}$$

where we related the boosted frame frequency, $\overline{\omega}$, according to the *Doppler shift* relative to the rest frame frequency, ω,

$$\overline{\omega} = \omega - \boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}. \tag{56.38}$$

Furthermore note that the free surface amplitude is unconstrained since these waves are invisible to the topography. We have thus identified a free wave solution, which arises for the special case of topography and reference flow satisfying $\omega_{\mathsf{R}}^2 = f^2 > 0$ so that $\omega^2 / f^2 = 1 + (|\boldsymbol{k}| \, L_{\mathsf{d}})^2$, which is the flat bottom frequency for free traveling inertia-gravity waves found in Section 55.8.

56.2.7 Non-stationary gravity wave adjustment

So far we have focused on the stationary waves that result after allowing for transient non-stationary waves to propagate away from the area of interest (formally, to propagate out to infinity). We here consider the case of non-stationary gravity waves ($f = 0$) generated by flow over topography. We assume the free surface fluctuation, η', is initially equal to the bottom topography and to have a zero initial tendency. With a zonal reference flow ($\boldsymbol{u}_{\mathsf{R}} = U \, \hat{\boldsymbol{x}}$) and zonally dependent bottom topography, $\eta'_{\mathsf{b}} = \eta'_{\mathsf{b}}(x)$, we are led to the initial value problem from equation (56.18)

$$(\partial_{\overline{t}\overline{t}} - c_{\mathsf{grav}}^2 \, \partial_{\overline{x}\overline{x}}) \eta' = U^2 \, \partial_{\overline{x}\overline{x}} \eta'_{\mathsf{b}} \tag{56.39a}$$

$$\eta'(\overline{x}, \overline{t} = 0) = \eta'_{\mathsf{b}}(\overline{x}) \tag{56.39b}$$

$$\partial_t \eta'(\overline{x}, \overline{t} = 0) = 0. \tag{56.39c}$$

This is an initial value problem formulated using the boosted reference frame coordinates, $(\overline{x}, \overline{t}) = (x - U\,t, t)$ from Section 56.2.2. Additionally, as shallow water gravity waves are non-dispersive, we can naively allow the bottom topography to be arbitrarily shaped.[3]

We do not expect the initial condition to remain fixed for all time. Rather, we expect the flow (in the limit of linear behavior) to adjust through gravity waves that propagate in both directions. Additionally, we expect this propagation to occur in the presence of the stationary solution from Section 56.2.5. This expectation motivates the ansatz

$$\eta'(\overline{x}, \overline{t}) = \eta'_{\text{stationary}}(\overline{x}) + \eta'_{\text{transient}}(\overline{x}, \overline{t}) = \frac{\text{Fr}^2}{\text{Fr}^2 - 1}\,\eta'_{\text{b}}(x) + \eta'_{\text{transient}}(\overline{x}, \overline{t}), \tag{56.40}$$

where we wrote the stationary solution in terms of the rest frame coordinates, (x, t), which is the frame where $\eta'_{\text{stationary}}$ is stationary. The transient solution embodies linear gravity waves propagating in both directions, and it satisfies equation (56.39a) with zero forcing and with initial conditions set according to equations (56.39b) and (56.39c)

$$(\partial_{\overline{t}\,\overline{t}} - c^2_{\text{grav}}\,\partial_{\overline{x}\,\overline{x}})\eta'_{\text{transient}} = 0 \tag{56.41a}$$

$$\eta'_{\text{transient}}(\overline{x}, \overline{t} = 0) = -\eta'_{\text{transient}}(\overline{x}, \overline{t} = 0) \tag{56.41b}$$

$$\partial_{\overline{t}}\eta'_{\text{transient}}(\overline{x}, \overline{t} = 0) = 0. \tag{56.41c}$$

The solution to the non-dispersive wave equation (56.41a) is given by the D'Alembert formula from Section 6.7.1, which takes the form

$$\eta'_{\text{transient}} = A\,\eta'_{\text{b}}(\overline{x} - c_{\text{grav}}\,\overline{t}) + B\,\eta'_{\text{b}}(\overline{x} + c_{\text{grav}}\,\overline{t}) \tag{56.42a}$$

$$= A\,\eta'_{\text{b}}[x - t\,(U + c_{\text{grav}})] + B\,\eta'_{\text{b}}[x - t\,(U - c_{\text{grav}})] \tag{56.42b}$$

$$= A\,\eta'_{\text{b}}(x - c_{(+)}\,t) + B\,\eta'_{\text{b}}(x - c_{(-)}\,t), \tag{56.42c}$$

where

$$c_{(\pm)} = U \pm c_{\text{grav}} \tag{56.43}$$

are the gravity wave speeds relative to the reference flow. The constants A and B are set according to the initial conditions (56.41b) and (56.41c), which yields

$$\eta'(x, t) = \frac{\text{Fr}^2}{\text{Fr}^2 - 1}\,\eta'_{\text{b}}(x) + \frac{1}{2}\left[\frac{\eta'_{\text{b}}(x - c_{(-)}\,t)}{1 - \text{Fr}} + \frac{\eta'_{\text{b}}(x - c_{(+)}\,t)}{1 + \text{Fr}}\right]. \tag{56.44}$$

For subcritical flow, with $U < c_{\text{grav}}$, we have

$$\text{subcritical} \Longrightarrow c_{(+)} = U + c_{\text{grav}} > 0 \quad \text{and} \quad c_{(-)} = U - c_{\text{grav}} < 0. \tag{56.45}$$

Since $|c_{(-)}| < |c_{(+)}|$, we find the transient solution consists of a relatively fast rightward moving signal, $\eta'_{\text{b}}(x - c_{(+)}\,t)/[2\,(1 + \text{Fr})]$, plus a relatively slow leftward moving signal, $\eta'_{\text{b}}(x - c_{(-)}\,t)/[2\,(1 - \text{Fr})]$. Since $\text{Fr} < 1$, the amplitude of the right moving signal is smaller than the left moving signal according to the ratio $0 < (1 - \text{Fr})/(1 + \text{Fr}) < 1$. The stationary solution has a negative amplitude of relatively absolute value. We depict an example in the left panel of Figure 56.2 for the case of a single Gaussian mountain with $\text{Fr} = 1/4$. We can make use of a Gaussian shaped mountain rather than a single Fourier mode since the linear responses are non-dispersive gravity waves that travel at the same speed. Hence, we can sum any number of non-dispersive gravity wave modes to render the Gaussian shaped wave response that remains coherent.

[3] We consider dispersive internal gravity waves in Section 58.3, which requires Fourier analysis methods to account for wave dispersion.

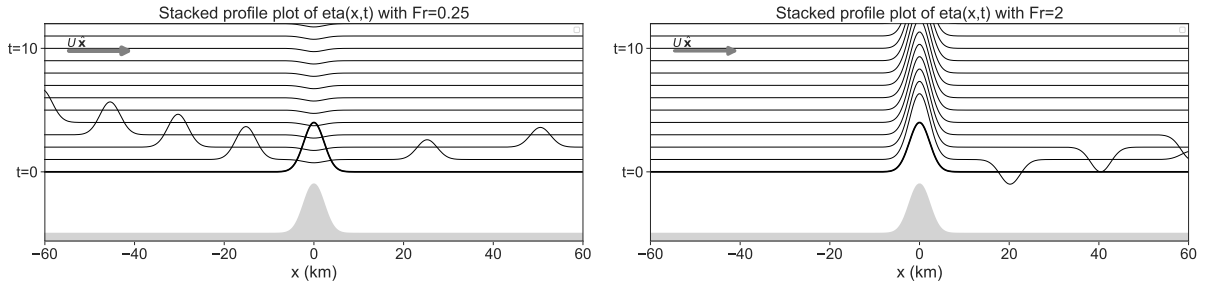

FIGURE 56.2: Stacked profiles of the free surface height that depicts the transient linear gravity wave adjustment of a shallow water layer flowing over a mountain, with the reference flow moving from left to right, $\boldsymbol{u}_{\text{R}} = U\,\hat{\boldsymbol{x}}$ with $U > 0$. Each line represents the free surface incremented in time (moving upward) by the amount $\Delta t = 20 \times 10^3$ m/$\sqrt{1000 \text{ m } 9.8 \text{ m s}^{-2}} \approx 200$ s. The left panel shows results for subcritical flow with Fr $= 1/4$, and the right panel shows supercritical flow with Fr $= 2$, both according to the solution (56.44). The initial condition for the free surface, $\eta'(\overline{x}, \overline{t} = 0) = \eta'_{\text{b}}(\overline{x})$, is shown as a thick black line. For the subcritical flow, the stationary solution has a relatively small and negative amplitude, whereas for the supercritical flow the stationary solution has a large a positive amplitude. The subcritical case reveals leftward and rightward moving gravity waves that propagate away from the mountain, with the leftward wave having a relatively large amplitude and slow speed. The supercritical case has both waves moving to the right, with the relatively small amplitude positive signal moving much faster than the larger amplitude negative signal.

For supercritical flow, with $U > c_{\text{grav}}$, have

$$\text{supercritical} \implies c_{(+)} = U + c_{\text{grav}} > 0 \quad \text{and} \quad c_{(-)} = U - c_{\text{grav}} > 0. \tag{56.46}$$

Since $c_{(\pm)} > 0$, both signals move to the right. The slower signal, $\eta'_{\text{b}}(x - c_{(-)}\,t)/[2\,(1 - \text{Fr})]$, has a negative amplitude since Fr > 1, with this amplitude larger in absolute sense than the faster signal, $\eta'_{\text{b}}(x - c_{(+)}\,t)/[2\,(1 + \text{Fr})]$, whose amplitude is positive. Furthermore, the stationary solution has a positive amplitude. We depict an example supercritical response in the right panel of Figure 56.2 for the case of a single Gaussian mountain with Fr $= 2$.

It is notable that the potential energy of the stationary state for subcritical flow is less than that of the initial condition, given the depressed free surface height, whereas the potential energy of the supercritical flow's stationary state is greater than the initial condition. We cannot perform a closed energy budget since the reference flow is assumed to be fixed. Even so, we understand the ability of the supercritical reference flow to lift the full column of shallow water fluid up and over the mountain, given its relatively large source of kinetic energy. In contrast, the subcritical reference flow insufficient kinetic energy to lift the free surface over the mountain.

56.2.8 Comments and further study

There is no vertical wave propagation in a shallow water layer (see Section 55.3.4). Hence, the layer responds to movement of the reference flow over variable bottom topography by conforming to the constraints from shallow water potential vorticity conservation. It is for this reason that we focused on the linearized potential vorticity equation (56.9c). A further focus on fluctuations with zero potential vorticity, $Q' = 0$, leads to the wave equation (56.18), just as for the free inertia-gravity waves in Section 55.8. In Section 58.2 we study the generation of internal inertia-gravity waves by flow over topography. That study extends the work done here for the shallow water fluid, and it reveals a richer phenomenology that is supported by continuous stratification and non-hydrostatic pressure. Chapter 5 of *Sutherland* (2010) works through a variety of examples for shallow water fluid layers moving over topography, including a study of the initial value problem that we considered in Section 56.2.7.

56.3 Geostrophic adjustment

The geostrophic balance presented in Sections 31.4 and 36.2 is very well maintained by the observed large-scale atmosphere and ocean. Hence, geostrophy (and the associated thermal wind) is a powerful diagnostic. In this section, we examine how a flow state that is initially not in geostrophic balance evolves towards geostrophy. We thus study the dynamical processes associated with the *geostrophic adjustment* problem. As we see, the adjustment occurs through the propagation of linear inertia-gravity waves.

A single shallow water layer on a flat f-plane is sufficient to introduce the main physical ideas of geostrophic adjustment. Furthermore, we focus on linear perturbations so that the governing equations are those derived in Section 55.8 when studying inertia-gravity waves. The adjustment consists of linear inertia-gravity waves that maintain a locally static potential vorticity (equation (55.23)). For brevity in notation, we here drop all primes on the linear fluctuating terms.

56.3.1 Potential vorticity inversion

Before studying the geostrophic adjustment problem, we offer a few comments about *potential vorticity inversion,* which generally refers to the process of determining the flow field given information about the potential vorticity. In a shallow water layer, the potential vorticity is given by

$$Q = h^{-1} (f + \zeta) = h^{-1} (f + \partial_x v - \partial_y u). \tag{56.47}$$

If we further assume the flow to be in geostrophic balance (Section 36.2), then

$$Q = \frac{f}{h} + \frac{1}{h} \left[\frac{\partial}{\partial x} \left(\frac{g}{f} \frac{\partial \eta}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{g}{f} \frac{\partial \eta}{\partial y} \right) \right]. \tag{56.48}$$

Assuming we know Q throughout the domain; assuming f and Q are uniformly of the same sign within the domain; and assuming we know boundary conditions for η, then equation (56.48) is a nonlinear elliptic boundary value problem (Section 6.5) for η. Nonlinearities come from the $h^{-1} = (\eta - \eta_b)^{-1}$ pre-factor, as well as the boundary conditions discussed below. Linearizing by setting $h^{-1} \approx H^{-1}$ and simplifying the boundary conditions (see below) allows equation (56.48) to be solved for η. This solution process is referred to as *inverting* the elliptic operator, so that this particular inversion process is referred to as *potential vorticity inversion.*

General boundary conditions for η can be rather complex to handle mathematically. Namely, in a domain with a sloping bottom, such as in Figure 35.1, the free surface deviation equals to the bottom deviation, $\eta = \eta_b$, along the domain boundaries since the layer thickness vanishes there. Furthermore, the horizontal position of the domain boundary is a function of time since the layer moves up and down the sloping bottom. Vanishing layers and the associated moving boundaries are intrinsically nonlinear; i.e., there is no way to linearize the process without removing it altogether. Instead, to facilitate the use of linear physics requires us to assume the layer thickness remains nonzero throughout the domain. Furthermore, we assume the layer thickness deviates only a small amount from the layer averaged thickness: $h/H \approx 1$. These assumptions are made in the following discussion of geostrophic adjustment.

56.3.2 Posing the initial value problem

We solve for the $t > 0$ evolution of surface height and velocity by making use of the linearized equations from Section 55.3[4]

$$\partial_t \boldsymbol{u} + f \, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -g \, \nabla \eta \tag{56.49a}$$

[4]Recall that to reduce notational clutter, we drop primes on the fluctuation variables in this section.

$$\partial_t \eta + H\,\nabla\cdot\boldsymbol{u} = 0 \tag{56.49b}$$

$$\zeta - f\,\eta/H = H\,Q(x,y). \tag{56.49c}$$

$Q(x,y)$ is the linearized potential vorticity that is static for the flat bottom f-plane and so it is fully determined by the initial conditions (Section 55.3.3). To illustrate the geostrophic adjustment in an analytically tractable manner, consider the following step initial conditions for the surface height

$$\eta(x,t=0) = \begin{cases} +\eta_\circ & x<0 \\ -\eta_\circ & x>0, \end{cases} \tag{56.50}$$

which can be written

$$\eta(x,t=0) = \eta_\circ\,[1-2\,\mathcal{H}(x)] = -\eta_\circ\,\mathrm{sgn}(x), \tag{56.51}$$

where the sign-function is given by

$$\mathrm{sgn}(x) = \begin{cases} -1 & \text{if } x<0 \\ 0 & \text{if } x=0 \\ 1 & \text{if } x>0, \end{cases} \tag{56.52}$$

which can also be written in terms of the Heaviside step function

$$\mathrm{sgn}(x) = 2\,\mathcal{H}(x) - 1, \tag{56.53}$$

where[5]

$$\mathcal{H}(x) = \begin{cases} 0 & \text{if } x<0 \\ 1/2 & \text{if } x=0 \\ 1 & \text{if } x>0. \end{cases} \tag{56.54}$$

The velocity is assumed to be zero initially

$$\boldsymbol{u}(x,y,t=0) = 0. \tag{56.55}$$

Correspondingly, the initial relative vorticity vanishes so that the linearized potential vorticity (equation (56.49c)) is

$$Q(x,y) = \frac{f\eta_\circ}{H^2}\,\mathrm{sgn}(x). \tag{56.56}$$

Since $\partial Q/\partial t = 0$ (equation (55.23)), the potential vorticity (56.56) is maintained at each point in space throughout the adjustment process. The velocity and surface height adjustment is thus constrained to keep potential vorticity static. This rather basic point is key to determining evolution of the velocity and surface height, and thus in determining the final (equilibrium) state for these fields.

56.3.3 Adjustment with $f = 0$

In the absence of planetary rotation ($f=0$), relative vorticity is constant at each grid point. With a zero initial velocity, relative vorticity remains zero throughout the adjustment. The adjustment is thus quite simple. Namely, it consists of linear gravity waves, which carry zero relative vorticity (equation (55.72)). These gravity waves propagate away from the initial step, converting the potential energy of the step into kinetic energy of waves that propagate to infinity. As the linear gravity waves are non-dispersive, they carry the initial pulse out to infinity without distortion in the wave form

$$\eta(x,t) = -\frac{\eta_\circ}{2}\left[\,\mathrm{sgn}(x + c_{\text{grav}}\,t) + \mathrm{sgn}(x - c_{\text{grav}}\,t)\right]. \tag{56.57}$$

[5] We discuss the Heaviside step function in Section 7.5.

The meridional velocity remains zero, whereas the zonal velocity equation

$$\partial_t u = -g\,\partial_x \eta, \tag{56.58}$$

leads to

$$u(x,t) = \frac{g\,\eta_o}{2\,c_{grav}}\left[\operatorname{sgn}(x + c_{grav}\,t) - \operatorname{sgn}(x - c_{grav}\,t)\right]. \tag{56.59}$$

After the transient waves have passed, the steady solution is a flat surface height with zero velocity. This steady solution is familiar from the case of a rock dropped into a still pond. After dropping the rock into the pond, the surface gravity waves radiate outward from the rock and are eventually damped upon reaching the shore. In equilibrium, the pond returns to a state of rest with a flat surface height.[6]

56.3.4 Adjustment on the f-plane

On a rotating f-plane, the transient solution consists of the inertia-gravity waves studied in Section 55.8, with these waves transmitting information about the initial surface height perturbation out to infinity. After the transient waves have passed, we might guess that the steady solution is either the trivial solution with flat surface height (as for the $f = 0$ case), or a nontrivial solution that is in geostrophic balance

$$f\hat{\boldsymbol{z}} \times \boldsymbol{u} = -g\,\nabla\eta \qquad \text{and} \qquad \nabla \cdot \boldsymbol{u} = 0 \qquad \text{and} \qquad Q = H^{-2}\,f\,\eta_o \operatorname{sgn}(x). \tag{56.60}$$

Conservation of potential vorticity chooses the geostrophic solution, so that a steady solution of no-motion is not allowed by potential vorticity conservation. This is a profound distinction from the adjustment with $f = 0$.

Computing the steady state

As the steady flow is geostrophic on an f-plane, we make use of the geostrophic streamfunction

$$\psi = g\,\eta/f. \tag{56.61}$$

The steady state is written in terms of the streamfunction according to

$$u = -\partial_y \psi \qquad \text{and} \qquad v = \partial_x \psi \qquad \text{and} \qquad \zeta = \nabla^2 \psi. \tag{56.62}$$

Making use of these expressions for the linearized potential vorticity (56.49c) leads to the elliptic partial differential equation for the streamfunction

$$\left[\nabla^2 - L_d^{-2}\right]\psi = H\,Q(x,y), \tag{56.63}$$

where we introduced the shallow water deformation radius, $L_d = c_{grav}/f$, from equation (55.54).

The initial condition (56.51) has no y-dependence. Furthermore, there is nothing in the adjustment process that breaks meridional symmetry. Hence, the steady state is a function only of x, in which case the streamfunction satisfies the ordinary differential equation

$$\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} - L_d^{-2}\,\psi = \frac{f\eta_o}{H}\operatorname{sgn}(x). \tag{56.64}$$

We solve this equation separately for $x > 0$ and $x < 0$ and match the function and its first derivative at $x = 0$, and furthermore constrain the streamfunction to vanish at $\pm\infty$. The $x > 0$

[6] For most ponds, waves are better studied using deep water equations rather than shallow water equations; see Section 52.3. Even so, the key physical points in this example are maintained.

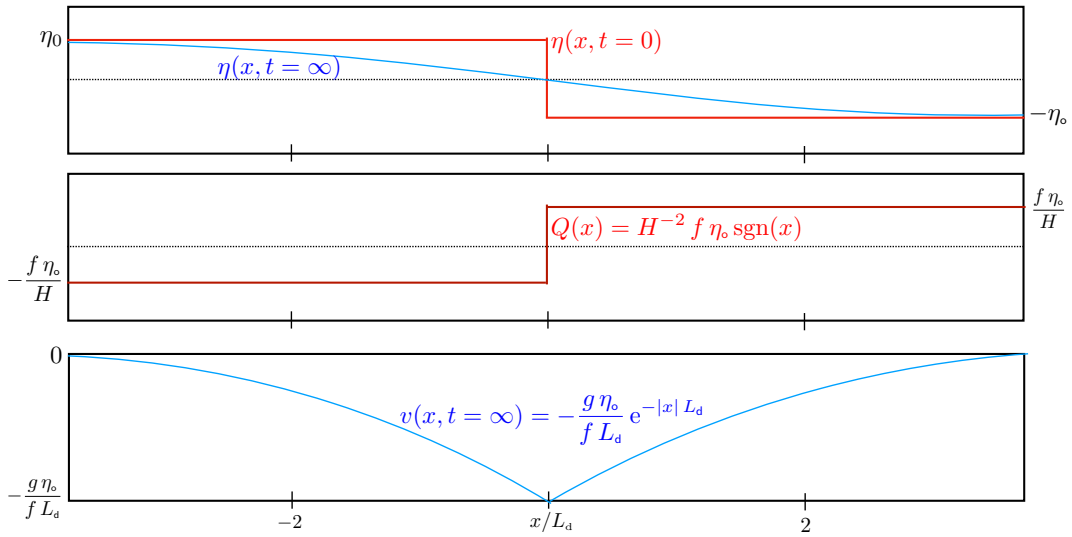

FIGURE 56.3: Depicting solutions to the linear geostrophic adjustment of a rotating shallow water layer on an f-plane. The top panel shows the initial (step-function) surface height (56.51) and the steady state (exponential) surface height (56.70). The second panel shows the static (step-function) potential vorticity (56.60). The third panel shows the steady state (exponential) meridional velocity (56.71) comprised of a jet centered at $x = 0$. The horizontal axis is scaled according to the shallow water deformation radius, $L_\mathrm{d} = f^{-1}\sqrt{g\,H}$. This figure is adapted from figure 3.10 of *Vallis* (2017).

streamfunction satisfies

$$\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} - L_\mathrm{d}^{-2}\,\psi = \frac{f\eta_\circ}{H}. \tag{56.65}$$

The particular solution is

$$\psi_\mathrm{p} = -L_\mathrm{d}^2\,H\,Q = -L_\mathrm{d}^2\,f\,\eta_\circ/H = -g\,\eta_\circ/f, \tag{56.66}$$

and the homogeneous solution is

$$\psi_\mathrm{h} = (g\,\eta_\circ/f)\,\mathrm{e}^{-x/L_\mathrm{d}}, \tag{56.67}$$

so that

$$\psi = -\frac{g\,\eta_\circ}{f}\left[1 - \mathrm{e}^{-x/L_\mathrm{d}}\right]. \tag{56.68}$$

The $x < 0$ solution is found similarly, so that the full solution is

$$\psi = \frac{g\,\eta_\circ}{f}\begin{cases} -\left(1 - \mathrm{e}^{-x/L_\mathrm{d}}\right) & x > 0 \\ \left(1 - \mathrm{e}^{x/L_\mathrm{d}}\right) & x < 0, \end{cases} \tag{56.69}$$

which means that the steady state surface height is

$$\eta = \eta_\circ\begin{cases} -\left(1 - \mathrm{e}^{-x/L_\mathrm{d}}\right) & x > 0 \\ \left(1 - \mathrm{e}^{x/L_\mathrm{d}}\right) & x < 0. \end{cases} \tag{56.70}$$

Note that the streamfunction vanishes at $x = 0$ and has a first derivative of $-\eta_\circ\sqrt{gH}/H$. Since the streamfunction only has a zonal dependence, the steady state velocity is purely meridional

$$u = 0 \qquad \text{and} \qquad v = -\frac{g\,\eta_\circ}{f\,L_\mathrm{d}}\,\mathrm{e}^{-|x|/L_\mathrm{d}}. \tag{56.71}$$

The steady state velocity thus consists of a jet that is perpendicular to the surface height front.

56.3.5 Concerning the deformation radius

As illustrated in Figure 56.3, the steady state profiles for the surface height and velocity both have an exponential decay, with decay length scale given by the deformation radius. The deformation radius is this length scale over which a signal can propagate before being affected or "deformed" by the Coriolis acceleration, thus motivating the name *deformation radius*. More precisely, the deformation radius measures the horizontal length scale over which a wave can propagate within the time $|f|^{-1}$ (the *inertial period* is $2\pi/|f|$), before feeling the effects of the Coriolis acceleration, thus making

$$L_{\text{d}} |f| = \sqrt{g H}. \tag{56.72}$$

In the $f = 0$ limit, the deformation radius is infinity and the steady solution returns to the case considered in Section 56.3.3, whereby the steady state free surface is flat and there is no flow. A key feature of the $f \neq 0$ case is that some of the potential energy contained within the initial perturbed free surface remains part of the steady state geostrophic flow. Conservation of potential vorticity constrains the flow so that all the initial potential energy cannot be converted to kinetic energy. Rather, the adjustment occurs only within a deformation radius distance from the initial perturbation.

We can extend the ideas introduced in this single-layer adjustment to a two-layer system as depicted in Figure 56.4, with the figure caption summarizing the physics. Again, adjustment leads to geostrophic flow when the lateral extent of the flow reaches the deformation scale. In this case, the deformation scale is much smaller than the single-layer fluid given that it is the reduced gravity that determines the velocity scale rather than the gravity.[7] The slower internal wave speeds propagate the internal wave signal a shorter distance before feeling the effects from Coriolis

$$L_{\text{d}} |f| = \sqrt{g' H} \ll \sqrt{g H}. \tag{56.73}$$

56.3.6 Comments and further reading

Our study of shallow water geostrophic adjustement shares some features with that of the gravity wave adjustment to flow over topography as studied in Section 56.2.7. For the topographic case we considered $f = 0$, whose linear gravity waves carry zero relative vorticity, whereas for the geostrophic adjustment we allow for $f \neq 0$, whose linear inertia-gravity waves carry zero potential vorticity. Transients for both cases consist of linear waves carrying information out to "infinity", leaving behind a stationary flow. For the topographic case the stationary flow is set according to the topography and the Froude number, whereas for the geostrophic case the stationary flow is set according to the Coriolis acceleration and initial conditions.

Section 3.9 of *Vallis* (2017) presents a far more thorough discussion of this linear geostrophic adjustment problem, including an elegant variational approach. Chapter 3 of *Pratt and Whitehead* (2008) provide a thorough discussion for both linear and nonlinear geostrophic adjustment.

56.4 Exercises

EXERCISE 56.1: DEFORMATION RADIUS

The deformation radius appears in many contexts within rotating fluid dynamics. Here, we compute this length scale for selective geophysical flow regimes at $30^\circ N$ latitude, where $f = 7.3 \times 10^{-5}$ s^{-1}.

[7] Recall from Section 55.6 that we study gravity waves in two shallow water layers, where we indeed find the reduced gravity determines the baroclinic phase speed.

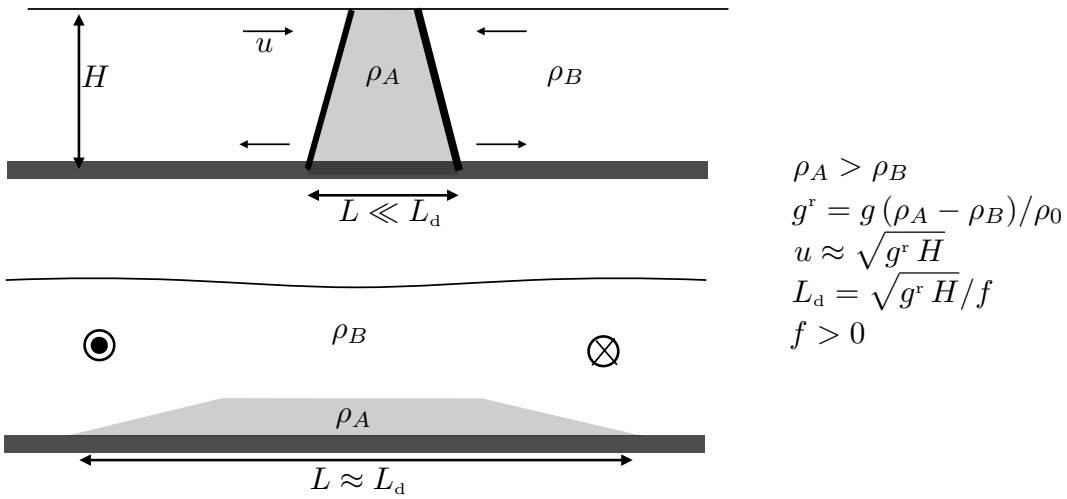

FIGURE 56.4: Two regions of uniform density fluid used to illustrate the adjustment under gravity acceleration and Coriolis acceleration in the absence of mixing. Top panel: two fluid layers each have uniform density with $\rho_A > \rho_B$ and with the heavy fluid sitting between two regions of the lighter fluid, with the fluids separated by a barrier. Lower panel: upon releasing the barrier, gravity causes the heavy fluid to slump under the lighter fluid. This process halts when the lateral scale of the heavier fluid reaches the deformation scale, $L_d = \sqrt{g^r\,H}/f$, where $\sqrt{g^r\,H} \approx N\,H$ is the speed of the internal gravity wave signal appearing in a two-layer fluid. The adjusted state reaches two-layer geostrophic balance as discussed in Section 36.2.2, whereby the difference in geostrophic flow in the two layers is proportional to the slope of the interface between the layers. By extension, if the initial region of heavy fluid had an initial lateral extent on the order of the deformation scale, then there will be minimal change in the lateral extent after the barrier is removed since the Coriolis acceleration will balance the pressure gradients to render a geostrophic flow. See Figure 15.4 of *Cushman-Roisin and Beckers* (2011) for more examples of geostrophic adjustment.

(a) Compute the shallow water deformation radius for an ocean continental shelf of depth 500 m.

(b) Compute the shallow water deformation radius for the deep ocean with depth 5000 m.

(c) The deformation radius defined in this chapter is sometimes called the *external deformation radius* as it makes use of the full depth of the fluid and the gravitational acceleration. In contrast, the deformation radius defined in terms of internal layer thickness and reduced gravity, g^r, leads to the internal deformation radius. The internal deformation radius, $L_d^{\text{int}} = \sqrt{g^r\,h}/f$ is the appropriate rotational length scale for density layers in the interior of the ocean or isentropic layers in the interior of the atmosphere. Compute the deformation radius for a density layer of thickness $h = 200$ m and reduced gravity of $g^r = g/1000$.

EXERCISE 56.2: GEOSTROPHIC ADJUSTMENT (BASED ON EXERCISE 4.6 OF *Vallis* (2019))
Consider the linear geostrophic adjustment problem on an f-plane with a single layer of shallow water fluid over a flat bottom. Rather than assume an initial free surface profile, as we did in Section 56.3, here we assume an initial meridional velocity profile given by

$$v(x, t = 0) = v_0\,\text{sgn}(x) = v_0\,(2\,\mathcal{H}(x) - 1), \tag{56.74}$$

where $v_0 > 0$ is a constant, sgn is the sign-function (equation (56.52)), and $\mathcal{H}$ is the Heaviside step function (equation (56.54)). The free surface is assumed to be initially flat.

(a) Show that the linearized potential vorticity, $H\,Q' = \zeta' - f\,\eta'/H$, is given by

$$H\,Q'(x) = 2\,v_0\,\delta(x), \tag{56.75}$$

where $\delta(x)$ is the Dirac delta with dimensions L^{-1}.

(b) As we did in Section 56.3, solve for the geostrophic streamfunction $\psi = g\,\eta/f$.

(c) Discuss the geostrophically adjusted streamfunction and velocity, and draw a sketch of ψ and v.

Here are some hints.

- We discuss properties of the Dirac delta in Chapter 7. However, to answer the first part of this question it is sufficient to know that the derivative of the Heaviside step function (a dimensionless step function) is the Dirac delta

$$\delta(x) = \frac{\mathrm{d}\mathcal{H}(x)}{\mathrm{d}x}, \tag{56.76}$$

  so that the Dirac delta has dimensions of inverse length.

- For the second part, note that the streamfunction is exponentially decaying on either side of the $x = 0$ according to $\psi = \psi_0\,\mathrm{e}^{-|x|/L_\mathrm{d}}$, which then leads to a jump in the derivative approaching the origin from each side. Carefully use equations (56.63) and (56.76) to determine ψ_0.

Chapter 57

INTERNAL INERTIA-GRAVITY WAVES

In this chapter we continue the study of how gravity affects wave motion in geophysical fluids, here focusing on gravity waves realized in a continuously stratified fluid. As part of anticipating this discussion, recall Section 55.6 where we studied gravity waves in two shallow water layers and decomposed the motion into two modes: the *barotropic mode* and *baroclinic mode*. When moving to a continuously stratified fluid we encounter an infinity of baroclinic modes. These modes are associated with motion of interior stratification surfaces, and have very little projection onto motion of the upper free surface. Consequently, these waves are generally referred to as internal gravity waves.

Although the shallow water system anticipated some features of gravity waves in a continuous system, there are many properties revealed only when moving to continuous stratification. In particular, the dispersion relation for internal gravity waves presents the peculiar feature of having a group velocity that is perpendicular to the phase velocity. In fact, this property was already encountered in Chapter 53 when studying inertial waves in a homogeneous fluid. We here focus most attention on the case of internal gravity waves in a non-rotating reference frame. Extending to the case of an f-plane is relatively straightforward and builds on the inertial wave material from Chapter 53 as well as the shallow water inertia-gravity waves studied in Section 55.8.

READER'S GUIDE TO THIS CHAPTER

We build on the prior wave mechanics chapters and assume familiarity with the equations for a Boussinesq ocean in Chapter 29 and the concept of Archimedean buoyancy from Chapter 30. Chapter 58 continues our study of internal inertia-gravity waves by focusing on a variety of geophysical mechanisms for the forcing of such waves.

Further resources for material in this chapter can be found in *Lighthill* (1978), *Gill* (1982), *Pedlosky* (2003), *Sutherland* (2010), *Cushman-Roisin and Beckers* (2011), *Kundu et al.* (2016), and *Vallis* (2017). The second half of this video offers some pedagogical visualizations of stratified flow phenomena, and this video provides more visualizations from simulations and laboratory tank experiments.

57.1 Loose threads

- energetic balances for reflected waves.
- Is there a general means to determine $\boldsymbol{c}_g \cdot \boldsymbol{k} = 0$ without going through the process of computing the group velocity? Why do some waves have this property but others do not?
- Vertical normal modes in Section 57.7 as per Lecture 9 of *Pedlosky* (2003) or Section 6.10 of *Gill* (1982).

57.2 Boussinesq ocean and its linearization

Throughout this chapter we work with the Boussinesq ocean equations in their inviscid/adiabatic limit, and linearize the governing equations around a rest state in exact hydrostatic balance. In

this section we review the governing equations from Chapter 29 and perform the linearization.

57.2.1 Boussinesq ocean equations

We make use of the governing equations for an adiabatic and inviscid Boussinesq ocean written in the form (see Section 29.1.7)

$$\rho_\circ \left[\partial_t \boldsymbol{v} + (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v} + 2\,\boldsymbol{\Omega}\times\boldsymbol{v}\right] = -\nabla p - \rho\, g\,\hat{\boldsymbol{z}} \quad \text{inviscid velocity equation} \tag{57.1a}$$

$$\nabla\cdot\boldsymbol{v} = 0 \quad \text{non-divergent flow} \tag{57.1b}$$

$$(\partial_t + \boldsymbol{v}\cdot\nabla)\,\rho = 0 \quad \text{adiabatic density equation} \tag{57.1c}$$

$$\rho = -\rho_\circ\,\alpha_\Theta\,\Theta \quad \text{linear equation of state.} \tag{57.1d}$$

The density field contains a nontrivial spatial structure

$$\rho = \rho(\boldsymbol{x}, t), \tag{57.2}$$

with the Boussinesq reference density, $\rho_\circ$, a constant, and we furthermore assume the thermal expansion coefficient, α_Θ, is a constant. Hence, the density and Conservative Temperature, Θ, are linearly proportional, with the adiabatic density equation (57.1c) meaning that Conservative Temperature is materially constant. The velocity field resolved by the Boussinesq ocean is non-divergent so that it does not support acoustic waves.[1] The inhomogeneous density field couples to the gravity field to render a nonzero buoyancy that appears in the velocity equation (57.1a). Buoyancy is the essential ingredient for the internal gravity waves studied in this chapter. Finally, we make use of the Traditional Approximation (Section 27.1.3) and tangent plane approximation (Section 24.5) with the planetary rotation approximated by

$$2\,\boldsymbol{\Omega} \approx f_\circ\,\hat{\boldsymbol{z}}, \tag{57.3}$$

where $f_\circ$ is the planetary vorticity set either to zero or a nonzero constant.

57.2.2 The prescribed reference state

We consider a three-component decomposition of density into a constant Boussinesq reference density, $\rho_\circ > 0$, plus a prescribed static reference density, $\rho_{\mathsf{R}}(z) > 0$, and a perturbation density, $\rho'(\boldsymbol{x}, t)$,

$$\rho(\boldsymbol{x}, t) = \rho_\circ + \rho_{\mathsf{R}}(z) + \rho'(\boldsymbol{x}, t). \tag{57.4}$$

We assume the following inequalities hold

$$\rho_{\mathsf{R}} \ll \rho_\circ \quad \text{and} \quad |\rho'| \ll \rho_{\mathsf{R}}, \tag{57.5}$$

with the first inequality following from the Boussinesq ocean approximation, and the second inequality supporting linearization in Section 57.2.4. The buoyancy is decomposed according to the density decomposition (57.4), so that

$$b = -g\,(\rho - \rho_\circ)/\rho_\circ = -g\,(\rho_{\mathsf{R}} + \rho')/\rho_\circ = b_{\mathsf{R}} + b'. \tag{57.6}$$

Likewise, we decompose pressure so that

$$p = p_\circ(z) + p_{\mathsf{R}}(z) + p'(\boldsymbol{x}, t), \tag{57.7}$$

[1] See Section 51.2 for more on how we interpret the quasi-compressible properties of the Boussinesq ocean.

where

$$\mathrm{d}p_{\circ}(z)/\mathrm{d}z = -\rho_{\circ}\, g \quad \text{and} \quad \mathrm{d}p_{\mathsf{R}}(z)/\mathrm{d}z = -\rho_{\mathsf{R}}(z)\, g, \tag{57.8}$$

so that $p_{\circ}$ and p_{R} are both hydrostatic base state pressures given by

$$p_{\circ}(z) = -\rho_{\circ}\, g\, z \quad \text{and} \quad p_{\mathsf{R}}(z) = g \int_{z}^{0} \rho_{\mathsf{R}}(z')\, \mathrm{d}z'. \tag{57.9}$$

The corresponding pressure and gravity contributions to the velocity equation (57.1a) take the form

$$-\nabla p - \rho\, g\, \hat{\boldsymbol{z}} = -\rho_{\circ}\, \nabla\varphi' - \rho'\, g\, \hat{\boldsymbol{z}} = -\rho_{\circ}\, (\nabla\varphi' - b'\, \hat{\boldsymbol{z}}), \tag{57.10}$$

where we introduced the normalized dynamic pressure (with dimensions of squared velocity)

$$\varphi' = p'/\rho_{\circ}. \tag{57.11}$$

Introducing the reference state into the velocity equation (57.1a) and density equation (57.1c) leads to

$$\partial_t \boldsymbol{v} + (\boldsymbol{v}\cdot\nabla)\, \boldsymbol{v} + f_{\circ}\, \hat{\boldsymbol{z}} \times \boldsymbol{v} = -\nabla\varphi' + b'\, \hat{\boldsymbol{z}} \quad \text{decomposed velocity equation} \tag{57.12a}$$

$$(\partial_t + \boldsymbol{v}\cdot\nabla)\, b' = -w\, N_{\mathsf{R}}^2 \quad \text{decomposed buoyancy equation.} \tag{57.12b}$$

In the buoyancy equation we introduced the reference state's squared buoyancy frequency

$$N_{\mathsf{R}}^2 = -\frac{g}{\rho_{\circ}} \frac{\mathrm{d}\rho_{\mathsf{R}}}{\mathrm{d}z}. \tag{57.13}$$

It is notable that the velocity equation (57.12a) is mathematically identical to the original velocity equation (57.1a). However, the fluctuating buoyancy equation (57.12b) is distinct from the original buoyancy equation (57.1c). Namely, the reference state squared buoyancy frequency couples to the vertical velocity to provide a source, $-w\, N_{\mathsf{R}}^2$, for the material evolution of the perturbation buoyancy.

57.2.3 Buoyancy frequency compared to surface gravity waves

As revealed in this chapter, the buoyancy frequency of the background state, N_{R}, sets the time scale for the internal gravity wave motions. To garner a sense for its scale, we compare this frequency to that found for the deep water surface gravity waves studied in Section 52.5.5. Making use of equation (52.123a) for deep water gravity waves leads to the ratio

$$\frac{N_{\mathsf{R}}^2}{\omega_{\mathrm{dww}}^2} = \frac{N_{\mathsf{R}}^2}{g\, |\boldsymbol{k}|_{\mathrm{dww}}} = \left| \frac{g}{\rho_{\circ}} \frac{\mathrm{d}\rho_{\mathsf{R}}}{\mathrm{d}z} \frac{\Lambda_{\mathrm{dww}}}{2\,\pi\, g} \right| = \left| \frac{\Delta\rho_{\mathsf{R}}}{2\,\pi\,\rho_{\circ}} \right|. \tag{57.14}$$

In the final step we took the deep water wave length, Λ_{dww}, as the vertical scale over which to measure the vertical density difference, $\Delta\rho_{\mathsf{R}}$. Now the deep water wavelength is just a few meters, which means that $|\Delta\rho_{\mathsf{R}}| \lll \rho_{\circ}$. We conclude that the buoyancy frequency is much less than the frequency of deep water surface gravity waves. We can understand this result by noting that the gravitational restoring force acting on deep water surface waves is far stronger than the reduced gravity acting on internal waves, so we expect the deep water waves to oscillate much faster.

Now consider the same calculation for shallow water surface gravity waves by making use of

the dispersion relaation (52.123b) to yield

$$\frac{N_{\mathsf{R}}^2}{\omega_{\text{sww}}^2} = \frac{N_{\mathsf{R}}^2}{|\boldsymbol{k}|_{\text{sww}}^2 \, c_{\text{grav}}^2} = \left| \frac{g}{\rho_{\circ}} \frac{\mathrm{d}\rho_{\mathsf{R}}}{\mathrm{d}z} \frac{\Lambda_{\text{sww}}}{2\,\pi\,|\boldsymbol{k}|_{\text{sww}}\, g\, H} \right| = \left| \frac{\Delta\rho_{\mathsf{R}}}{\rho_{\circ}} \frac{1}{2\,\pi\,|\boldsymbol{k}|_{\text{sww}}\, H} \right|. \tag{57.15}$$

In this case the density difference, $\Delta\rho_{\mathsf{R}}$, is computed over a vertical length scale equal to the wavelength, Λ_{sww}. But since $|\boldsymbol{k}|_{\text{sww}}\, H \ll 1$ for shallow water gravity waves, we take $\Delta\rho_{\mathsf{R}}$ over the full depth of the ocean. Even so, the density ratio remains small, $\Delta\rho_{\mathsf{R}}/\rho_{\circ} \ll 1$. Yet now this ratio is divided by the small number $2\,\pi\,|\boldsymbol{k}|_{\text{sww}}\, H = (2\,\pi)^2\, H/\Lambda_{\text{sww}} \ll 1$. We thus find that the internal gravity wave frequency can be on the order of the shallow water gravity wave frequency. So although the shallow water waves feel the full gravitational acceleration, just like deep water gravity waves, the huge scale for shallow water waves leads to far slower wave motion than the deep water gravity waves. As a result, the frequency for shallow water waves is on the order of that for internal waves.

57.2.4 Linearization around the background state of rest

The second of the density inequalities (57.5) implies the buoyancy inequality

$$|b'| \ll b_{\mathsf{R}}. \tag{57.16}$$

Evidently, fluctuations in the buoyancy field, which can be positive or negative, are far smaller in magnitude than the reference state buoyancy. These small fluctuations in buoyancy lead to correspondingly small fluctuations in dynamic pressure, φ', and small fluctuations in the velocity, $\boldsymbol{v}'$. The linearized velocity equation (57.12a) and buoyancy equation (57.12b) are obtained by dropping nonlinear product of fluctuating fields

$$\partial_t \boldsymbol{u}' + f_{\circ}\, \hat{\boldsymbol{z}} \times \boldsymbol{u}' = -\nabla_{\mathsf{h}} \varphi' \qquad \text{linearized horizontal velocity equation} \tag{57.17a}$$

$$\partial_t w' = -\partial_z \varphi' + b' \qquad \text{linearized vertical-velocity equation} \tag{57.17b}$$

$$\partial_t b' = -w'\, N_{\mathsf{R}}^2 \qquad \text{linearized buoyancy equation} \tag{57.17c}$$

$$\nabla \cdot \boldsymbol{v}' = 0 \qquad \text{continuity for velocity fluctuations.} \tag{57.17d}$$

The final equation expresses the non-divergent nature of the fluctuating velocity field.[2] These three linear equations are the linearized governing equations used in this chapter.

57.2.5 Energetics

We studied the energetics of the nonlinear equation set (57.1a)-(57.1d) in Section 29.6. We here revisit that discussion and then derive energetics for the linearized equations (57.17a)-(57.17d).

Adiabatic inviscid Boussinesq ocean

The kinetic energy per volume and potential energy per volume in a Boussinesq ocean are given by

$$\rho_{\circ}\, \mathcal{K} = \rho_{\circ}\, \boldsymbol{v} \cdot \boldsymbol{v}/2 \quad \text{and} \quad \rho\, \Phi = \rho\, g\, z, \tag{57.18}$$

where we introduced the kinetic energy per mass and potential energy per mass (i.e., the geopotential)

$$\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v}/2 \quad \text{and} \quad \Phi = g\, z. \tag{57.19}$$

[2] The velocity has been decomposed into its background state flow, $\boldsymbol{v}_{\mathsf{R}}$, which is assumed here to be zero, plus a fluctuation around the background flow, $\boldsymbol{v}'$. Since $\nabla \cdot \boldsymbol{v} = 0$ and $\boldsymbol{v}_{\mathsf{R}} = 0$, we see that $\nabla \cdot \boldsymbol{v}' = 0$.

Material evolution of the kinetic energy is derived by making use of the velocity equation (57.1a), in which

$$\rho_o \, \mathrm{D}\mathcal{K}/\mathrm{D}t = -\nabla \cdot (\boldsymbol{v}\, p) - \rho\, g\, w. \tag{57.20}$$

Material evolution of the potential energy per volume for an adiabatic Boussinesq ocean is given by

$$\mathrm{D}(\rho\, \Phi)/\mathrm{D}t = g\, \rho\, w. \tag{57.21}$$

We are thus led to the mechanical energy equation for the adiabatic and inviscid Boussinesq ocean

$$\rho_o \, \mathrm{D}\mathcal{K}/\mathrm{D}t + \rho\, \mathrm{D}\Phi/\mathrm{D}t = -\nabla \cdot (\boldsymbol{v}\, p), \tag{57.22}$$

so that mechanical energy following a fluid element is modified by convergence of the pressure flux. We thus identify $\boldsymbol{v}\, p$ as the flux of mechanical energy in the Boussinesq ocean.

Linearized adiabatic inviscid Boussinesq ocean

In the process of deriving the linearized equation set (57.17a)-(57.17d), we gave no attention to the energetic balances. Hence, it is not *a priori* clear that a sensible energetic balance exists for these linear equations. However, as we now show, there is indeed an energetic balance that manifests a physically relevant exchange of mechanical energy between its kinetic and potential forms. For the kinetic energy per mass, $\mathcal{K}' = \boldsymbol{v}' \cdot \boldsymbol{v}'/2$, use of the velocity equation (57.17a) readily yields

$$\partial_t \mathcal{K}' = -\nabla \cdot (\boldsymbol{v}'\, \varphi') + w'\, b'. \tag{57.23}$$

The potential energy is a bit less straightforward. Namely, multiplying the linear buoyancy equation (57.17c) by b' readily finds

$$\partial_t \mathcal{A}' = -w'\, b' \quad \text{with} \quad \mathcal{A}' = (b'/N_{\mathsf{R}})^2/2. \tag{57.24}$$

Recall the discussion in Section 29.9.4, where $\mathcal{A}$ is identified as a measure of the available potential energy contained in small amplitude fluctuations of buoyancy surfaces.[3] Evidently, the linearized Boussinesq ocean has a mechanical energy budget given by

$$\partial_t(\mathcal{K}' + \mathcal{A}') = -\nabla \cdot (\boldsymbol{v}'\, \varphi'). \tag{57.25}$$

Hence, a time tendency for the sum of the kinetic energy plus the available potential energy is driven by convergences in the dynamic pressure flux, $\boldsymbol{v}'\, \varphi'$.

57.3 Buoyancy oscillations

As a starting point to studying small amplitude flow features emerging from the linearized Boussinesq ocean equations (57.17a)-(57.17d), consider $\boldsymbol{\Omega} = 0$ (flow in a non-rotating reference frame), in which the buoyancy equation and vertical velocity equation are

$$\partial_t b' + w'\, N_{\mathsf{R}}^2 = 0 \quad \text{and} \quad \partial_t w' = -\partial_z \varphi' + b'. \tag{57.26}$$

The time derivative of the velocity equation and use of the buoyancy equation, along with the complement operations, yield

$$(\partial_{tt} + N_{\mathsf{R}}^2)\, w' = -\partial_{tz} \varphi' \quad \text{and} \quad (\partial_{tt} + N_{\mathsf{R}}^2)\, b' = N_{\mathsf{R}}^2\, \partial_z \varphi'. \tag{57.27}$$

[3] In Section 57.5.14 we offer a further interpretation of the available potential energy as it appears for an internal gravity wave.

Each of these equations describes a forced oscillator with angular frequency given by the buoyancy frequency, N_{R}. We determine the forcing by determining the pressure, which satisfies the Poisson equation

$$-\nabla^2\varphi' = -\partial_z b', \tag{57.28}$$

along with boundary conditions specific to the domain. As studied in Sections 29.3 and 30.11, this pressure equation results from taking the divergence of the velocity equation (57.17a) (with $\boldsymbol{\Omega} = 0$) and using the continuity equation, $\nabla \cdot \boldsymbol{v}' = 0$. In the absence of any vertical structure to the buoyancy (i.e., $\partial_z b' = 0$), the pressure satisfies Laplace's equation, $\nabla^2\varphi' = 0$, which renders a zero pressure fluctuation in the absence of boundary effects.

57.3.1 Unforced buoyancy oscillations

Ignoring the pressure forcing in the forced oscillator equations (57.27) leads to free oscillations for the buoyancy and vertical velocity

$$(\partial_{tt} + N_{\mathsf{R}}^2)w'_{\text{free}} = 0 \quad \text{and} \quad (\partial_{tt} + N_{\mathsf{R}}^2)b'_{\text{free}} = 0. \tag{57.29}$$

Evidently, both the vertical velocity and the buoyancy exhibit simple harmonic oscillations with angular frequency, N_{R}. Such free oscillations occur when the pressure field has zero vertical gradient, $\partial_z\varphi' = 0$, in which case there is no resistance to free oscillations in the vertical.

By ignoring the pressure fluctuations, we are in effect ignoring the impact of the buoyancy fluctuation on pressure. This approach is not dynamically self-consistent. However, it is a common approach, sometimes referred to as the *parcel method*, whereby we consider the motion of a test fluid element that is assumed to have no impact on the surrounding fluid.[4] We considered the pros and cons of this approach when studying Archimedean buoyancy in Section 30.4 and effective buoyancy in Section 30.11.

As seen in Section 57.5.11, fluid particles exhibit free oscillations when they move in directions that parallel the surfaces of constant phase for internal gravity waves *if* the phase surfaces are not horizontal. On constant phase surfaces the pressure is spatially constant so that the only force acting on the fluid particle arises from gravity in a vertically stratified fluid; i.e., buoyancy. We return to this conceptual picture in Section 57.5.11 as it is fundamental to the forces acting within an internal gravity wave.

57.3.2 The lack of oscillations with horizontal homogeneity

When discussing buoyancy oscillations one sometimes finds it convenient to consider a horizontally homogenous fluid and conceive of the oscillations moving horizontal stratification surfaces up and down. However, there are caveats to this conceptual picture that offer further hints at the physics of gravity waves.

Horizontal homogeneity means that the horizontal pressure gradient vanishes, and thus the horizontal velocity vanishes (remember we are assuming a non-rotating reference frame so that $\boldsymbol{\Omega} = 0$). To maintain continuity for the Boussinesq ocean requires $\partial_z w' = 0$, which means, with zero horizontal motion, that $w' = 0$ throughout the domain. It follows that for a Boussinesq ocean there can be no buoyancy fluctuation with $\boldsymbol{v}' = 0$. Although this conclusion might be clear enough, we step through the details to further support an undestanding of the linear equations.

A vanishing vertical velocity in the forced oscillator equation (57.27) means that the vertical pressure gradient is time independent, $\partial_t(\partial_z\varphi') = 0$. Furthermore, horizontal homogeneity for the pressure equation (57.28) means that

$$\partial_z(\partial_z\varphi' - b') = 0, \tag{57.30}$$

[4] See Sections 17.2.5 and 30.4 for more on test fluid elements.

so that $\partial_z \varphi' - b' = B(t)$, where B is an arbitrary function of time. Taking a time derivative, and using $\partial_t(\partial_z \varphi') = 0$, leads to $\partial_t b' = -\partial_t B$, which means that the buoyancy fluctuation is vertically independent. A vertically independent buoyancy in the forced buoyancy oscillator equation (57.27) means that $N_{\mathsf{R}}^2 \, \partial_z \varphi'$ is also vertically independent, which can be satisfied if $\partial_z \varphi' = 0$. But then $w' = 0$ and $\partial_z \varphi' = 0$ in the vertical velocity equation (57.29) then means that $b' = 0$. We are thus led to conclude that the horizontally homogeneous linear Boussinesq system is dynamically consistent only with the trivial solution: $\boldsymbol{v}' = 0$ and $b' = 0$. That is, horizontal homogeneity means exact hydrostatic balance in which, for a Boussinesq fluid, there is zero motion and zero buoyancy oscillations.[5]

As we see in the following sections, the study of internal gravity waves leads to fluctuations that have both horizontal and vertical spatial variations, thus allowing for nontrivial wave motions. Now a surface of constant phase for a plane wave has homogeneous flow properties, in which case fluid particles exhibit free buoyant oscillations along these surfaces.[6] Yet as seen in the following, such buoyancy oscillations exist only if the phase surfaces are sloped relative to the horizontal plane, thus allowing the background buoyancy to produce buoyancy oscillations along the phase surfaces. No internal gravity waves occur if the phase surface is strictly horizontal, with this result consistent with the above arguments. We further detail this physical picture in Section 57.5.11.

57.4 The linear Boussinesq ocean with $f = 0$

We here study properties of the linearized Boussinesq equations (57.17a)-(57.17d) in a non-rotating reference frame

$$\partial_t \boldsymbol{v}' = -\nabla \varphi' + b' \, \hat{\boldsymbol{z}} \quad \text{linearized } \boldsymbol{\Omega} = 0 \text{ velocity equation} \tag{57.31a}$$

$$\partial_t b' = -w' \, N_{\mathsf{R}}^2 \quad \text{linearized buoyancy equation} \tag{57.31b}$$

$$\nabla \cdot \boldsymbol{v}' = 0 \quad \text{continuity for velocity fluctuations.} \tag{57.31c}$$

57.4.1 Relative vorticity

Taking the curl of the velocity equation (57.31a) leads to the evolution equation for the relative vorticity[7]

$$\partial_t (\nabla \times \boldsymbol{v}') = \nabla \times b' \, \hat{\boldsymbol{z}} \implies \partial_t \boldsymbol{\omega}' = -\hat{\boldsymbol{z}} \times \nabla b'. \tag{57.32}$$

The right hand side is the baroclinicity vector (40.152) for a Boussinesq fluid. Hence, in the linearized Boussinesq equations for a fluid in a non-rotating reference frame, relative vorticity has a local time tendency driven by baroclinicity. In the absence of a buoyancy gradient, the vorticity vector in the linear theory is static and remains zero if initialized to zero.

As noted in Section 40.7.2, baroclinicity in a Boussinesq fluid only affects vorticity in the

[5] A non-Boussinesq fluid can exhibit vertical motion even if the fluid has its density modified in a manner that does not introduce horizontal density gradients. For example, a horizontally homogeneous heating in an ocean with constant salinity will reduce the density and expand the water column, without introducing any horizontal inhomogeneities. This expansion results from the divergent nature of the flow field in a non-Boussinesq fluid. However, this expansion is not represented by a Boussinesq ocean. Namely, the Boussinesq ocean has a prognostic flow field that is non-divergent, so that a uniform heating is not directly felt by the flow. In Section 72.7.6 we discuss implications of this limitation of the Boussinesq ocean for the study of global mean sea level.

[6] This conclusion follows since internal gravity waves in a Boussinesq ocean are transverse waves, so that fluid particles move along constant phase surfaces.

[7] Be careful to distinguish the relative vorticity vector, $\boldsymbol{\omega}' = \nabla \times \boldsymbol{v}'$, from the angular frequency, ω, of a plane wave, and from the vertical component of the velocity vector, $\boldsymbol{v} = \hat{\boldsymbol{x}} \, u + \hat{\boldsymbol{y}} \, v + \hat{\boldsymbol{z}} \, w$.

horizontal directions, here seen for the linearized vorticity equation (57.32) since

$$\hat{\boldsymbol{z}} \cdot (\hat{\boldsymbol{z}} \times \nabla b') = 0. \tag{57.33}$$

One interpretation of internal gravity waves is that they arise from oscillations of the baroclinicity vector that leads to an oscillation of the horizontal components of the relative vorticity.[8] Since the vertical component to the vorticity is unaffected by baroclinicity, in the linear theory the vertical vorticity is locally static

$$\partial_t \zeta' = 0 \quad \text{with} \quad \zeta' = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{v}'). \tag{57.34}$$

So if the flow starts with a zero vertical vorticity, then the linearized Boussinesq ocean maintains $\zeta' = 0$. In Section 55.5.1 we also found a static vertical component of relative vorticity holds for the shallow water gravity waves in a non-rotating reference frame (see equation (55.72)).

57.4.2 Wave equation for the vertical velocity

In Section 57.3 we derived the forced harmonic oscillator equation (57.27) for the vertical velocity

$$(\partial_{tt} + N_{\mathsf{R}}^2) w' = -\partial_{tz} \varphi'. \tag{57.35}$$

We find it useful to derive a wave equation solely in terms of w', which is then used to derive the dispersion relation for internal gravity waves. To eliminate pressure, start by taking the horizontal divergence of the horizontal components to the velocity equation (57.31a)

$$\partial_t (\nabla_{\mathsf{h}} \cdot \boldsymbol{u}') = -\nabla_{\mathsf{h}}^2 \varphi', \tag{57.36}$$

where we introduced the horizontal gradient operator and horizontal Laplacian operator

$$\nabla_{\mathsf{h}} = \hat{\boldsymbol{x}}\, \partial_x + \hat{\boldsymbol{y}}\, \partial_y \quad \text{and} \quad \nabla_{\mathsf{h}}^2 = \nabla_{\mathsf{h}} \cdot \nabla_{\mathsf{h}} = \partial_{xx} + \partial_{yy}. \tag{57.37}$$

Equation (57.36) says that time evolution of the horizonal velocity divergence is driven by the negative horizontal Laplacian acting on the dynamic pressure. Since the full velocity is non-divergent, $\nabla \cdot \boldsymbol{v}' = \nabla_{\mathsf{h}} \cdot \boldsymbol{u}' + \partial_z w' = 0$, equation (57.36) becomes an equation for the vertical divergence of the vertical velocity

$$\partial_t (\partial_z w') = \nabla_{\mathsf{h}}^2 \varphi'. \tag{57.38}$$

Taking the horizontal Laplacian of the forced oscillator equation (57.35) (recall $N_{\mathsf{R}} = N_{\mathsf{R}}(z)$) yields

$$(\partial_{tt} + N_{\mathsf{R}}^2) \nabla_{\mathsf{h}}^2 w' = -\partial_{tz} \nabla_{\mathsf{h}}^2 \varphi', \tag{57.39}$$

and then using equation (57.38) leads to the wave equation for the vertical velocity

$$(\partial_{tt} \nabla^2 + N_{\mathsf{R}}^2 \nabla_{\mathsf{h}}^2)\, w' = 0. \tag{57.40}$$

There is anisotropy in this equation due to the gravity force that distinguishes the vertical direction from the horizontal. The anisotropy manifests by the fully three dimensional Laplacian, ∇^2, in the first term in equation (57.40), whereas just the horizontal Laplacian, ∇_{h}^2, appears in the second term. We furthermore observe that the wave equation (57.40) shares features with the wave equation (53.27) satisfied by the inertial waves in a homogeneous fluid in a constantly rotating reference frame. Gravity, coupled to nonzero density gradients, breaks symmetry in the Boussinesq ocean by introducing the buoyancy acceleration that then supports internal gravity waves. Analogously, a rotating reference frame breaks symmetry of the homogeneous fluid by

[8] For example, see the 16 minute mark of this video from Prof. Long.

introducing the Coriolis acceleration that then supports inertial waves.

57.4.3 Linearized boundary conditions

For much of this chapter, we study freely traveling internal inertia-gravity waves in the absence of boundaries. However, we do have occasions to study waves within a bounded or semi-bounded domain, in which case we need to apply boundary conditions. Hence, we here formulate the linearized boundary conditions for these cases. To be specific, we orient the domain with $z = 0$ the vertical position of a resting upper free surface boundary, such as for a resting ocean domain. However, when studying waves generated by bottom topography in Section 58.2, we place $z = 0$ at the position of a flat bottom domain.

Kinematic boundary conditions

Since the reference flow is assumed to vanish, the kinematic no-normal flow boundary condition holds for the fluctuating flow

$$\boldsymbol{v}' \cdot \hat{\boldsymbol{n}} = 0 \quad \text{at solid boundaries.} \tag{57.41}$$

At a moving material boundary (Section 19.6.2), such as the ocean free surface at $z = \eta(x, y, t)$, the kinematic boundary condition (19.66)

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\eta = w' \quad \text{at } z = \eta \tag{57.42}$$

is linearized to

$$\partial_t \eta = w' \quad \text{at } z = \eta. \tag{57.43}$$

In fact, we must go one step further to fully linearize this boundary condition. The reason is that $w(\eta)$ is nonlinear, as seen by a Taylor expansion about the resting $z = 0$ free surface position

$$w'(z = \eta) \approx w'(z = 0) + \eta\, \partial_z w'. \tag{57.44}$$

The term, $\eta\, \partial_z w'$, and all higher order terms, are nonlinear and so are dropped for the linear theory. We are thus led to the linearized surface kinematic boundary condition

$$\partial_t \eta = w' \quad \text{at } z = 0. \tag{57.45}$$

We made use of this same boundary condition linearization in Section 52.3.4 when studying linear surface gravity waves and surface capillary waves, in which we also evaluate boundary terms at $z = 0$ rather than $z = \eta$.

Dynamic boundary condition for pressure

Following our treatment of stresses acting at an interface in Section 25.10, we make use of Newton's third law to set the pressure boundary condition at the free surface. Namely, pressure, in the absence of surface tension (which we ignore here), is continuous across the free surface. We find it useful to determine a boundary condition for the pressure written as the decomposition (57.7)

$$p(\boldsymbol{x}, t) = p_{\circ}(z) + p_{\mathsf{R}}(z) + p'(\boldsymbol{x}, t) = -\rho_{\circ}\, g\, z + g \int_z^0 \rho_{\mathsf{R}}(z')\, \mathrm{d}z' + p'(\boldsymbol{x}, t). \tag{57.46}$$

Assuming the atmospheric pressure applied on the free surface is a constant, which we take to be zero without loss of generality, leads to

$$0 = -\rho_o \, g \, \eta + g \int_\eta^0 \rho_R(z') \, dz' + p'(x, y, z = \eta, t). \tag{57.47}$$

Since the free surface height is small for linear waves, we Taylor expand the reference density around $z' = 0$ so that the integral becomes

$$\int_\eta^0 \rho_R(z') \, dz' \approx \int_\eta^0 \left[\rho_R(0) + (d\rho_R/dz)_{z=0} \, z'\right] dz' = -\eta \, \rho_R(0) - (\eta^2/2) \, (d\rho_R/dz)_{z=0}. \tag{57.48}$$

Dropping the term η^2 since it is nonlinear then leads to the boundary condition for the dynamic pressure evaluated at the free surface

$$\varphi'(x, y, z = \eta, t) = g \, \eta \, [\rho_o + \rho_R]/\rho_o \quad \text{at } z = \eta. \tag{57.49}$$

We fully linearize by evaluating the pressure at $z = 0$ and note that $\rho_R \ll \rho_o$ so that the boundary condition becomes

$$\varphi' = g \, \eta \quad \text{at } z = 0. \tag{57.50}$$

Evidently, the dynamic pressure at the ocean surface is determined by the free surface height. This boundary condition is identical to that used for the surface gravity waves as derived in Sections 52.3.2 and 52.3.3. Here, we needed to work a bit harder than for surface gravity waves. The reason is that here the fluid is stratified whereas we studied surface gravity waves at the surface of a homogeneous ocean that resulted in irrotational motion, and thus a rather simple expression of Bernoulli's theorem (Section 52.3).

Vertical velocity boundary condition

We further combine the pressure boundary condition (57.50) with the linearized surface kinematic boundary condition (57.45) to eliminate the free surface in favor of the vertical velocity

$$\partial_t \varphi' = g \, w' \quad \text{at } z = 0. \tag{57.51}$$

When studying vertical normal modes in an ocean domain in Section 57.7, we find it more convenient to have a boundary condition just for the vertical velocity. To eliminate the pressure we take the divergence of the horizontal velocity equation, $\partial_t \boldsymbol{u}' = -\nabla_h \varphi'$, and use the non-divergence condition on the velocity to yield

$$\partial_{tz} w' = \nabla_h^2 \varphi'. \tag{57.52}$$

Taking another time derivative and evaluating the expression at $z = 0$ yields

$$\partial_{ttz} w' = \nabla_h^2 \partial_t \varphi' \implies \partial_{ttz} w' = g \, \nabla_h^2 w' \quad \text{at } z = 0, \tag{57.53}$$

where we used the boundary condition (57.51) to eliminate pressure in favor of the vertical velocity.

57.5 Free internal gravity waves with constant stratification

Thus far we have assumed that the reference state buoyancy frequency is a function of the vertical direction. We now specialize to the case of a constant frequency, N_R, in which case we study free plane internal gravity waves. We return in Section 58.4 to the more realistic case of vertically varying buoyancy frequency, $N_R(z)$, which requires the WKBJ approximation.

57.5.1 Plane wave ansatz

To examine the physics of internal gravity waves in a fluid with constant buoyancy frequency, we introduce a traveling plane wave ansatz for the velocity, dynamic pressure, and buoyancy

$$\boldsymbol{v}' = \widetilde{\boldsymbol{v}}\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)} \quad \text{and} \quad \varphi' = \widetilde{\varphi}\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}, \quad \text{and} \quad b' = \widetilde{b}\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}, \tag{57.54}$$

where the amplitudes, $\widetilde{\boldsymbol{v}}$, $\widetilde{\varphi}$, and $\widetilde{b}$, are generally complex numbers, and where we write the three dimensional and horizontal wavevectors as

$$\boldsymbol{k} = k_x\, \hat{\boldsymbol{x}} + k_y\, \hat{\boldsymbol{y}} + k_z\, \hat{\boldsymbol{z}} \quad \text{and} \quad \boldsymbol{k}_{\mathrm{h}} = k_x\, \hat{\boldsymbol{x}} + k_y\, \hat{\boldsymbol{y}}. \tag{57.55}$$

Substitution of the ansatz (57.54) into the linearized Boussinesq equations (57.31a)-(57.31c) allows us to determine relations between the velocity, pressure, and buoyancy for a traveling plane wave. These relations are referred to as *polarization* relations. Furthermore, as part of developing polarization relations we derive the dispersion relation (Section 57.5.7) that connects the wavevector, $\boldsymbol{k}$, to the wave angular frequency, ω.

57.5.2 Transverse nature of internal gravity waves

The non-divergence condition holding for the Boussinesq ocean flow, $\nabla \cdot \boldsymbol{v}' = 0$, means that internal gravity waves are transverse, so that the velocity amplitude satisfies

$$\boldsymbol{k} \cdot \widetilde{\boldsymbol{v}} = \boldsymbol{k}_{\mathrm{h}} \cdot \widetilde{\boldsymbol{u}} + k_z\, \widetilde{w} = 0. \tag{57.56}$$

Consequently, fluid particles within a plane internal gravity wave move within the planes defined by constant phase, and these planes are perpendicular to the wavevector. Recall from Chapter 53 that plane inertial waves are also transverse.

57.5.3 Relative vorticity

The relative vorticity vector satisfies equation (57.32), which for a plane wave takes on the form

$$\omega\, \boldsymbol{k} \times \widetilde{\boldsymbol{v}} = -\mathrm{i}\, \widetilde{b}\, (\hat{\boldsymbol{z}} \times \boldsymbol{k}) \Longrightarrow \boldsymbol{k} \times (\omega\, \widetilde{\boldsymbol{v}} - \mathrm{i}\, \hat{\boldsymbol{z}}\, \widetilde{b}) = 0. \tag{57.57}$$

Evidently, the vector, $\omega\, \widetilde{\boldsymbol{v}} - \mathrm{i}\, \hat{\boldsymbol{z}}\, \widetilde{b}$, is parallel to the wavevector. Taking the dot product of the $\boldsymbol{k}$-space relative vorticity equation (57.57) with $\hat{\boldsymbol{z}}$ leads to

$$\hat{\boldsymbol{z}} \cdot (\boldsymbol{k} \times \widetilde{\boldsymbol{v}}) = 0, \tag{57.58}$$

which is the $\boldsymbol{k}$-space expression for a zero vertical component to the relative vorticity, $\zeta' = 0$. This constraint means that the plane waves maintain $\zeta' = 0$ since the horizontal velocity amplitudes are related by

$$k_x\, \widetilde{v} = k_y\, \widetilde{u}. \tag{57.59}$$

57.5.4 Amplitude of pressure fluctuations

Substitution of the plane wave ansatz into the pressure equation (57.28) renders

$$\widetilde{\varphi}/\widetilde{b} = -\mathrm{i}\, k_z/|\boldsymbol{k}|^2. \tag{57.60}$$

Hence, the pressure and buoyancy in the plane wave are $\pi/2$ radians out of phase. Observe that the pressure amplitude vanishes for a horizontal wavevector, in which $k_z = 0$. We expect this

result for a free wave since vertical structure in the fluctuating buoyancy (i.e., $k_z \neq 0$) provides the source for pressure fluctuations as per the pressure Poisson equation (57.28).

57.5.5 Vertical velocity component

For the vertical velocity component, make use of the forced oscillator equation (57.35) to render a relation between the vertical velocity amplitude and amplitude of the dynamic pressure

$$\widetilde{w}/\widetilde{\varphi} = -\frac{k_z\,\omega}{N_{\mathsf{R}}^2 - \omega^2}. \tag{57.61}$$

We can also relate the vertical velocity amplitude to the buoyancy amplitude through use of the pressure equation (57.60)

$$\widetilde{w}/\widetilde{b} = \frac{\mathrm{i}\,k_z^2\,\omega}{|\boldsymbol{k}|^2\,(N_{\mathsf{R}}^2 - \omega^2)}. \tag{57.62}$$

Evidently, the vertical velocity is either in phase or π radians out of phase with the pressure (depending on the sign of k_z), whereas the vertical velocity is $\pi/2$ out of phase with buoyancy.

57.5.6 Horizontal velocity

The horizontal portion of the velocity equation (57.31a) leads to the relation satisfied by the plane wave

$$\omega\,\boldsymbol{k}_{\mathsf{h}} \cdot \widetilde{\boldsymbol{u}} = \widetilde{\varphi}\,|\boldsymbol{k}_{\mathsf{h}}|^2 = -\mathrm{i}\,\widetilde{b}\,k_z\,|\boldsymbol{k}_{\mathsf{h}}|^2/|\boldsymbol{k}|^2, \tag{57.63}$$

where we used the pressure equation (57.60) for the second equality. Equivalently, we can use the transverse nature of the wave as per equation (57.56) to write

$$\omega\,\boldsymbol{k}_{\mathsf{h}} \cdot \widetilde{\boldsymbol{u}} = -\omega\,k_z\,\widetilde{w} = -\frac{\mathrm{i}\,k_z^3\,\omega^2\,\widetilde{b}}{|\boldsymbol{k}|^2\,(N_{\mathsf{R}}^2 - \omega^2)}, \tag{57.64}$$

where we used equation (57.62) for the vertical velocity.

57.5.7 Dispersion relation

Equating equations (57.63) and (57.64) yields the dispersion relation for internal gravity waves

$$\omega^2 = |\boldsymbol{k}_{\mathsf{h}}|^2\,N_{\mathsf{R}}^2/|\boldsymbol{k}|^2 = N_{\mathsf{R}}^2\cos^2\gamma \Longrightarrow 0 \leq \omega \leq N_{\mathsf{R}}. \tag{57.65}$$

In the second equality we introduced the angle between the wavevector and the horizontal plane

$$\cos\gamma = |\boldsymbol{k}_{\mathsf{h}}|/|\boldsymbol{k}|, \tag{57.66}$$

with the geometry illustrated in Figure 57.1. An alternative means to write the dispersion relation (57.65) is given by

$$\frac{N_{\mathsf{R}}^2 - \omega^2}{\omega^2} = \frac{k_z^2}{|\boldsymbol{k}_{\mathsf{h}}|^2} = \tan^2\gamma. \tag{57.67}$$

This expression makes it clear that internal gravity waves with maximum frequency, $\omega = N_{\mathsf{R}}$, correspond to a horizontal phase velocity, $k_z = 0$ and $\gamma = 0$. Conversely, the angular frequency goes to zero when $\gamma = \pi/2$ whereby the waves have a purely vertical phase velocity, $\boldsymbol{k}_{\mathsf{h}} = 0$.

The dispersion relation (57.65) can be directly derived from the wave equation (57.40) satisfied by the vertical velocity

$$(\partial_{tt}\nabla^2 + N_{\mathsf{R}}^2\,\nabla_{\mathsf{h}}^2)\,w' = 0 \Longrightarrow \omega^2\,|\boldsymbol{k}|^2 - N_{\mathsf{R}}^2\,|\boldsymbol{k}_{\mathsf{h}}|^2 = 0. \tag{57.68}$$

Furthermore, note that if we only extract the horizontal and time harmonic portion of w', so that

$$w' = W(z)\, e^{i\,(\boldsymbol{k}_h \cdot \boldsymbol{x} - \omega\, t)}, \tag{57.69}$$

then the vertical structure function, $W(z)$, satisfies the ordinary differential equation

$$\left[\frac{d^2}{dz^2} + \frac{|\boldsymbol{k}_h|^2\,(N_R^2 - \omega^2)}{\omega^2}\right] W = 0 \Longrightarrow \left[\frac{d^2}{dz^2} + k_z^2\right] W = 0. \tag{57.70}$$

This equation is satisfied if $W = e^{i\,k_z\,z}$, which is what we use for the constant N_R case now being studied. However, in Section 58.4 we find that equation (57.70) is generalized for the case with the background buoyancy frequency a function of the vertical, $N_R = N_R(z)$, in which case $W \neq e^{i\,k_z\,z}$.

57.5.8 Concerning the upper limit on the frequency

The internal gravity wave dispersion relation (57.65) says that no internal gravity waves exist with angular frequency greater than the buoyancy frequency of the background reference state, $\omega \leq N_R$. What happens if a stratified fluid is agitated at a frequency $\omega_{source} > N_R$? In this case, fluid particles do not have time to exhibit buoyancy oscillations. Instead, the fluid particles follow whatever displacements are forced on them by the external forcing, and with fluid particles in phase with the forcing. No propagating internal gravity waves are formed, and any energy imparted to the fluid stays local to the agitation. Indeed, with enough agitation the fluid becomes a forced turbulent soup.[9] For a mechanical analog, consider a forced linear pendulum where the forcing frequency is greater than the pendulum's natural frequency. In this case, the forcing fails to generate a natural oscillation, but instead it causes an incoherent and non-periodic back and forth motion of the pendulum.

57.5.9 Unpacking the dispersion relation

The angular frequency for an internal gravity wave only depends on the buoyancy frequency and the cosine of the angle the wavevector makes with the horizontal plane, whereas it is independent of the wavenumber, $|\boldsymbol{k}|$, and thus of the wavelength, $2\pi/|\boldsymbol{k}|$. Furthermore, the angular frequency possesses rotational (azimuthal) symmetry around the vertical direction. As such, the angular frequency is the same along the surface of a cone for wavevectors extending out from the origin along the $\hat{\boldsymbol{z}}$ axis in either direction. Figure 57.1 provides an illustration for the two cones associated with a particular γ. The upper cone has $k_z > 0$ and so waves on this code have an upward phase velocity, whereas waves on the lower cone, with $k_z < 0$, have a downward phase velocity.

57.5.10 Group velocity

The dispersion relation (57.65) leads to the group velocity, $\boldsymbol{c}_g = \nabla_{\boldsymbol{k}} \varpi(\boldsymbol{k})$, which for internal gravity waves is given by

$$\boldsymbol{c}_g = \frac{N_R\, k_z}{|\boldsymbol{k}|^3\, |\boldsymbol{k}_h|}\,(k_z\, \boldsymbol{k}_h - |\boldsymbol{k}_h|^2\, \hat{\boldsymbol{z}}). \tag{57.71}$$

In this section we identify a number of properties satisfied by the group velocity and summarize these properties in Figure 57.2.

[9] See Section 13.2 of *Cushman-Roisin and Beckers* (2011) for further discussion on this point.

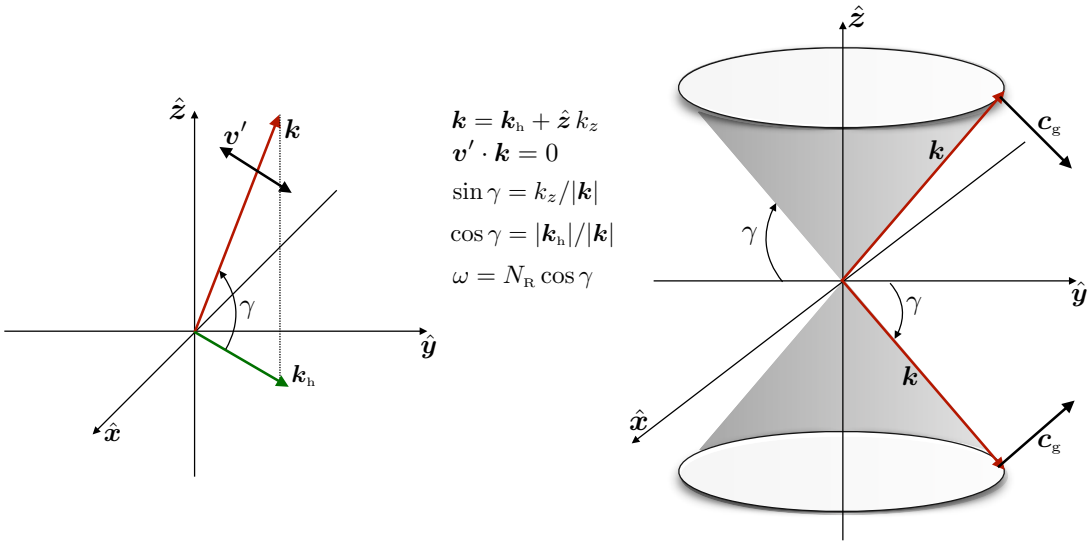

FIGURE 57.1: Left panel: A sample wavevector, $\boldsymbol{k} = \boldsymbol{k}_\mathrm{h} + \hat{\boldsymbol{z}}\, k_z$, for a plane internal gravity wave. The wave is transverse so that the velocity of fluid particles is orthogonal to the wavevector, $\boldsymbol{k} \cdot \boldsymbol{v}' = 0$. The dispersion relation, $\omega = N_\mathrm{R} \cos\gamma$, is independent of the wavenumber, $|\boldsymbol{k}|$, but instead only depends on the cosine of the angle made with the horizontal plane, $\cos\gamma = |\boldsymbol{k}_\mathrm{h}|/|\boldsymbol{k}|$. Right panel: another depiction of the dispersion relation. The angular frequency is the same for all wavevectors on the surface of an ω-cone extending from the origin along the $\hat{\boldsymbol{z}}$ axis and with arbitrary magnitude. Correspondingly, with the phase velocity given by $\boldsymbol{c}_\mathrm{p} = \hat{\boldsymbol{k}}\,(\omega/|\boldsymbol{k}|)$, higher wavenumber waves along a particular ω-cone have slower phase speeds than lower wavenumber waves. Cones with $k_z > 0$ correspond to internal gravity waves with an upward phase velocity, and those with $k_z < 0$ are downward. The group velocity, $\boldsymbol{c}_\mathrm{g} = \nabla_{\boldsymbol{k}} \varpi(\boldsymbol{k})$, points in the $\boldsymbol{k}$-space direction of steepest ascent for the angular frequency, and so it is orthogonal to surfaces of constant ω. For internal gravity waves, the group velocity is orthogonal to the phase velocity ($\boldsymbol{c}_\mathrm{g} \cdot \hat{\boldsymbol{k}} = 0$), and the group velocity points towards the horizontal plane (i.e., smaller $|\gamma|$) since that is the direction of increasing angular frequency. Hence, waves with an upward phase velocity have a downward group velocity, and downward phase velocity waves have an upward group velocity. Evidently, internal wave energy is directed away from the inside of the ω-cone and thus toward the horizontal plane.

Group velocity is orthogonal to the phase velocity

The internal wave group velocity (57.71) is orthogonal to the phase velocity

$$\boldsymbol{c}_\mathrm{g} \cdot \boldsymbol{c}_\mathrm{p} = 0, \tag{57.72}$$

where the phase velocity is

$$\boldsymbol{c}_\mathrm{p} = (\omega/|\boldsymbol{k}|)\, \hat{\boldsymbol{k}}. \tag{57.73}$$

Hence, the group velocity is aligned parallel to constant phase surfaces, as with motion of fluid particles within an internal gravity wave. Recall that these properties also hold for inertial waves discussed in Section 53.3.3.

We geometrically understand the orientation of the phase and group velocities as follows. The phase velocity is aligned with the wavevector, $\boldsymbol{k}$. All wavevectors emanating from the origin that make an angle, γ, have the same angular frequency and so form points along a particular ω-cone (Figure 57.1). Consequently, surfaces of constant angular frequency are parallel to all these wavevectors. Now the group velocity, $\boldsymbol{c}_\mathrm{g} = \nabla_{\boldsymbol{k}} \varpi(\boldsymbol{k})$, points in the $\boldsymbol{k}$-space direction of steepest ascent for the angular frequency, so that the group velocity is normal to surfaces of constant angular frequency. Hence, the group velocity points in a direction normal to the ω-cone, and as such it is orthogonal to the phase velocity, $\boldsymbol{c}_\mathrm{p} \cdot \boldsymbol{c}_\mathrm{g} = 0$.

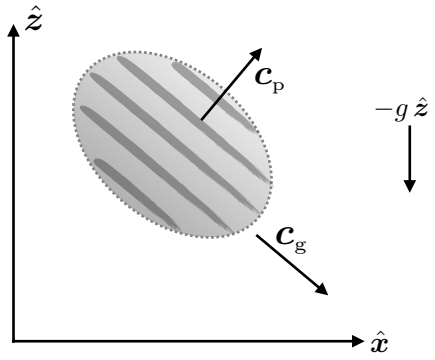

FIGURE 57.2: An example elliptical packet of internal gravity waves, with the packet moving down to the right according to the group velocity, $\boldsymbol{c}_{\mathrm{g}}$, whereas phase lines move upward to the right. The packet moves parallel to the phase lines, with the phase velocity, $\boldsymbol{c}_{\mathrm{p}}$, directed up and to the right.

The phase velocity and group velocity have opposing vertical components

The vertical component to the group velocity has the opposite sign of the vertical component to the phase velocity, which is seen by

$$(\boldsymbol{c}_{\mathrm{p}} \cdot \hat{\boldsymbol{z}})\,(\boldsymbol{c}_{\mathrm{g}} \cdot \hat{\boldsymbol{z}}) = -\frac{\omega\, k_z}{|\boldsymbol{k}|^2}\,\frac{N_{\mathsf{R}}\, k_z\, |\boldsymbol{k}_{\mathrm{h}}|}{|\boldsymbol{k}|^3} = -\frac{\omega^2 \sin^2\gamma}{|\boldsymbol{k}|^2} < 0. \tag{57.74}$$

The phase velocity is directed away from the $\gamma = 0$ horizontal plane, whereas the group velocity is directed toward the horizontal plane. This property is depicted in Figures 57.1 and 57.4. Evidently, the internal gravity wave energy, which is fluxed in the direction of the group velocity, is directed away from the inside of the ω-cone and towards the horizontal plane.

The group velocity magnitude

The squared magnitude of the group velocity is given by

$$\boldsymbol{c}_{\mathrm{g}} \cdot \boldsymbol{c}_{\mathrm{g}} = \frac{N_{\mathsf{R}}^2\, k_z^2}{|\boldsymbol{k}|^4} = \frac{N_{\mathsf{R}}^2 \sin^2\gamma}{|\boldsymbol{k}|^2} \quad \text{where} \quad \sin\gamma = k_z/|\boldsymbol{k}|. \tag{57.75}$$

To help understand this expression it is useful to consider two extreme cases.

The group velocity vanishes when the wavevector is horizontal ($k_z = 0$ and $\gamma = 0$). As a result, no wave energy is propagated when the wavevector is horizontal.[10] When the wavevector is horizontal, all fluid particle motion in the wave is vertical, with fluid particles exhibiting vertical buoyancy oscillations at the maximum allowable gravity wave frequency, $\omega = N_{\mathsf{R}}$. So even though the wave has energy when it has a horizontal phase velocity, the wave energy is not propagated since $\boldsymbol{c}_{\mathrm{g}} = 0$. Rather, the wave energy is stationary as fluid particles exhibit vertical buoyancy oscillations.

At the opposite extreme, when the phase velocity is vertical, so that $\boldsymbol{k}_{\mathrm{h}} = 0$ and $\gamma = \pi/2$, the fluid particles move along a horizontal plane in an arbitrary horizontal direction. The group velocity is also horizontal and takes the form

$$\boldsymbol{c}_{\mathrm{g}} = (N_{\mathsf{R}}/|k_z|)\,\hat{\boldsymbol{k}}_{\mathrm{h}} \quad \text{with } \boldsymbol{k}_{\mathrm{h}} = 0, \tag{57.76}$$

where $\hat{\boldsymbol{k}}_{\mathrm{h}}$ is any horizontal direction. The angular frequency (57.65) vanishes ($\omega = 0$) so that the wave is stationary; i.e., phase lines do not move when $\gamma = \pi/2$.

[10] In Section 57.5.14 we see that the mechanical energy flux of an internal gravity wave is proportional to the group velocity, which is the case for any linear waves (see Chapter 50).

Relating the dispersion relation for internal gravity waves and inertial waves

The internal gravity wave dispersion relation (57.65) shares features with that for inertial waves, whose dispersion relation is given by equation (53.33), so that we have

$$\omega_{\text{igw}}^2 = N_{\text{R}}^2 \cos^2\gamma \quad \text{and} \quad \omega_{\text{inertial}}^2 = f^2 \sin^2\gamma. \tag{57.77}$$

Both dispersion relations are independent of the wavenumber, depending only on the wave's orientation. For the gravity wave, the vertical is a special direction since it is the direction of the gravitational acceleration, whereas for the inertial wave, the horizontal direction is special since is the direction of the Coriolis acceleration. Indeed, the switch from $\cos^2\gamma$ to $\sin^2\gamma$ arises since gravitation acts in the vertical whereas the Coriolis acts in the horizontal.[11] Both angular frequencies have an upper bound, with inertial waves having angular frequencies no larger than the Coriolis frequency, $|f|$, and internal gravity waves having angular frequencies no larger than the buoyancy frequency, N_{R}.

57.5.11 Force balance within an internal gravity wave

To help further understand the internal gravity wave dispersion relation (57.65), consider a test fluid element that moves with the wave in the transverse direction; i.e., parallel to surfaces of constant phase. As discussed in Section 17.2.5, a test fluid element is assumed to have zero impact on the surrounding fluid, in particular it has no impact on the pressure. This assumption is broken when considering real fluid elements, since all fluid elements affect the surrounding fluid. However, the pressure is spatially constant along a constant phase direction. Hence, for a particle displaced in this direction it only feels the change in buoyancy. So our critique of the test fluid elements in Section 57.3.1 is tempered when considering motion along directions that parallel phase surfaces. In the following, we refer to the test fluid element as a fluid particle both for brevity and to accord with the literature.

Fluid particle displacement vector

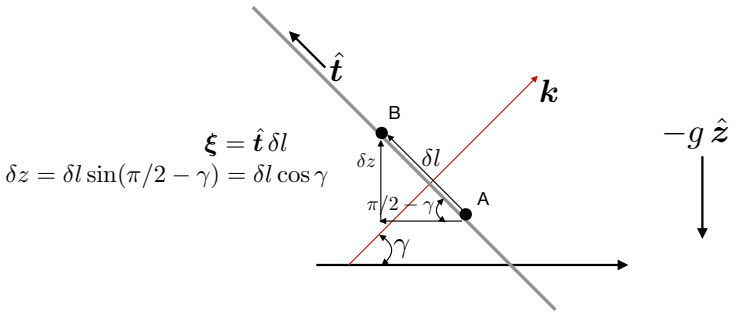

FIGURE 57.3: Depicting the displacement of a fluid particle along a direction transverse to a constant phase surface for a plane internal gravity wave whose wavevector makes an angle γ with the horizontal. We write the displacement vector as $\boldsymbol{\xi}(\boldsymbol{x}, t) = \delta l\, \hat{\boldsymbol{t}}$, with the local tangent vector, $\hat{\boldsymbol{t}}$, pointing in a transverse direction orthogonal to the wavevector, $\boldsymbol{k}$. The displacement of the fluid particle from point A to point B occurs over a distance, δl, with a corresponding change in vertical position given by $\delta z = \delta l \cos\gamma$.

As depicted in Figure 57.3, we measure a fluid particle's position relative to its equilibrium position through a displacement field,

$$\boldsymbol{\xi}(\boldsymbol{x}, t) = \hat{\boldsymbol{x}}\,\delta x + \hat{\boldsymbol{y}}\,\delta y + \hat{\boldsymbol{z}}\,\delta z. \tag{57.78}$$

[11] We discuss the force balances for an internal gravity wave in Section 57.5.11 and then for an intertia-gravity wave in Section 57.9.3.

The displacement field vanishes when the fluid particle is at its equilibrium position, and it has a time tendency that equals to the velocity of a fluid particle[12]

$$\partial_t \boldsymbol{\xi}(\boldsymbol{x}, t) = \boldsymbol{v}'(\boldsymbol{x}, t). \tag{57.79}$$

Evidently, since the plane wave is transverse,

$$\boldsymbol{v}' \cdot \boldsymbol{k} = (\partial_t \boldsymbol{\xi}) \cdot \boldsymbol{k} = 0. \tag{57.80}$$

If the fluid particle moves in the vertical, it moves through the background reference density field, $\rho_{\mathsf{R}}(z)$. Referring to Figure 57.3, assume the fluid particle starts at point A with local buoyancy equal to the reference buoyancy. As it rises an infinitesimal amount to point B, its buoyancy referenced to the local environment is negative since it started from a denser level. As such, the fluid particle wants to return to its deeper level. We can express the locally referenced buoyancy anomaly felt at point B in terms of the particle displacement

$$b' = -\boldsymbol{\xi} \cdot \nabla b_{\mathsf{R}} = -\delta z \, (\mathrm{d}b_{\mathsf{R}}/\mathrm{d}z) = -\delta z \, N_{\mathsf{R}}^2. \tag{57.81}$$

As a check on this expression, we find that if $\delta z > 0$, so that the fluid particle rises, then the buoyancy anomaly is negative, $b' < 0$, since it started from a deeper level where the density is larger. Hence, there is a buoyant acceleration back to the deeper level. Also observe that the time derivative of equation (57.81) leads to

$$\partial_t b' = -w' \, N_{\mathsf{R}}^2, \tag{57.82}$$

which is the linearized buoyancy equation (57.17c).

Equation of motion

We now make use of the result (57.81) in the equation of motion (57.31a). More precisely, we project that equation onto the transverse direction, $\hat{\boldsymbol{t}}$. This direction is fixed in time for a plane wave so that we have

$$\partial_t(\hat{\boldsymbol{t}} \cdot \boldsymbol{v}') = \hat{\boldsymbol{t}} \cdot (-\nabla \varphi' + b' \, \hat{\boldsymbol{z}}). \tag{57.83}$$

As noted above, there is no spatial gradient of flow properties along a constant phase surface. Hence, the tangential component of the pressure gradient vanishes

$$\hat{\boldsymbol{t}} \cdot \nabla \varphi' = 0, \tag{57.84}$$

which means pressure has no affect on fluid particles moving in the direction transverse to the wavevector. We write δl for the displacement along the phase surface, so that

$$\hat{\boldsymbol{t}} \cdot \boldsymbol{v}' = \partial_t(\delta l), \tag{57.85}$$

which brings the equation of motion (57.83) to the form

$$\partial_{tt}(\delta l) - \hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{t}} \, b' = 0. \tag{57.86}$$

[12]We make use of a one dimensional displacement field in Section 51.3 when considering acoustic waves using a Lagrangian perspective. We also make use of fluid particle displacement vectors when studying the generalized Lagrangian mean in Section 70.2, as well as for tracer kinematics in Section 70.3. The present discussion is heuristic and skims over details explored in these other sections. We can afford some degree of informality since all perturbations here are small.

Noting that $\hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{t}} = \cos\gamma$ and making use of equation (57.81) for the buoyancy anomaly leads to

$$\partial_{tt}(\delta l) + \cos\gamma\, N_{\mathsf{R}}^2\, \delta z = 0. \tag{57.87}$$

Finally, we set $\delta z = \delta l \cos\gamma$ to render the simple harmonic oscillator equation for displacements along the constant phase line

$$(\partial_{tt} + N_{\mathsf{R}}^2 \cos^2\gamma)\, \delta l = 0. \tag{57.88}$$

The angular frequency of the oscillations, $N_{\mathsf{R}} \cos\gamma$, is precisely that arising from the internal gravity wave dispersion relation (57.65).

Summary of the physical picture for internal gravity waves

The above analysis suggests the following physical picture for internal gravity waves. Namely, the waves consist of fluid particle motion in directions that parallel the constant phase surfaces, which accords with the property of all transverse waves. As the particles move along the transverse direction, $\hat{\boldsymbol{t}}$, they sample the background buoyancy field and thus experience buoyancy accelerations that act to return the particle to its neutral buoyancy position. The buoyancy force acting on the particles only depends on the angle of the phase lines relative to the horizontal. Oscillatory motion arises from over-shooting the neutral buoyancy position, with the oscillations having an angular frequency, $N_{\mathsf{R}} \cos\gamma$. The oscillations have their maximum angular frequency when the angle, $\gamma = 0$, which arises since the particles are moving vertically and thus fully sampling the background buoyancy field. In contrast, there are no oscillations when the particles move along a horizontal phase surface ($\gamma = \pi/2$ so that $\hat{\boldsymbol{k}} = \hat{\boldsymbol{z}}$) since horizontal surfaces sample the same background buoyancy. The vanishing of oscillations with $\gamma = \pi/2$ accords with our discussion in Section 57.3.2. The force balance dependence on the angle, γ, explains the geometry of the ω-cones in Figure 57.1, which, in turn, explains why the group velocity is perpendicular to the phase velocity.

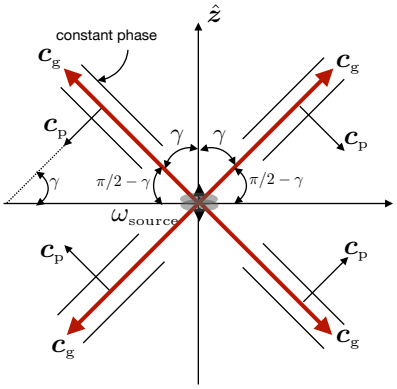
We emphasize that although the fluid particles are moving in a direction that parallels the constant phase surfaces, they are *not* moving with those surfaces. Rather, the fluid particles are oscillating in the transverse direction, and it is their oscillation that gives rise to the wave itself and thus to the movement of the phase surfaces through the fluid.

57.5.12 Forced internal gravity wave packets

A further remark about the dispersion relation written as in equation (57.67) concerns the case where we know the frequency of the wave and the buoyancy frequency, in which case the angle γ is specified. For example, consider a local source (say an oscillating disk) with angular frequency, ω_{source}, moving with a small amplitude in a stratified fluid with $\omega_{\text{source}} < N_{\mathsf{R}}$. This source preferentially forces internal waves of angular frequency $\omega = \omega_{\text{source}}$. Consequently, the left hand side of the dispersion relation (57.67) is specified.

Gravity wave packets extend outward from the oscillating source and define the group velocity direction (not the phase velocity direction). Consequently, the group velocity extends outward from the source at an angle $\pi/2 - \gamma$ from the horizontal. The reason the source defines the group velocity is that energy is input to the wave field by the oscillating source, and the wave energy propagates along the group velocity direction with the wave packets (we discuss internal gravity wave energy in Section 57.5.14). The phase velocity is directed perpendicular to the group velocity and it makes an angle γ with the horizontal. Hence, as the source angular frequency approaches the buoyancy frequency, γ approaches zero so that the group velocity "cross" pattern steepens toward the vertical axis. Figure 57.4 provides a schematic of the experiment along with links to videos illustrating the remarkable wave patterns in a laboratory setting as well as a

numerical simulation.[13]



$$\omega_\mathrm{source} < N_\mathrm{R}$$
$$\tan^2\gamma = \frac{N_\mathrm{R}^2 - \omega_\mathrm{source}^2}{\omega_\mathrm{source}^2}$$
$$\boldsymbol{c}_\mathrm{p}\cdot\boldsymbol{c}_\mathrm{g} = 0$$
$$(\boldsymbol{c}_\mathrm{p}\cdot\hat{\boldsymbol{z}})(\boldsymbol{c}_\mathrm{g}\cdot\hat{\boldsymbol{z}}) < 0$$

FIGURE 57.4: A small amplitude oscillating source in a stratified fluid with angular frequency, $\omega_\mathrm{source} < N_\mathrm{R}$. If the source has small amplitude then it generates linear internal gravity waves with $\omega = \omega_\mathrm{source}$. These waves radiate wave packets with group velocity, $\boldsymbol{c}_\mathrm{g}$, away from the source and with an angle, $\pi/2-\gamma$, from the horizontal. The angle, γ, is determined by the dispersion relation through $\tan^2\gamma = (N_\mathrm{R}^2 - \omega_\mathrm{source}^2)/\omega_\mathrm{source}^2$. The group velocity is parallel to lines of constant phase and perpendicular to the phase velocity so that $\boldsymbol{c}_\mathrm{p}\cdot\boldsymbol{c}_\mathrm{g} = 0$. Furthermore, the phase and group velocities are oriented so that $(\boldsymbol{c}_\mathrm{g}\cdot\hat{\boldsymbol{z}})(\boldsymbol{c}_\mathrm{p}\cdot\hat{\boldsymbol{z}}) < 0$, so that if the group velocity is directed upward then the phase velocity is directed downward, and vice versa. As the source angular frequency approaches the buoyancy frequency, γ approaches zero so that the group velocity "cross" pattern steepens toward the vertical axis. The pattern is sometimes referred to as *St. Andrew's cross*. This video and this video, both from the geophysical fluids laboratory at The Australian National University, as well as this video from Prof. Rhines' lab at the University of Washington, illustrate the phenomena in a laboratory settings, whereas this animation from Prof. Durran's website at the University of Washington illustrates the phenomena in a numerical simulation. *Sutherland* (2010) in his Chapter 5 works through the boundary value problems arising from both an oscillating cylinder and a sphere, thus illustrating the analytical methods available to solve for the generated internal gravity wave fields.

Internal gravity waves have an angular frequency that is bounded above by the buoyancy frequency: $0 \le \omega \le N_\mathrm{R}$. There are no internal gravity waves with frequency larger than the buoyancy frequency of the background reference state. This limit exists since internal gravity waves are coherent patterns of buoyancy oscillations, with the angular frequency of that oscillation taken from the background stratification (see Section 57.5.11 for more on this perspective).

57.5.13 Polarization relations and structure of a plane wave

We now piece together the polarization relations to provide expressions for the velocity, pressure, and buoyancy within a wave. We first express all fields in terms of the buoyancy amplitude, $\widetilde{b}$, and then in terms of the pressure amplitude, $\widetilde{\varphi}$. These amplitudes are related via the pressure equation from Section 57.5.4, whereby

$$\widetilde{\varphi}/\widetilde{b} = -\mathrm{i}\,k_z/|\boldsymbol{k}|^2 = -\mathrm{i}\sin\gamma/|\boldsymbol{k}|. \tag{57.89}$$

Neither is more fundamental, and yet one amplitude might be more readily available than the other so it is useful to provide both expressions.

[13] It is notable that this video from Prof. Rhines' lab shows both a St. Andrew's cross, which is well described by linear theory, as well as horizontal phase lines indicative of $\gamma = \pi/2$ vertical phase propagation and horizontal group propagation. Paraphrasing from an email discussion with Prof. Rhines, the horizontal phase lines are in part the result of mixing (a nonlinear process) at the oscillating circular cylinder, which affects the background buoyancy frequency enough to alter the linear waves a bit. This mixing causes a diffusive drift away from the source that excites low frequency internal waves, which move rapidly ahead of the turbulently mixed fluid.

Vertical velocity component

The dispersion relation in the form of equation (57.67) brings the vertical velocity expressions (57.61) and (57.62) into the tidy forms

$$\widetilde{w}/\widetilde{\varphi} = -\frac{k_z\,\omega}{N_{\mathsf{R}}^2 - \omega^2} = -\frac{|\boldsymbol{k}_{\mathsf{h}}|^2}{\omega\,k_z} \tag{57.90a}$$

$$\widetilde{w}/\widetilde{b} = \frac{\mathrm{i}\,k_z^2\,\omega}{|\boldsymbol{k}|^2\,(N_{\mathsf{R}}^2 - \omega^2)} = \frac{\mathrm{i}\,|\boldsymbol{k}_{\mathsf{h}}|^2}{\omega\,|\boldsymbol{k}|^2} = \frac{\mathrm{i}\cos\gamma}{N_{\mathsf{R}}}. \tag{57.90b}$$

Notice how the vertical velocity and pressure are in phase (or π out of phase), whereas the vertical velocity and buoyancy are $\pi/2$ out of phase.

Horizontal velocity

For the horizontal velocity we use the transverse nature of the wave (Section 57.5.2) to relate the horizontal components to the vertical

$$\boldsymbol{k}_{\mathsf{h}} \cdot \widetilde{\boldsymbol{u}} = -k_z\,\widetilde{w}, \tag{57.91}$$

as well as the zero vertical component of the relative vorticity (Section 57.5.3) so that

$$k_x\,\widetilde{v} = k_y\,\widetilde{u}. \tag{57.92}$$

These two relations, along with the vertical velocity amplitude equations (57.90a) and (57.90b), lead to

$$\widetilde{\boldsymbol{u}} = -\frac{\mathrm{i}\,\widetilde{b}\,\boldsymbol{k}_{\mathsf{h}}\sin\gamma}{N_{\mathsf{R}}\,|\boldsymbol{k}_{\mathsf{h}}|}. \tag{57.93}$$

As for the vertical velocity, we here find that the horizontal velocity is $\pi/2$ out of phase with the buoyancy.

Wave solutions in terms of the buoyancy amplitude

Bringing the previous results together allows us to express the solutions for the velocity, pressure, and buoyancy within a freely propagating internal gravity wave. The solutions in terms of a real buoyancy amplitude, $\widetilde{b}$, are given by

$$b' = \widetilde{b}\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) \tag{57.94a}$$

$$\varphi' = \frac{\widetilde{b}\sin\gamma}{|\boldsymbol{k}|}\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) \tag{57.94b}$$

$$\boldsymbol{u}' = \frac{\widetilde{b}\,\boldsymbol{k}_{\mathsf{h}}\sin\gamma}{N_{\mathsf{R}}\,|\boldsymbol{k}_{\mathsf{h}}|}\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) \tag{57.94c}$$

$$w' = -\frac{\widetilde{b}\cos\gamma}{N_{\mathsf{R}}}\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) \tag{57.94d}$$

$$\boldsymbol{v}' = \frac{\boldsymbol{c}_{\mathrm{g}}\,\widetilde{b}\,|\boldsymbol{k}|^2}{N_{\mathsf{R}}^2\,k_z}\sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t). \tag{57.94e}$$

Equation (57.94e) for $\boldsymbol{v}'$ made use of equation (57.71) for the group velocity, thus exposing the parallel nature of the particle velocity and group velocity for plane internal gravity waves. Note that the buoyancy is $\pi/2$ out of phase with the pressure along with the three components of the velocity.

Wave solutions in terms of the pressure amplitude

An alternative suite of wave solutions arises when assuming a real pressure amplitude, $\widetilde{\varphi}$, which leads to

$$\varphi' = \widetilde{\varphi} \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) \tag{57.95a}$$

$$b' = -\frac{\widetilde{\varphi}\, |\boldsymbol{k}|^2}{k_z} \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) \tag{57.95b}$$

$$\boldsymbol{u}' = \frac{\widetilde{\varphi}\, \boldsymbol{k}_{\text{h}}}{\omega} \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) \tag{57.95c}$$

$$w' = -\frac{\widetilde{\varphi}\, |\boldsymbol{k}_{\text{h}}|^2}{\omega\, k_z} \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) \tag{57.95d}$$

$$\boldsymbol{v}' = \frac{\boldsymbol{c}_{\text{g}}\, \widetilde{\varphi}\, |\boldsymbol{k}|^4}{N_{\text{R}}^2\, k_z^2} \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t). \tag{57.95e}$$

57.5.14 Energetics of a plane internal gravity wave

In Section 57.2.5 we derived the energetics for the linearized Boussinesq ocean equations and were led to the energy equation (57.25)

$$\partial_t(\mathcal{K}' + \mathcal{A}') = -\nabla \cdot (\boldsymbol{v}'\, \varphi') \quad \text{with} \quad \mathcal{K}' = \boldsymbol{v}' \cdot \boldsymbol{v}'/2 \quad \text{and} \quad \mathcal{A}' = (b'/N_{\text{R}})^2/2, \tag{57.96}$$

where $\mathcal{K}'$ is the kinetic energy per mass of the linear fluctuation, and $\mathcal{A}'$ is the corresponding available potential energy per mass. We only consider energetics of a plane internal wave. This idealized physical system has rather trivial energetics since for a plane wave there is no spatial convergence of the phase averaged energy flux, which means that the phase averaged energy is fixed in time. Even so, it is useful to work through the maths to gain practice in developing the phase averaged energy relations.

Interpreting the available potential energy

We saw in Section 57.2.5 that $\mathcal{A}' = (b'/N_{\text{R}})^2/2$ measures the available potential energy per mass arising from the small amplitude buoyancy fluctuation. When those fluctuations are part of a plane wave we can introduce the fluid particle displacement as in equation (57.81), in which

$$\mathcal{A}' = (b'/N_{\text{R}})^2/2 = (\delta z\, N_{\text{R}})^2/2. \tag{57.97}$$

This expression is identical to the potential energy (15.131) that we encountered for a point mass connected to a spring, where here the spring constant per mass equals to N_{R}^2.

Mechanical energy in the wave field

Assuming the small amplitude fluctuations are given by the wave relations (57.95a)-(57.95d) leads to

$$\mathcal{K}' = \frac{\widetilde{\varphi}^2\, |\boldsymbol{k}|^4}{2\, N_{\text{R}}^2\, k_z^2} \cos^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t) \tag{57.98a}$$

$$\mathcal{A}' = \frac{\widetilde{\varphi}^2\, |\boldsymbol{k}|^4}{2\, N_{\text{R}}^2\, k_z^2} \sin^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t), \tag{57.98b}$$

so that

$$\mathcal{K}' + \mathcal{A}' = \frac{\widetilde{\varphi}^2\, |\boldsymbol{k}|^4}{2\, N_{\text{R}}^2\, k_z^2} = \frac{\widetilde{\varphi}^2\, |\boldsymbol{k}_{\text{h}}|^2\, |\boldsymbol{k}|^2}{2\, \omega^2\, k_z^2}. \tag{57.99}$$

It is notable that the wave's mechanical energy, $\mathscr{K}' + \mathscr{A}'$, is independent of the space and time position. Furthermore, the phase averaged kinetic energy equals to that of the available potential energy

$$\langle \mathscr{K}' \rangle = \langle \mathscr{A}' \rangle, \tag{57.100}$$

which manifests equipartition for the wave field.[14] We can relate the total mechanical energy to the phase average of the squared vertical velocity through use of equation (57.95d), which yields

$$\mathscr{K}' + \mathscr{A}' = \langle w' \, w' \rangle \, |\boldsymbol{k}|^2 / |\boldsymbol{k}_\mathsf{h}|^2 = \langle w' \, w' \rangle / \cos^2 \gamma. \tag{57.101}$$

Note that the first expression in equation (57.99) indicates that for vertical waves, where $\gamma = \pi/2$, the sum $\mathscr{K}' + \mathscr{A}'$ is non-singular since $(w')^2$ vanishes. More precisely, we set $\boldsymbol{k}_\mathsf{h} = 0$ in equation (57.99) and find that a vertical phase velocity wave has mechanical energy

$$\mathscr{K}' + \mathscr{A}' = \frac{\widetilde{\varphi}^2 \, k_z^2}{2 \, N_\mathsf{R}^2} \quad \text{if } \boldsymbol{k}_\mathsf{h} = 0. \tag{57.102}$$

Energy flux and group velocity

The flux of mechanical energy can be written as

$$\boldsymbol{v}' \, \varphi' = \frac{\widetilde{\varphi}^2 \cos^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t)}{k_z \, \omega} \, (k_z \, \boldsymbol{k}_\mathsf{h} - \hat{\boldsymbol{z}} \, |\boldsymbol{k}_\mathsf{h}|^2) = \frac{\boldsymbol{c}_\mathsf{g} \, \widetilde{\varphi}^2 |\boldsymbol{k}|^4 \cos^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t)}{N_\mathsf{R}^2 k_z^2}, \tag{57.103}$$

where we used equation (57.71) for the group velocity. Taking the phase average then leads to

$$\langle \boldsymbol{v}' \, \varphi' \rangle = \frac{\boldsymbol{c}_\mathsf{g} \, \widetilde{\varphi}^2 |\boldsymbol{k}|^4}{2 \, N_\mathsf{R}^2 k_z^2} = \boldsymbol{c}_\mathsf{g} \, (\mathscr{K}' + \mathscr{A}'). \tag{57.104}$$

We thus confirm that the phase averaged flux of mechanical energy contained in an internal gravity wave equals to the group velocity times the total mechanical energy. This result accords with both the group velocity and the particle velocity being parallel to lines of constant phase and hence perpendicular to the wavevector

$$\boldsymbol{c}_\mathsf{g} \cdot \boldsymbol{k} = \boldsymbol{v}' \cdot \boldsymbol{k} = 0. \tag{57.105}$$

Energetics in terms of buoyancy amplitude

The above energetics made use of the polarization relations (57.95a)-(57.95e), written in terms of the pressure amplitude, $\widetilde{\varphi}$. Here we briefly expose the results making use of equations (57.94a)-(57.94e), in which we write the fields in terms of the buoyancy amplitude, $\widetilde{b}$. For this purpose we write for the kinetic energy

$$\mathscr{K}' = \frac{\boldsymbol{c}_\mathsf{g} \cdot \boldsymbol{c}_\mathsf{g} \, \widetilde{b}^2 \, |\boldsymbol{k}|^4}{2 \, N_\mathsf{R}^4 \, k_z^2} \sin^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t) = \frac{\widetilde{b}^2}{2 \, N_\mathsf{R}^2} \sin^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t), \tag{57.106}$$

where we used equation (57.75) for $\boldsymbol{c}_\mathsf{g} \cdot \boldsymbol{c}_\mathsf{g}$. The corresponding available potential energy is

$$\mathscr{A}' = (b'/N_\mathsf{R})^2/2 = \frac{\widetilde{b}^2}{2 \, N_\mathsf{R}^2} \cos^2(\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t), \tag{57.107}$$

[14] See Section 12.7.3 for the underlying reason for the equipartition of energy within linear waves, which is related to the virial theorem of classical mechanics.

so that the total mechanical energy is

$$\mathcal{K}' + \mathcal{A}' = \frac{\widetilde{b}^2}{2\,N_{\mathsf{R}}^2}, \tag{57.108}$$

and the phase averaged energy flux is

$$\langle \boldsymbol{v}'\,\varphi' \rangle = \frac{\boldsymbol{c}_{\mathrm{g}}\,\widetilde{b}^2}{2\,N_{\mathsf{R}}^2} = \boldsymbol{c}_{\mathrm{g}}\,(\mathcal{K}' + \mathcal{A}'). \tag{57.109}$$

57.6 Reflection of gravity waves

In Section 54.4.3 we studied the reflection of planetary Rossby wave packets from a smooth solid surface. That approach made use of some methods from geometric optics, in which we assume the waves reflect from the boundary without dissipation. Consequently, we only need to invoke the kinematic boundary condition to derive relations between incident and reflected waves. Here we pursue a similar study for internal gravity waves. Rossby waves (and many other waves such as acoustic waves and electromagnetic waves) exhibit specular reflection, whereby the angle the incident wave packet makes with the surface is preserved upon reflection. In contrast, the dispersion relation for internal gravity waves leads to a distinctly *non-specular* property. Namely, the angle the wave makes with the horizontal plane remains unchanged, rather than the angle the wave makes with the surface of reflection. Correspondingly, we encounter a particularly striking ability for the internal gravity wave, hitting the plane surface at a critical angle, to have an unbounded (infinite) wavenumber upon reflection.

57.6.1 Reflection conditions

Consider a packet of internal gravity waves with group velocity, $\boldsymbol{c}_{\mathrm{gi}}$, that is incident on a plane solid boundary, with the boundary making an angle, β, with the horizontal (see Figure 57.5). Let the carrier wave in the wave packet have an angular frequency, ω_{i}, and wavevector, $\boldsymbol{k}_{\mathrm{i}}$, with $\boldsymbol{c}_{\mathrm{gi}} \cdot \boldsymbol{k}_{\mathrm{i}} = 0$. Since the velocity of fluid particles is parallel to the group velocity for internal waves, we write the velocity of fluid particles in the carrier wave as

$$\boldsymbol{v}_{\mathrm{i}}' = \boldsymbol{c}_{\mathrm{gi}}\,A_{\mathrm{i}} \cos(\boldsymbol{k}_{\mathrm{i}} \cdot \boldsymbol{x} - \omega_{\mathrm{i}}\,t), \tag{57.110}$$

with the amplitude,

$$A_{\mathrm{i}} = A_{\mathrm{i}}(\boldsymbol{k}_{\mathrm{i}}) \tag{57.111}$$

a shorthand for the amplitudes in either equation (57.94e) or (57.95e). As such, A_{i} is a function of the incident wavevector, $\boldsymbol{k}_{\mathrm{i}}$, and the buoyancy frequency, N_{R}. The same considerations hold for the velocity of fluid particles in the reflected wave, so that

$$\boldsymbol{v}_{\mathrm{r}}' = \boldsymbol{c}_{\mathrm{gr}}\,A_{\mathrm{r}} \cos(\boldsymbol{k}_{\mathrm{r}} \cdot \boldsymbol{x} - \omega_{\mathrm{r}}\,t), \tag{57.112}$$

with $A_{\mathrm{r}} = A_{\mathrm{r}}(\boldsymbol{k}_{\mathrm{r}})$, $\boldsymbol{k}_{\mathrm{r}}$, and ω_{r}, the amplitude, wavevector, and angular frequency of the velocity of the reflected wave.

Now consider a steady state situation in which there are both incident and reflected waves, so that the fluid velocity at any given point in the fluid is given by the sum[15]

$$\boldsymbol{v}' = \boldsymbol{v}_{\mathrm{i}}' + \boldsymbol{v}_{\mathrm{r}}'. \tag{57.113}$$

[15]Recall that steady state does not mean static. Here, we assume steady state in the sense that the incident and reflected waves are fully established, so that our concern is not with the initial value problem. Instead, we are concerned with the boundary value problem.

The no-normal flow boundary condition at a solid boundary couples the incident and reflected wave properties, in which case

$$\boldsymbol{v}' \cdot \hat{\boldsymbol{n}} = (\boldsymbol{v}'_{\text{i}} + \boldsymbol{v}'_{\text{r}}) \cdot \hat{\boldsymbol{n}} = 0 \quad \text{at } \boldsymbol{x} = \boldsymbol{x}_{\text{w}}. \tag{57.114}$$

In these equations, $\hat{\boldsymbol{n}}$ is the outward normal on the solid boundary and $\boldsymbol{x}_{\text{w}} = |\boldsymbol{x}_{\text{w}}| \, \hat{\boldsymbol{t}}$ is a point on the boundary with $\hat{\boldsymbol{t}}$ the unit vector pointing tangent to the boundary so that $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{t}} = 0$.

As for Rossby wave reflection considered in Section 54.4.3, the boundary condition (57.114) leads to the reflection conditions for the angular frequency and wavevectors

$$\omega_{\text{i}} = \omega_{\text{r}} \quad \text{and} \quad (\boldsymbol{k}_{\text{i}} - \boldsymbol{k}_{\text{r}}) \cdot \hat{\boldsymbol{t}} = 0. \tag{57.115}$$

These conditions hold so long as the velocity amplitude and the group velocity satisfy

$$A_{\text{i}} \, \boldsymbol{c}_{\text{gi}} \cdot \hat{\boldsymbol{n}} = -A_{\text{r}} \, \boldsymbol{c}_{\text{gr}} \cdot \hat{\boldsymbol{n}}. \tag{57.116}$$

57.6.2 Specializing to internal gravity waves

The wavevector condition in equation (57.115) means that there is an equal projection onto the tangent direction of the incident and reflected wavevectors. This same condition holds for other waves, such as we found when studying Rossby wave reflection in Section 54.4.3 and as found for inertial waves in Exercise 57.1. Even so, the angular frequency condition, $\omega_{\text{i}} = \omega_{\text{r}}$, when coupled to the internal gravity wave dispersion relation (57.65), leads to non-specular wave reflection. The reason is that specification of the angular frequency and the background buoyancy frequency fixes the angle of the gravity wave relative to the horizontal plane. Hence, the angle that a reflected internal gravity wave makes relative to the solid boundary is generally different from the angle made by the incident wave. To prove this result requires trigonometry based on the boundary conditions (57.115), with details provided in Figure 57.5.

Non-specular nature of internal gravity wave reflection

For internal gravity waves, the frequency condition in equation (57.115) means that the angle the wavevector makes with the horizontal, γ, remains unchanged upon reflection

$$\omega_{\text{i}} = \omega_{\text{r}} = N_{\text{R}} \cos\gamma. \tag{57.117}$$

This relation holds no matter what angle, β, the solid wall makes with the horizontal. This identity is depicted in Figure 57.5, where the angle α_{i}, which is the angle the incident packet makes with the horizontal, equals to the reflected angle, α_{r}. It follows that the angle that the wave packet makes relative to the solid surface is different for the incident and reflected waves. This property is referred to as *non-specular*. For the example of Figure 57.5, the reflected wave is more nearly parallel to the solid boundary than the incident wave. Reversing the sense for the wave packet provides an example of a reflected packet that is less aligned with the boundary than the incident packet.

Basic identities for internal gravity wave reflection

The frequency identity (57.117), the wavevector relation (57.115), along with some basic vector and trigonometric analysis, lead to the following identities

$$\hat{\boldsymbol{t}} = \hat{\boldsymbol{h}} \cos\beta + \hat{\boldsymbol{z}} \sin\beta \tag{57.118a}$$

$$\hat{\boldsymbol{k}}_{\text{i}} = \hat{\boldsymbol{h}} \cos\gamma + \hat{\boldsymbol{z}} \sin\gamma \tag{57.118b}$$

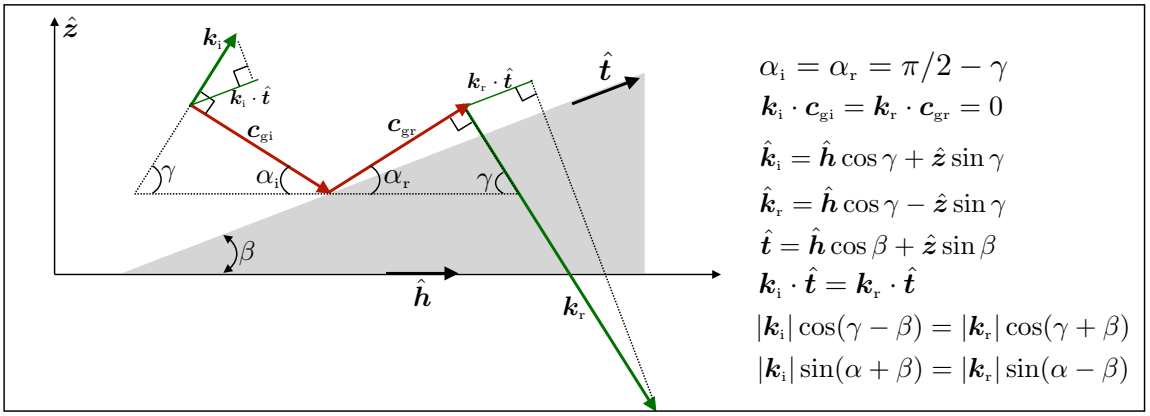


FIGURE 57.5: Depicting the reflection of an internal gravity wave packet as viewed within the geometrical optics approximation. Here the packet reflects from a planar inclined solid boundary that makes an angle, β, with the horizontal direction, $\hat{\boldsymbol{h}}$. The downward incident wave packet has a group velocity, $\boldsymbol{c}_{\rm gi}$, and an upward carrier wavevector, $\boldsymbol{k}_{\rm i}$, with $\boldsymbol{c}_{\rm gi} \cdot \boldsymbol{k}_{\rm i} = 0$. The incident group velocity makes an angle, $\alpha_{\rm i} = \pi/2 - \gamma$, with the horizontal, whereas $\boldsymbol{k}_{\rm i}$ makes an angle, γ, with the horizontal. The upward reflected wave packet has group velocity, $\boldsymbol{c}_{\rm gr}$, and a downward carrier wavevector, $\boldsymbol{k}_{\rm r}$, with $\boldsymbol{c}_{\rm gr} \cdot \boldsymbol{k}_{\rm r} = 0$. The angular frequency of the incident carrier wave is the same as the reflected wave, $\omega_{\rm i} = \omega_{\rm r} = \omega = N_{\rm R}\cos\gamma$, which then means that $\boldsymbol{k}_{\rm r}$ makes an angle, γ, with the horizontal. Consequently, the reflected group velocity makes an angle $\alpha_{\rm r} = \pi/2 - \gamma$, which is the same as the incident wave, $\alpha_{\rm r} = \alpha_{\rm i}$. The projection of the incident wavevector onto the surface tangent direction equals to that of the reflected wavevector, $\boldsymbol{k}_{\rm i} \cdot \hat{\boldsymbol{t}} = \boldsymbol{k}_{\rm r} \cdot \hat{\boldsymbol{t}}$, which means that $|\boldsymbol{k}_{\rm i}|\cos(\gamma - \beta) = |\boldsymbol{k}_{\rm r}|\cos(\gamma + \beta)$, or equivalently, $|\boldsymbol{k}_{\rm i}|\sin(\alpha + \beta) = |\boldsymbol{k}_{\rm r}|\sin(\alpha - \beta)$. For this example, the reflected wave has a larger wavenumber, $|\boldsymbol{k}_{\rm r}|$, than the incident wave, $|\boldsymbol{k}_{\rm i}|$, since $\alpha - \beta$ is smaller than $\alpha + \beta$. Indeed, for a packet with incident group velocity angle equal to the boundary angle, $\alpha = \beta$, then the reflected wave has an infinite wavenumber, which is an indication that the linear theory breaks down. To the right of the schematic we list the basic relations between the incident and reflected waves.

$$\hat{\boldsymbol{k}}_{\rm r} = \hat{\boldsymbol{h}}\cos\gamma - \hat{\boldsymbol{z}}\sin\gamma \tag{57.118c}$$

$$\hat{\boldsymbol{k}}_{\rm i} \cdot \hat{\boldsymbol{t}} = \cos\gamma\cos\beta + \sin\gamma\sin\beta = \cos(\gamma - \beta) = \sin(\alpha + \beta) \tag{57.118d}$$

$$\hat{\boldsymbol{k}}_{\rm r} \cdot \hat{\boldsymbol{t}} = \cos\gamma\cos\beta - \sin\gamma\sin\beta = \cos(\gamma + \beta) = \sin(\alpha - \beta), \tag{57.118e}$$

where $\hat{\boldsymbol{h}}$ is a unit vector in the horizontal. With these results we find that the wavevector boundary condition, $\boldsymbol{k}_{\rm i} \cdot \hat{\boldsymbol{t}} = \boldsymbol{k}_{\rm r} \cdot \hat{\boldsymbol{t}}$, (equation (57.115)) leads to the equivalent relations

$$|\boldsymbol{k}_{\rm i}|\cos(\gamma - \beta) = |\boldsymbol{k}_{\rm r}|\cos(\gamma + \beta) \tag{57.119a}$$

$$|\boldsymbol{k}_{\rm i}|\sin(\alpha + \beta) = |\boldsymbol{k}_{\rm r}|\sin(\alpha - \beta). \tag{57.119b}$$

Critical reflection of internal gravity waves

The identity (57.119b) makes it clear that a most remarkable result holds when the incident packet hits the boundary at an angle that equals to the solid wall angle, $\alpha = \beta$. In this case the reflected wavenumber, $|\boldsymbol{k}_{\rm r}|$, is unbounded, which means that the reflected waves have arbitrarily small wavelength. In a real fluid such small wavelength waves will eventually feel the impacts from viscous dissipation (e.g., Section 25.8), and/or they will break. In either case, such *critical reflection* of internal gravity waves provides an important mechanism for the transfer of energy from large to small scales, with the small scale features more prone to dissipative mixing.

57.6.3 Comments and further reading

Figure 57.5 provides an example where the reflected wave has a higher wavenumber than the incident wave. We can reverse all vectors to provide an example where a reflected wave has a smaller wavenumber than the incident wave. However, in a real fluid the reflections are not

generally reversible since higher wavenumber waves are more subject to irreversible mixing, either through viscous dissipation or breaking. These, and other, wave-induced ocean mixing processes are reviewed in *MacKinnon et al.* (2013), *MacKinnon et al.* (2017), and *Buijsman et al.* (2019).

57.7 Vertical normal modes

We here look for gravity waves in an ocean domain that is bounded below by a flat bottom at $z = -H$ and free surface at $z = \eta$. Since the bottom is flat we assume the waves are traveling only in the horizontal, in which we consider an ansatz of the form

$$w' = W(z)\, \mathrm{e}^{\mathrm{i}\,(k_x\, x + k_y\, y - \omega\, t)}. \tag{57.120}$$

Plugging this ansatz into the wave equation (57.40) for the vertical velocity leads to the eigenvalue problem for the vertical structure function

$$\left[\frac{\mathrm{d}^2}{\mathrm{d}z^2} + \frac{|\boldsymbol{k}_\mathrm{h}|^2\,(N_\mathrm{R}^2 - \omega^2)}{\omega^2}\right] W = 0 \qquad -H < z < 0 \tag{57.121a}$$

$$W = 0 \qquad \text{at } z = -H \tag{57.121b}$$

$$\omega^2 \mathrm{d}W/\mathrm{d}z = g\,|\boldsymbol{k}_\mathrm{h}|^2\, W \qquad \text{at } z = 0, \tag{57.121c}$$

where we used the flat bottom kinematic boundary condition at $z = -H$, and the upper ocean boundary condition (57.53) for equation (57.121c).

INCOMPLETE.

57.8 Linear Boussinesq ocean on an f-plane

We here establish some general properties of the linear Boussinesq ocean on an f-plane as described by equations (57.17a)-(57.17d)

$$\partial_t \boldsymbol{u}' + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}' = -\nabla_\mathrm{h}\varphi' \qquad \text{horizontal velocity equation} \tag{57.122a}$$

$$\partial_t w' = -\partial_z \varphi' + b' \qquad \text{vertical velocity equation} \tag{57.122b}$$

$$\partial_t b' = -w'\, N_\mathrm{R}^2 \qquad \text{buoyancy equation} \tag{57.122c}$$

$$\nabla \cdot \boldsymbol{v}' = 0 \qquad \text{continuity equation.} \tag{57.122d}$$

Since we are only concerned with f-plane motion, Rossby waves are not included in the physical system. As we see, the discussion reveals many forced oscillator equations satisfied by the linear fields, thus providing insight into the workings of the inertia-gravity waves discussed in Section 57.9. These oscillator equations also prove of use when developing the polarization relations for the plane inertia-gravity wave in Section 57.9.5.

57.8.1 Forced oscillator equation for horizontal velocity

Taking the time derivative of the horizontal velocity equation (57.122a) and back-substituting in the horizontal velocity tendency leads to

$$(\partial_{tt} + f^2)\, \boldsymbol{u}' = f\,\hat{\boldsymbol{z}} \times \nabla_\mathrm{h}\varphi' - \partial_t(\nabla_\mathrm{h}\varphi'). \tag{57.123}$$

This equation takes the form of a forced harmonic oscillator with natural angular frequency, f, and with forcing from the horizontal pressure gradient. Evidently, if we know the horizontal pressure gradient then that is sufficient to determine the horizontal velocity. Note that this is

the same forced oscillator equation as (53.17) found for inertial oscillations in a homogeneous fluid.

57.8.2 Vertical component to the relative vorticity

Evolution of the vertical component to the relative vorticity is derived by taking the curl of the horizontal velocity equation (57.122a) and projecting onto the vertical, in which we find

$$\partial_t \zeta' = f \, \partial_z w'. \tag{57.124}$$

Hence, relative vorticity evolves when there is vertical stretching in the presence of planetary rotation. This property accords with the more general understanding of vortex mechanics studied in Section 40.7.3. It also reduces to the $f = 0$ case, in which ζ' is static since $f = 0$ (Section 57.4.1). Finally, we can derive a forced oscillator equation for relative vorticity by taking the curl of the velocity equation (57.123) to find

$$(\partial_{tt} + f^2) \, \zeta' = f \, \nabla_{\mathsf{h}}^2 \varphi'. \tag{57.125}$$

Evidently, the relative vorticity exhibits forced inertial oscillations, with the forcing proportional to the horizontal Laplacian of the pressure field as weighted by the Coriolis parameter.

57.8.3 Forced oscillator and free wave equations for vertical velocity

Taking the divergence of the horizontal velocity equation (57.122a), and then using the continuity equation (57.122d), leads to

$$\partial_t (\nabla_{\mathsf{h}} \cdot \boldsymbol{u}') - f \, \zeta' = -\nabla_{\mathsf{h}}^2 \varphi' \implies \partial_{tz} w' + f \, \zeta' = \nabla_{\mathsf{h}}^2 \varphi'. \tag{57.126}$$

Now taking a time derivative and using the relative vorticity stretching equation (57.124) leads to the forced inertial oscillator equation for the vertical derivative of the vertical velocity

$$(\partial_{tt} + f^2) \partial_z w' = \partial_t \nabla_{\mathsf{h}}^2 \varphi'. \tag{57.127}$$

This equation says that when the horizontal flow has a nonzero divergence in the presence of rotation, then it experiences a forced inertial oscillation. Notice that if the pressure is constant in the horizontal direction, then the inertial oscillations are unforced.

We can derive another forced oscillator equation, this one for w'. To do so, take the time derivative of the vertical velocity equation (57.122b) and then use the linearized buoyancy equation (57.122c), which yields the forced buoyancy oscillator equation

$$\partial_{tt} w' = -\partial_{tz} \varphi' + \partial_t b' \implies (\partial_{tt} + N_{\mathsf{R}}^2) \, w' = -\partial_{tz} \varphi'. \tag{57.128}$$

We already encountered this equation in Section (57.3) when studying buoyancy oscillations. It says that vertical motion in the presence of a buoyancy field leads to forced buoyancy oscillations. Furthermore, if the pressure is constant in the vertical then the buoyancy oscillations are unforced.

Just like in the case of a non-rotating reference frame in Section 57.4.2, we can derive a free wave equation for w' by taking the vertical derivative of equation (57.127), the horizontal Laplacian of equation (57.128), and then adding to cancel the pressure contribution

$$(\partial_{tt} \, \nabla^2 + N_{\mathsf{R}}^2 \, \nabla_{\mathsf{h}}^2 + f^2 \, \partial_{zz}) \, w' = 0. \tag{57.129}$$

This is the fundamental wave equation for internal inertia-gravity waves. The build-up to this equation offers signatures of the forces acting within these waves. Namely, $\partial_z w'$ exhibits forced

inertial oscillations with natural angular frequency f (equation (57.127)). Such oscillations are associated, through continuity, with horizontally diverging flow that feels the Coriolis acceleration. Likewise, w' exhibits forced buoyancy oscillations with natural angular frequency N_{R} (equation (57.128)). These oscillations are associated with vertical motion that feels the effects from the background vertical stratification and associated buoyancy. By eliminating the pressure forcing the two complementary modes of oscillation, we reveal a free wave equation for w'. The free wave equation exposes the roles for Coriolis and buoyancy accelerations, yet hides the intermediate role of pressure accelerations that force the oscillations.

57.8.4 Forced oscillator equation for buoyancy

Since the flow is non-divergent at each time instant, we know that

$$\nabla \cdot \partial_t \boldsymbol{v}' = \partial_t \nabla \cdot \boldsymbol{v}' = 0. \tag{57.130}$$

Hence, taking the divergence of the horizontal velocity equation (57.122a) and adding to the vertical derivative of the vertical velocity equation (57.122b) leads to the pressure equation

$$-\nabla^2 \varphi' = -(f\,\zeta' + \partial_z b'). \tag{57.131}$$

Evidently, a source for the dynamic pressure arises from vertical buoyancy gradients along with relative vorticity. We characterized the phyics of these sources in Section 29.3.4 when studying the pressure equation in a Boussinesq ocean.

Taking the time derivative of the pressure equation (57.131) and using the stretching relative vorticity equation (57.124) leads to

$$f^2\,\partial_z w' = \partial_t(\nabla^2 \varphi' - \partial_z b'). \tag{57.132}$$

One more time derivative and use of the vertical velocity equation (57.122b) yields the forced inertial oscillator equation for the vertical derivative of buoyancy

$$(\partial_{tt} + f^2)\,\partial_z b' = (\partial_{tt}\nabla^2 + f^2\,\partial_{zz})\,\varphi'. \tag{57.133}$$

57.8.5 An equation for pressure

We now consider an equation for pressure that is based on taking the time derivative of the forced inertial oscillator equation (57.133) for $\partial_z b'$. Focusing on the left hand side we find

$$\begin{aligned}
\partial_t[(\partial_{tt} + f^2)\,\partial_z b'] &= \partial_z[(\partial_{tt} + f^2)\,\partial_t b'] && \text{swap } \partial_z \text{ and } \partial_t && (57.134a)\\
&= -\partial_z[(\partial_{tt} + f^2)\,w'\,N_{\mathsf{R}}^2] && \text{equation (57.122c)} && (57.134b)\\
&= -\partial_z N_{\mathsf{R}}^2\,(\partial_{tt} + f^2)\,w' - N_{\mathsf{R}}^2\,(\partial_{tt} + f^2)\,\partial_z w' && \text{product rule} && (57.134c)\\
&= -\partial_z N_{\mathsf{R}}^2\,(\partial_{tt} + f^2)\,w' - N_{\mathsf{R}}^2\,\partial_t \nabla_{\mathsf{h}}^2 \varphi' && \text{equation (57.127)} && (57.134d)
\end{aligned}$$

Combining with the time derivative on the right hand side of equation (57.133) leads to the pressure equation

$$\partial_t[(\partial_{tt}\nabla^2 + f^2\,\partial_{zz} + N_{\mathsf{R}}^2\,\nabla_{\mathsf{h}}^2)\,\varphi'] = -\partial_z N_{\mathsf{R}}^2\,(\partial_{tt} + f^2)\,w'. \tag{57.135}$$

In the special case of a constant background stratification we find

$$\partial_t[(\partial_{tt}\nabla^2 + f^2\,\partial_{zz} + N_{\mathsf{R}}^2\,\nabla_{\mathsf{h}}^2)\,\varphi'] = 0 \quad \text{if } \partial_z N_{\mathsf{R}} = 0, \tag{57.136}$$

which is nearly the same as the free wave equation (57.129) for w'.[16]

57.8.6 Potential vorticity

Although inertia-gravity waves modify relative vorticity, we here show they retain the linearized potential vorticity unchanged. For this purpose, use the relative vorticity equation (57.124) and the buoyancy equation (57.122c) to find[17]

$$\partial_t[\zeta' + f\,\partial_z(b'/N_{\mathsf{R}}^2)] = 0 \Longrightarrow \partial_t Q' = 0 \quad \text{with} \quad Q' = \zeta' + f\,\partial_z(b'/N_{\mathsf{R}}^2). \tag{57.137}$$

Hence, an inertia-gravity wave does not alter the potential vorticity, at least to linear order. This means that any vortical portion of the flow (i.e., flow with $Q' \neq 0$), such as a background static geostrophic flow, can exist without either the waves or the background flow affecting one another. Furthermore, we observe that the linearized potential vorticity (57.137) accords with the relative vorticity and buoyancy contribution to the quasi-geostrophic potential vorticity (45.53). In the present case, however, we are concerned with the f-plane rather than the β-plane considered for quasi-geostrophy. Another difference is that the potential vorticity (57.137) is locally static, $\partial_t Q' = 0$, whereas the quasi-geostrophic potential vorticity remains constant when following the geostrophic flow.

Potential vorticity and layer thickness

For yet another way to interpret the linear potential vorticity (57.137), write the buoyancy fluctuation in terms of the particle displacement as in equation (57.81)

$$\delta z = -b'/N_{\mathsf{R}}^2, \tag{57.138}$$

which brings the linearized potential vorticity to the form

$$Q' = \zeta' + f\,\partial_z(b'/N_{\mathsf{R}}^2) = \zeta' - f\,\partial_z(\delta z). \tag{57.139}$$

Since Q' is a static field, the presence of $\partial_z(\delta z)$ leads in a rotating reference frame to a compensating relative vorticity. In an internal gravity wave, δz measures the periodic compression and expansion of the vertical distance between constant buoyancy surfaces. This layer interpretation of potential vorticity accords with our understanding of potential vorticity from shallow water theory in Section 39.3, as well as potential vorticity in isopycnal/buoyancy coordinate models in Section 66.3.

Connection to pressure and buoyancy

The various harmonic oscillator equations established thus far in this section are not satisfied by Q' since it is a static field. However, we can derive an expression for Q' in terms of pressure and buoyancy through the following manipulations

$$(\partial_{tt} + f^2)\,Q' = f^2\,Q' \tag{57.140a}$$

$$= (\partial_{tt} + f^2)[\zeta' + f\,\partial_z(b'/N_{\mathsf{R}}^2)] \tag{57.140b}$$

$$= f\,\nabla_{\mathsf{h}}^2\varphi' + N_{\mathsf{R}}^{-2}\,(\partial_{tt}\nabla^2 + f^2\,\partial_{zz})\,\varphi' + \partial_z(N_{\mathsf{R}}^{-2})\,(\partial_{tt} + f^2)\,b', \tag{57.140c}$$

[16] See Lecture 11 in *Pedlosky* (2003) for connection between the pressure equation (57.136) to the potential vorticity equation in the case of constant N_{R}.

[17] Note that in this chapter we define potential vorticity with dimensions of inverse time, T^{-1}, as for the continuously stratified quasi-geostrophic potential vorticity in Section 45.3.7. In contrast, in our study of shallow water waves in Chapter 55, we defined Q' in Section 55.3.3 to have dimensions of $L^{-1}\,T^{-1}$.

where equation (57.140a) follows since $\partial_t Q' = 0$, equation (57.140b) used the definition of Q' from equation (57.137), and equation (57.140c) used the forced harmonic oscillator equations (57.125) and (57.127). Multiplying by N_{R}^2 leads to

$$f\, N_{\mathsf{R}}^2\, Q' = (\partial_{tt}\nabla^2 + N_{\mathsf{R}}^2\, \nabla_{\mathsf{h}}^2 + f^2\, \partial_{zz})\, \varphi' + N_{\mathsf{R}}^2\, \partial_z(N_{\mathsf{R}}^{-2})\, (\partial_{tt} + f^2)\, b'. \tag{57.141}$$

Decomposing vortical and divergent motions for constant vertical stratification

In the special case of a constant N_{R}, we see that the potential vorticity can be written entirely in terms of the pressure

$$f\, N_{\mathsf{R}}^2\, Q' = (\partial_{tt}\nabla^2 + N_{\mathsf{R}}^2\, \nabla_{\mathsf{h}}^2 + f^2\, \partial_{zz})\, \varphi' \quad \text{if } \partial_z N_{\mathsf{R}} = 0. \tag{57.142}$$

Evidently, for constant background stratification the static nature of the potential vorticity is equivalent to the wave equation (57.136)

$$\partial_t Q' = 0 \Longrightarrow \partial_t[(\partial_{tt}\nabla^2 + N_{\mathsf{R}}^2\, \nabla_{\mathsf{h}}^2 + f^2\, \partial_{zz})\, \varphi'] = 0 \quad \text{if } \partial_z N_{\mathsf{R}} = 0. \tag{57.143}$$

We found the same connection between the potential vorticity equation and the wave equation in Section 55.8.2 when studying shallow water inertia-gravity waves (see equation (55.153)). As for the shallow water, we conclude that for the case of constant stratification the vortical motions associated with f-plane geostrophy (hence with zero vertical velocity) are decoupled from the divergent motions associated with inertia-gravity waves. Hence, we can describe the fluid motion by a static potential vorticity whose non-zero value is set by f-plane geostrophic (vortical) flow, plus a zero potential vorticity flow arising from inertia-gravity waves. In the linear theory, and for constant vertical stratification, there is no exchange of potential vorticity between the vortical flow and divergent waves. As a practical matter, one often has knowledge of the static potential vorticity arising from the geostrophic motion. We can obtain the associated geostrophic pressure field from inverting the elliptic operator in equation (57.142).

57.9 Free inertia-gravity waves

In this section we study the free *inertia-gravity* waves that arise under small amplitude fluctuations in a continuously stratified fluid on an f-plane. To enable plane wave solutions we assume the stratification is constant.

57.9.1 Dispersion relation

Returning to the wave equation (57.129) for w'

$$(\partial_{tt}\, \nabla^2 + N_{\mathsf{R}}^2\, \nabla_{\mathsf{h}}^2 + f^2\, \partial_{zz})\, w' = 0, \tag{57.144}$$

we take the plane wave ansatz

$$w' = \widetilde{w}\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)} \tag{57.145}$$

which readily leads to the dispersion relation

$$\varpi^2(\boldsymbol{k}) = \frac{N_{\mathsf{R}}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2 + f^2\, k_z^2}{|\boldsymbol{k}|^2}. \tag{57.146}$$

Just like the case of internal gravity waves studied in Section 57.5, the dispersion relation is only a function of the wave direction. To manifest this property we introduce the angle, γ, between

the wavevector and the horizontal plane

$$\varpi^2(\boldsymbol{k}) = N_{\mathsf{R}}^2 \cos^2\gamma + f^2 \sin^2\gamma = (N_{\mathsf{R}}^2 - f^2)\cos^2\gamma + f^2 = N_{\mathsf{R}}^2 - (N_{\mathsf{R}}^2 - f^2)\sin^2\gamma. \tag{57.147}$$

The dispersion relation reduces to that for internal gravity waves when $f = 0$ given as by equation (57.65).

57.9.2 Near-inertial waves

In stably stratified geophysical fluids we typically find the squared buoyancy frequency is larger than the squared Coriolis frequency, $N_{\mathsf{R}}^2 > f^2$. In this case the plane inertia-gravity wave angular frequency is bounded by

$$f^2 \leq \omega^2 \leq N_{\mathsf{R}}^2 \quad \text{when } N_{\mathsf{R}}^2 > f^2. \tag{57.148}$$

Indeed, in many cases we have $f^2 \ll N_{\mathsf{R}}^2$. Even so, there are weakly stratified regions with $N_{\mathsf{R}}^2 < f^2$, in which case the opposite frequency range holds whereby $N_{\mathsf{R}}^2 \leq \omega^2 \leq f^2$. In the limit with $N_{\mathsf{R}} = 0$, then the inertia-gravity waves reduce to the *inertial waves* studied in Chapter 53, which are waves appearing for motion on the f-plane within a fluid with homogeneous density ($N_{\mathsf{R}} = 0$).

Inertia-gravity waves typically have horizontal scales much larger than vertical, in which case $|\boldsymbol{k}_{\mathsf{h}}|^2 \ll k_z^2$. As discussed in Exercise 57.2, such waves satisfy hydrostatic scaling in which

$$\frac{\text{vertical scales in the waves}}{\text{horizontal scales in the waves}} = \frac{|\boldsymbol{k}_{\mathsf{h}}|}{|k_z|} \ll 1 \Longleftarrow \text{hydrostatic motion.} \tag{57.149}$$

The reason for this anisotropy in the waves is related to the processes forcing the waves. In particular, for the ocean the forcing by winds occurs with large horizontal patterns characteristic of the atmosphere. With $|\boldsymbol{k}_{\mathsf{h}}|^2 \ll k_z^2$, the phase velocity for the waves is nearly vertical so that $\gamma \approx \pi/2$. We thus find that the dominant forcing frequency for inertia-gravity waves is near that of the Coriolis frequency

$$\omega^2 = f^2 + (N_{\mathsf{R}}^2 - f^2)\cos^2\gamma \gtrsim f^2. \tag{57.150}$$

Such waves are referred to as *near-inertial waves*.

57.9.3 Force balance in an inertia-gravity wave

In Section 57.5.11 we studied the buoyancy forces acting on a fluid particle that moves transverse to the constant phase surfaces in a gravity wave. We pursue the same analysis here with the added feature of the Coriolis acceleration. This analysis offers a force balance interpretation of the dispersion relation (57.147).

For a phase surface that has a nonzero slope in the vertical, the displaced fluid particle moving parallel to the phase surface feels the effects from buoyancy forces. Likewise, when including the Coriolis acceleration on an f-plane, a horizontal displacement of a fluid particle induces a Coriolis acceleration. Given the nature of the Coriolis acceleration, the particle turns in the horizontal. Hence, a fluid particle moving in the direction of contant phase surfaces feels the effects of the buoyant acceleration when it moves vertically plus the Coriolis acceleration when it moves horizontally. For small amplitude motion, these forces give rise to simple harmonic oscillator motion, and they represent the essential features of an an inertia-gravity wave. We here detail the mechanics of this motion.

Particle displacements and Coriolis acceleration

Following the approach in Section 57.5.11, we make use of the fluid particle displacement field, $\boldsymbol{\xi}(\boldsymbol{x}, t)$, whose time derivative yields the velocity of the fluid particle in a small amplitude wave

$$\partial_t \boldsymbol{\xi}(\boldsymbol{x}, t) = \boldsymbol{v}'(\boldsymbol{x}, t). \tag{57.151}$$

To understand the role of the Coriolis acceleration, consider an inertial particle that satisfies the equation of motion

$$\partial_t \boldsymbol{v}' + f\, \hat{\boldsymbol{z}} \times \boldsymbol{v}' = 0 \Longrightarrow \partial_t \left(\partial_t \boldsymbol{\xi} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{\xi} \right) = 0. \tag{57.152}$$

Hence, in terms of particle displacements, the inertial particle satisfies

$$\partial_t \boldsymbol{\xi} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{\xi} = \text{constant}, \tag{57.153}$$

with the constant determined by initial conditions, which can be set to zero without loss of generality. Evidently, an inertial particle in a rotating reference frame, displaced in a direction perpendicular to the rotation axis (horizontal direction here), induces a time tendency for motion in the orthogonal horizontal direction

$$\partial_t \boldsymbol{\xi} = -f\, \hat{\boldsymbol{z}} \times \boldsymbol{\xi}. \tag{57.154}$$

Particle displacements with buoyancy and Coriolis

The linearized equation of motion that includes the effects from pressure, Coriolis, and buoyancy, is given by

$$\partial_t \boldsymbol{v}' + f\, \hat{\boldsymbol{z}} \times \boldsymbol{v}' = -\nabla \varphi' + b'\, \hat{\boldsymbol{z}}. \tag{57.155}$$

Focusing on a fluid particle in the presence of a transverse wave, we project the equation of motion onto the transverse direction, $\hat{\boldsymbol{t}}$, with this direction static for a plane wave. Doing so eliminates the pressure gradient since it is constant along a surface of constant phase, so that fluid particle motion in the transverse direction satisfies

$$\partial_t (\hat{\boldsymbol{t}} \cdot \boldsymbol{v}') + f\, \hat{\boldsymbol{t}} \cdot (\hat{\boldsymbol{z}} \times \boldsymbol{v}') = b'\, \hat{\boldsymbol{t}} \cdot \hat{\boldsymbol{z}}. \tag{57.156}$$

Introducing the particle displacement yields

$$\hat{\boldsymbol{t}} \cdot \boldsymbol{v}' = \partial_t (\hat{\boldsymbol{t}} \cdot \boldsymbol{\xi}) = \partial_t \delta l \tag{57.157a}$$

$$b'\, \hat{\boldsymbol{t}} \cdot \hat{\boldsymbol{z}} = -N_{\mathsf{R}}^2\, \delta z \cos\gamma = -N_{\mathsf{R}}^2\, \delta l \cos^2\gamma, \tag{57.157b}$$

with the buoyancy expression in equation (57.157b) following from equation (57.81) derived when studying internal gravity waves ($f = 0$). For the Coriolis acceleration we make use of equation (57.154) to write

$$f\, \hat{\boldsymbol{t}} \cdot (\hat{\boldsymbol{z}} \times \boldsymbol{v}') = f\, \boldsymbol{v}' \cdot (\hat{\boldsymbol{t}} \times \hat{\boldsymbol{z}}) \tag{57.158a}$$

$$= f\, \partial_t \boldsymbol{\xi} \cdot (\hat{\boldsymbol{t}} \times \hat{\boldsymbol{z}}) \tag{57.158b}$$

$$= -f^2\, (\hat{\boldsymbol{z}} \times \boldsymbol{\xi}) \cdot (\hat{\boldsymbol{t}} \times \hat{\boldsymbol{z}}) \tag{57.158c}$$

$$= f^2\, \delta l \sin^2\gamma, \tag{57.158d}$$

where we used the vector identity (1.73c) and set $\hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{t}} = \sin\gamma$.

Bringing the above results together leads to the equation of motion for particle displacements

$$(\partial_{tt} + N_{\mathsf{R}}^2 \cos^2\gamma + f^2 \sin^2\gamma)\, \delta l = 0. \tag{57.159}$$

This is an equation for a simple harmonic oscillator with angular frequency

$$\omega^2 = N_{\mathsf{R}}^2 \cos^2\gamma + f^2 \sin^2\gamma, \tag{57.160}$$

which is the dispersion relation derived in Section 57.9.1 through use of the plane wave ansatz.

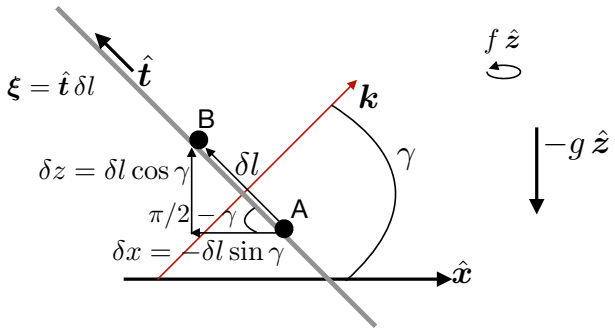

FIGURE 57.6: An extension of Figure 57.3 to now allow for a fluid particle to feel accelerations from both buoyancy and Coriolis as it moves in the direction transverse to the plane waves. The wavevector makes an angle, γ, with the horizontal. We show a view in the x-z plane with the particle displacement vector, $\boldsymbol{\xi}(\boldsymbol{x}, t) = \delta l\, \hat{\boldsymbol{t}}$. The local transverse unit vector, $\hat{\boldsymbol{t}}$, points in a direction that is orthogonal to the wavevector, $\boldsymbol{k}$. The displacement of the fluid particle from point A and point B occurs over a distance, δl, with a corresponding change in vertical position given by $\delta z = \delta l \cos\gamma$ and horizontal position changes by $\delta x = -\delta l \sin\gamma$. This displacement causes the fluid particle to experience accelerations from both buoyancy and Coriolis.

57.9.4 Group velocity

The wavevector gradient of the dispersion relation (57.160) yields the group velocity for inertia-gravity waves

$$\boldsymbol{c}_{\mathsf{g}} = \frac{(N_{\mathsf{R}}^2 - f^2)\, k_z}{|\boldsymbol{k}|^4\, \omega}\, (k_z\, \boldsymbol{k}_{\mathsf{h}} - |\boldsymbol{k}_{\mathsf{h}}|^2\, \hat{\boldsymbol{z}}). \tag{57.161}$$

As for internal gravity waves in equation (57.71), we find that the group velocity is perpendicular to the phase velocity ($\boldsymbol{c}_{\mathsf{p}} = \hat{\boldsymbol{k}}\, \omega/|\boldsymbol{k}|$)

$$\boldsymbol{c}_{\mathsf{g}} \cdot \boldsymbol{c}_{\mathsf{p}} = 0. \tag{57.162}$$

We also find that

$$(\boldsymbol{c}_{\mathsf{g}} \cdot \hat{\boldsymbol{z}})\, (\boldsymbol{c}_{\mathsf{p}} \cdot \hat{\boldsymbol{z}}) = -\frac{(N_{\mathsf{R}}^2 - f^2)\, k_z^2\, |\boldsymbol{k}_{\mathsf{h}}|^2}{|\boldsymbol{k}|^4\, \omega}, \tag{57.163}$$

so that

$$(\boldsymbol{c}_{\mathsf{g}} \cdot \hat{\boldsymbol{z}})\, (\boldsymbol{c}_{\mathsf{p}} \cdot \hat{\boldsymbol{z}}) < 0 \quad \text{if } f^2 < N_{\mathsf{R}}^2 \tag{57.164a}$$

$$(\boldsymbol{c}_{\mathsf{g}} \cdot \hat{\boldsymbol{z}})\, (\boldsymbol{c}_{\mathsf{p}} \cdot \hat{\boldsymbol{z}}) > 0 \quad \text{if } f^2 > N_{\mathsf{R}}^2. \tag{57.164b}$$

The usual case for the atmosphere and ocean finds $f^2 < N_{\mathsf{R}}^2$, so that if the group velocity is upward then the phase velocity is downward, and vice versa. However, if $f^2 > N_{\mathsf{R}}^2$, as for inertial waves where $N_{\mathsf{R}} = 0$ (Chapter 53, Exercise 57.1), or more generally for inertia-gravity waves in very weak vertical stratification, then the group and phase velocities have the same orientation with respect to the vertical.

57.9.5 Polarization relations for a plane wave

We now make use of the plane wave ansatz (57.54) to derive the polarization relations that determine the structure of a plane wave. For this purpose we make use of the various forced harmonic oscillator equations from Section 57.8 to express the velocity and buoyancy in terms

of a real pressure amplitude, $\widetilde{\varphi}$, where pressure is assumed to take the form

$$\varphi' = \widetilde{\varphi} \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t). \tag{57.165}$$

We also make use of the dispersion relation (57.147) to write the polarization relations in a variety of forms. In the limit with $f = 0$, each of the expressions below reduce to the gravity wave polarization relations (57.90a)-(57.90b) derived in Section 57.5.13.

Buoyancy

Buoyancy satisfies the forced oscillator equation (57.133), which for a plane wave takes the form

$$(-\omega^2 + f^2)\, \mathrm{i}\, k_z\, \widetilde{b} = (\omega^2\, |\boldsymbol{k}|^2 - f^2\, k_z^2)\, \widetilde{\varphi}. \tag{57.166}$$

Various forms of the dispersion relation given in Section 57.9.1 lead to the identities

$$\omega^2\, |\boldsymbol{k}|^2 - f^2\, k_z^2 = N_{\mathsf{R}}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2 \tag{57.167a}$$

$$\omega^2 - f^2 = (N_{\mathsf{R}}^2 - f^2)\, |\boldsymbol{k}_{\mathsf{h}}|^2 / |\boldsymbol{k}|^2 = (N_{\mathsf{R}}^2 - \omega^2)\, |\boldsymbol{k}_{\mathsf{h}}|^2 / k_z^2 \tag{57.167b}$$

so that the ratio of amplitudes can be written in the equivalent manners

$$\widetilde{b}/\widetilde{\varphi} = \frac{\mathrm{i}\, (\omega^2\, |\boldsymbol{k}|^2 - f^2\, k_z^2)}{k_z\, (\omega^2 - f^2)} = \frac{\mathrm{i}\, N_{\mathsf{R}}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2}{k_z\, (\omega^2 - f^2)} = \frac{\mathrm{i}\, N_{\mathsf{R}}^2\, |\boldsymbol{k}|^2}{k_z\, (N_{\mathsf{R}}^2 - f^2)} = \frac{\mathrm{i}\, N_{\mathsf{R}}^2\, k_z}{N_{\mathsf{R}}^2 - \omega^2}, \tag{57.168}$$

which means that the real buoyancy wave is given by

$$b'/\widetilde{\varphi} = -\frac{N_{\mathsf{R}}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2 \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}{k_z\, (\omega^2 - f^2)} = -\frac{N_{\mathsf{R}}^2\, k_z \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}{N_{\mathsf{R}}^2 - \omega^2}. \tag{57.169}$$

Vertical velocity component

From Section 57.8.3 we know that the vertical velocity satisfies the two forced oscillator equations (57.127) and (57.128)

$$(\partial_{tt} + f^2)\partial_z w' = \partial_t \nabla_{\mathsf{h}}^2 \varphi' \quad \text{and} \quad (\partial_{tt} + N_{\mathsf{R}}^2)\, w' = -\partial_{tz} \varphi'. \tag{57.170}$$

For a plane wave these equations lead to

$$\widetilde{w}/\widetilde{\varphi} = -\frac{\omega\, |\boldsymbol{k}_{\mathsf{h}}|^2}{k_z\, (\omega^2 - f^2)} = -\frac{\omega\, k_z}{N_{\mathsf{R}}^2 - \omega^2} = -\frac{\omega\, |\boldsymbol{k}|^2}{k_z\, (N_{\mathsf{R}}^2 - f^2)}, \tag{57.171}$$

so that the real wave takes on the form

$$w'/\widetilde{\varphi} = -\frac{\omega\, |\boldsymbol{k}_{\mathsf{h}}|^2 \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}{k_z\, (\omega^2 - f^2)} = -\frac{\omega\, k_z \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}{N_{\mathsf{R}}^2 - \omega^2} = -\frac{\omega\, |\boldsymbol{k}|^2 \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t)}{k_z\, (N_{\mathsf{R}}^2 - f^2)}. \tag{57.172}$$

Horizontal velocity

Equation (57.123) for the horizontal velocity leads to the relation for the plane wave amplitude

$$\widetilde{\boldsymbol{u}}/\widetilde{\varphi} = \frac{\omega\, \boldsymbol{k}_{\mathsf{h}} - \mathrm{i}\, f\, (\hat{\boldsymbol{z}} \times \boldsymbol{k}_{\mathsf{h}})}{\omega^2 - f^2}, \tag{57.173}$$

so that the real plane wave polarization relation is given by

$$\boldsymbol{u}/\widetilde{\varphi} = \frac{\omega\, \boldsymbol{k}_{\mathsf{h}} \cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t) + f\, (\hat{\boldsymbol{z}} \times \boldsymbol{k}_{\mathsf{h}}) \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}{\omega^2 - f^2}, \tag{57.174}$$

which compares directly to the shallow water polarization relation (55.174a).

57.9.6 Energetics of a plane inertia-gravity wave

We here extend the energetic analysis of plane internal gravity waves in Section 57.5.14 to the case of plane inertia-gravity waves, making use of the polarization relations from Section 57.9.5. Each of the expressions found here reduce to the internal gravity waves case when taking $f = 0$.

Instantaneous energetics

The plane inertia-gravity wave has squared velocity components

$$\boldsymbol{u}' \cdot \boldsymbol{u}'/\widetilde{\varphi}^2 = \frac{\omega^2\, |\boldsymbol{k}_{\mathsf{h}}|^2 \cos^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t) + f^2\, |\boldsymbol{k}_{\mathsf{h}}|^2 \sin^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}{(\omega^2 - f^2)^2} \tag{57.175a}$$

$$(w')^2/\widetilde{\varphi}^2 = \frac{\omega^2\, |\boldsymbol{k}_{\mathsf{h}}|^4 \cos^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}{k_z^2\, (\omega^2 - f^2)^2}, \tag{57.175b}$$

so that the wave's kinetic energy is

$$\mathcal{K}' = \frac{\widetilde{\varphi}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2}{2\, (\omega^2 - f^2)^2} \big[\omega^2\, (1 + |\boldsymbol{k}_{\mathsf{h}}|^2/k_z^2) \cos^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t) + f^2 \sin^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)\big], \tag{57.176}$$

which can be written in the more tidy form through use of the dispersion relation (57.147)

$$\mathcal{K}' = \frac{\widetilde{\varphi}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2 [f^2 + (N_{\mathsf{R}}^2 \cot^2\gamma) \cos^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)]}{2\, (\omega^2 - f^2)^2}, \tag{57.177}$$

where we set

$$\cot\gamma = |\boldsymbol{k}_{\mathsf{h}}|/k_z. \tag{57.178}$$

Likewise, the available potential energy is given by

$$\mathcal{A}' = \frac{\widetilde{\varphi}^2\, (|\boldsymbol{k}_{\mathsf{h}}|^2\, N_{\mathsf{R}}^2 \cot^2\gamma) \sin^2(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}{2\, (\omega^2 - f^2)^2}. \tag{57.179}$$

Taking the sum leads to the total mechanical energy in a plane inertia-gravity wave

$$\mathcal{K}' + \mathcal{A}' = \frac{\widetilde{\varphi}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2\, (f^2\, k_z^2 + N_{\mathsf{R}}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2)}{2\, k_z^2\, (\omega^2 - f^2)^2} \tag{57.180}$$

Time independence of mechanical energy for the plane inertia-gravity wave accords with the result (57.99) for the plane internal gravity wave.

Phase averaged energetics

Taking the phase averages on the kinetic energy and available potential energy leads to

$$\langle \mathcal{K}' \rangle = \frac{\widetilde{\varphi}^2\, |\boldsymbol{k}_{\mathsf{h}}|^2\, (\omega^2\, |\boldsymbol{k}|^2 + f^2\, k_z^2)}{4\, k_z^2\, (\omega^2 - f^2)^2} \quad \text{and} \quad \langle \mathcal{A}' \rangle = \frac{\widetilde{\varphi}^2\, N_{\mathsf{R}}^2\, |\boldsymbol{k}_{\mathsf{h}}|^4}{4\, k_z^2\, (\omega^2 - f^2)^2}, \tag{57.181}$$

whose sum is

$$\langle \mathcal{K}' + \mathcal{A}' \rangle = \frac{\widetilde{\varphi}^2 \, |\boldsymbol{k}_{\mathsf{h}}|^2 \, (\omega^2 \, |\boldsymbol{k}|^2 + f^2 \, k_z^2 + N_{\mathsf{R}}^2 \, \boldsymbol{k}_{\mathsf{h}}^2)}{4 \, k_z^2 \, (\omega^2 - f^2)^2} = \frac{\widetilde{\varphi}^2 \, |\boldsymbol{k}_{\mathsf{h}}|^2 \, (f^2 \, k_z^2 + N_{\mathsf{R}}^2 \, \boldsymbol{k}_{\mathsf{h}}^2)}{2 \, k_z^2 \, (\omega^2 - f^2)^2} \tag{57.182}$$

and ratio is

$$\frac{\langle \mathcal{K}' \rangle}{\langle \mathcal{A}' \rangle} = 1 + 2 \, (f/N_{\mathsf{R}})^2 \tan^2 \gamma = \frac{\omega^2 \, |\boldsymbol{k}|^2 + f^2 \, k_z^2}{N_{\mathsf{R}}^2 \, |\boldsymbol{k}_{\mathsf{h}}|^2}. \tag{57.183}$$

It is notable that the ratio is bounded below by unity, so that the kinetic energy is never less than the available potential energy. The ratio is unity when the phase velocity is horizontal ($\gamma = 0$), in which fluid particles have vertical trajectories and thus exhibit purely vertical buoyancy oscillations. This equipartition of kinetic and available potential energies (again, holding with$\gamma = 0$) was found for the internal gravity wave in Section 57.5.14. When the phase velocity is vertical, so that $\gamma = \pi/2$, the plane waves have no available potential energy since the fluid particles are exhibiting horizontal inertial oscillations and do not sample the background buoyancy field.

Phase averaged mechanical energy flux

The phase averaged mechanical energy flux is given by

$$\frac{\langle \boldsymbol{v}' \, \varphi' \rangle}{\widetilde{\varphi}^2} = \frac{\omega \, (k_z \, \boldsymbol{k}_{\mathsf{h}} - \hat{\boldsymbol{z}} \, |\boldsymbol{k}_{\mathsf{h}}|^2)}{2 \, k_z \, (\omega^2 - f^2)} \tag{57.184a}$$

$$= \frac{\omega^2 \, |\boldsymbol{k}|^4 \, \boldsymbol{c}_{\mathsf{g}}}{2 \, k_z^2 \, (N_{\mathsf{R}}^2 - f^2) \, (\omega^2 - f^2)} \tag{57.184b}$$

$$= \frac{\boldsymbol{c}_{\mathsf{g}} \, |\boldsymbol{k}_{\mathsf{h}}|^2 \, (f^2 \, k_z^2 + N_{\mathsf{R}}^2 \, |\boldsymbol{k}_{\mathsf{h}}|^2)}{2 \, k_z^2 \, (\omega^2 - f^2)^2}, \tag{57.184c}$$

where we made use of the inertia-gravity wave group velocity (57.161). Now the phase averaged mechanical energy is given by equation (57.182), so that the plane inertia-gravity waves exhibit the group velocity property also found for internal gravity waves in equation (57.104)

$$\langle \boldsymbol{v}' \, \varphi' \rangle = \boldsymbol{c}_{\mathsf{g}} \, (\mathcal{K}' + \mathcal{A}'). \tag{57.185}$$

That is, a plane inertia-gravity wave has a phase averaged mechanical energy flux equal to the group velocity times the phase averaged mechanical energy.

57.9.7 Comments

The inertial waves studied in Chapter 53 are the $N_{\mathsf{R}} = 0$ limit of inertia-gravity waves studied in the present section. It is notable that in the presence of any nonzero vertical stratification, the squared angular frequency of propagating inertia-waves is super-inertial, $\omega^2 \geq f^2$, whereas when $N_{\mathsf{R}} = 0$ the waves are sub-inertial, $\omega^2 \leq f^2$. If an inertial wave from an unstratified region, with $\omega^2 \leq f^2$, encounters stratification, then this low frequency wave cannot propagate into the stratified region.

57.10 Exercises

EXERCISE 57.1: REFLECTION CONDITIONS FOR INERTIAL WAVES
Inertial waves studied in Chapter 53 are the $N^2 = 0$ limit of inertia-gravity waves from Section

57.9. Emulating the analysis in Section 57.6.2 for internal gravity waves, determine the reflection conditions for packets of plane inertial waves. Figure 57.5 is drawn for internal gravity waves. Redraw this figure for inertial waves.

EXERCISE 57.2: INERTIA-GRAVITY WAVES IN A HYDROSTATIC FLUID

Throughout this chapter we studied inertia-gravity waves as they appear in a non-hydrostatic flow that satisfies the linear Boussineseq equations (57.17a)-(57.17d). However, inertia-gravity waves also exist in flows maintaining an approximate hydrostatic balance, and in this exercise we derive their dispersion relation and discuss the relation to the non-hydrostatic waves. Hint: see Section 57.9.2 as well as page 280 of *Vallis* (2017).

(a) Write the hydrostatic version of the linear Boussinesq equations (57.17a)-(57.17d).

(b) Following the methods from Section 57.9, derive the free wave equation satisfied by the vertical velocity, w', in a hydrostatic flow. That is, derive the hydrostatic version of equation (57.129). Show all steps.

(c) Derive the dispersion relation for inertia-gravity waves in a hydrostatic flow with a constant reference buoyancy frequency, N_{R}.

(d) Start from the dispersion relation for inertia-gravity waves in a non-hydrostatic flow. Discuss the maths and physics of the length scale limiting process that results in the dispersion relation for inertia-gravity waves in a hydrostatic flow.

(e) What does the hydrostatic limit say about the angular frequency of inertia-gravity waves relative to non-hydrostatic inertia-gravity waves?

Chapter 58

INTERNAL GRAVITY WAVES: CASE STUDIES

In this chapter we consider some case studies that help further our understanding of internal gravity waves as they appear in geophysical fluids. Sections 58.2 and 58.3 consider the generation of internal gravity waves via flow over topography, thus giving rise to *mountain waves*. Mountain waves arise when stratified fluid flows over topography in both the atmosphere (hence their name) and the ocean. We limit the analysis to *stationary waves*, which are time independent in the rest frame. Doing so allows us to avoid some of the more mathematical questions of transient adjustment. Even so, the discussion exposes us to some mathematical methods commonly used to study waves. It also deepens our understanding of gravity wave mechanics within a geophysical context.

Section 58.4 examines gravity waves within a gently varying stratification, making use of the ray theory presented in Chapter 50.

READER'S GUIDE TO THIS CHAPTER

This chapter is a natural extension of material studied in Chapter 57. Further resources for this chapter can be found in *Lighthill* (1978), *Pedlosky* (2003), *Sutherland* (2010), *Cushman-Roisin and Beckers* (2011), *Kundu et al.* (2016), *Vallis* (2017), and *Buijsman et al.* (2019). The second half of this video offers some pedagogical visualizations of stratified flow phenomena, and this video provides more visualizations from simulations and laboratory tank experiments.

58.1 Loose threads

- Work through the examples Legg notes, as well as material from *Vallis* (2017).
- Expand the ray theory in Section 58.4. Follow elements from Chapter 6 of *Sutherland* (2010).

58.2 Gravity waves from a sinusoidal mountain range

Following the discussion for inertial waves in Section 53.5.2, and for shallow water inertia-gravity waves in Section 56.2, we here consider a prescribed and fixed constant horizontal reference (background) flow on a stratified f-plane that moves over small amplitude topography (e.g., mountains) in an otherwise unbounded domain. The flow over a non-flat bottom provides a forcing of vertical motion as imposed by the bottom kinematic boundary condition, with a vertically moving fluid parcel sampling the continuously stratified reference buoyancy. As such, flow over topography in a continuously stratified fluid serves as a forcing for internal inertia-gravity waves. Those waves that propagate do so both vertically and horizontally throughout the domain. The horizontal wavenumber of the waves is set by the horizontal wavenumber of the topography. The angular frequency of stationary waves is fully determined by the Doppler shift from the moving reference flow, which is set by the wavevector of the topography and the flow speed. The vertical wavenumber of stationary waves is determined by the dispersion relation. As for surface gravity waves in Chapter 52, waves with high horizontal wavenumber are exponentially trapped near the mountains, whereas waves with lower horizontal wavenumber propagate vertically. The transition between evanescence and propagation is set by the ratio of the reference stratification to the reference flow.

The *mountain waves* studied in this section represent a rich area of geophysical fluid mechanics of primary importance for waves and mixing in the ocean and atmosphere. For the ocean, barotropic (depth independent) tidal motions offers an important source for the reference flow, with barotropic tidal motions generating internal waves that are referred to as *internal tides*. Our goal is to introduce some of the richness of this geophysical system by mathematically formulating the generation of linear internal waves and studying their properties. For simplicity, we focus on the *stationary waves* that arise from a fully developed wave field.[1] Some of the formulation in this section is analogous to that of the shallow water in Section 56.2, yet with two key distinctions. First, the fluid here is continuously stratified, and second, the flow is non-hydrostatic. Both of these properties support a rich wave field that is not constrained by the columnar motion found in hydrostatic shallow water layers.

58.2.1 Linearized equations with constant reference flow

Figure 58.1 depicts the physical system studied in this section, in which we consider a reference flow whose velocity is given by

$$\boldsymbol{v} = \boldsymbol{u}_{\mathrm{R}} + \boldsymbol{v}', \tag{58.1}$$

[1] Recall from Section 49.2 that stationary waves have no time dependence in the rest frame. We here encounter stationary waves as the steady solution to the propagating internal gravity wave equations. The initial value problem requires more mathematical machinery beyond our scope.

where $\boldsymbol{u}_{\mathsf{R}}$ is a prescribed space-time constant horizontal reference flow, and $\boldsymbol{v}'$ is the space-time dependent flow relative to this reference. Furthermore, we assume that the steady reference flow is in geostrophic balance with a prescribed reference pressure field

$$f_{\circ}\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathsf{R}} = -\nabla\varphi_{\mathsf{R}}. \tag{58.2}$$

Alternatively, for the case with $f_{\circ} = 0$, we simply assume the reference flow is down the prescribed gradient of the reference pressure. In either case we have no concern for how the reference pressure field is maintained, only that it supports the steady reference flow.

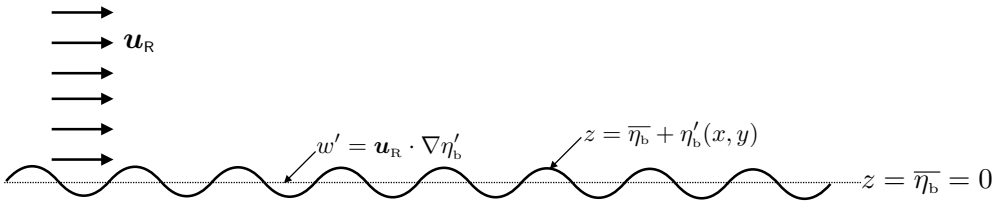

FIGURE 58.1: Schematic of a constant reference flow, $\boldsymbol{u}_{\mathsf{R}}$, moving over small amplitude monochromatic bottom topography, $z = \overline{\eta_{\mathsf{b}}} + \eta'_{\mathsf{b}}(x,y) = 0 + \eta_{\circ}\,\mathrm{e}^{\boldsymbol{k}_{\mathsf{b}}\cdot\boldsymbol{x}}$, where we assume $\overline{\eta_{\mathsf{b}}} = 0$, and with $\eta_{\circ}$ a real amplitude, and $\boldsymbol{k}_{\mathsf{b}}$ a horizontal wavevector. We choose to orient the topography wavevector so that $\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}_{\mathsf{b}} < 0$, which is based on noting that the reference flow, $\boldsymbol{u}_{\mathsf{R}}$, when viewed in the rest frame, is equivalent to topography moving in the direction opposite to $\boldsymbol{u}_{\mathsf{R}}$ when viewed in the boosted frame. We assume the topography has a small amplitude in the sense that $\eta_{\circ}\,|\boldsymbol{k}_{\mathsf{b}}| \ll 1$, thus ensuring that the generated waves are linear. There is no upper boundary nor side boundary, so waves generated by flow over the bottom are free to propagate horizonally and vertically. At the bottom, the full flow must satisfy the kinematic boundary condition, $w = \boldsymbol{u} \cdot \nabla\eta_{\mathsf{b}}$. Linearizing this boundary condition brings about its evaluation at $z = \overline{\eta_{\mathsf{b}}} = 0$ rather than at $z = \eta_{\mathsf{b}}(x,y)$. Additionally, with η'_{b} of small amplitude, the linearized bottom boundary condition is $w' = \boldsymbol{u}_{\mathsf{R}} \cdot \nabla\eta'_{\mathsf{b}} = \mathrm{i}\,(\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}_{\mathsf{b}})\,\eta'_{\mathsf{b}}$ at $z = 0$.

Following the steps in Section 57.2, we decompose the density and pressure according to

$$\rho(\boldsymbol{x},t) = \rho_{\circ} + \rho_{\mathsf{R}}(\boldsymbol{x}) + \rho'(\boldsymbol{x},t), \tag{58.3}$$

where the reference density, ρ_{R}, is a function of all three spatial coordinates, and where we consider two static pressures, $p_{\circ}$ and p_{R}, that are in hydrostatic balance with their corresponding densities

$$\frac{\mathrm{d}p_{\circ}}{\mathrm{d}z} = -\rho_{\circ}\,g \quad \text{and} \quad \frac{\partial p_{\mathsf{R}}}{\partial z} = -\rho_{\mathsf{R}}\,g. \tag{58.4}$$

Inserting this density and pressure decomposition in the Boussinesq equations (57.1a)-(57.1d), and then linearizing, leads to the linearized governing equations

$$(\partial_t + \boldsymbol{u}_{\mathsf{R}} \cdot \nabla)\boldsymbol{u}' + f_{\circ}\,\hat{\boldsymbol{z}} \times \boldsymbol{u}' = -\nabla_{\mathsf{h}}\varphi' \qquad \text{linear horizontal velocity equation} \tag{58.5a}$$

$$(\partial_t + \boldsymbol{u}_{\mathsf{R}} \cdot \nabla)w' = -\partial_z\varphi' + b' \qquad \text{linear vertical velocity equation} \tag{58.5b}$$

$$(\partial_t + \boldsymbol{u}_{\mathsf{R}} \cdot \nabla)b' = -w'\,N_{\mathsf{R}}^2 \qquad \text{linear buoyancy equation} \tag{58.5c}$$

$$\nabla \cdot \boldsymbol{v}' = 0 \qquad \text{continuity for velocity fluctuations,} \tag{58.5d}$$

which reduce to equations (57.17a)-(57.17d) when $\boldsymbol{u}_{\mathsf{R}} = 0$.

58.2.2 Bottom topography and bottom boundary condition

As for the shallow water case studied in Section 56.2 (in particular, see Section 56.2.4), we consider the domain to be bounded from below with monochromatic bottom topography undulations given by

$$\eta'_{\mathsf{b}}(x,y) = \eta_{\circ}\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}_{\mathsf{b}}\cdot\boldsymbol{x}}, \tag{58.6}$$

such as depicted in Figure 58.1. In this expression, $\eta_\circ$ is the real and constant amplitude of the topography and $\boldsymbol{k}_\flat$ is a horizontal wave number that specifies the direction and wavelength of the topography. Linearity of the waves generated by the topography is ensured by assuming

$$\eta_\circ \, |\boldsymbol{k}_\flat| \ll 1, \tag{58.7}$$

so that the amplitude of the topography is small on the length scale set by the topography's wavelength.

We orient the topography's wavevector, $\boldsymbol{k}_\flat$, to be opposite that of the reference flow, so that

$$\omega_\mathsf{R} = -\boldsymbol{u}_\mathsf{R} \cdot \boldsymbol{k}_\flat \geq 0, \tag{58.8}$$

where ω_R is an angular frequency of the bottom boundary forcing induced by the flow over the topography. As discussed in Section 56.2.5 when studying shallow water waves generated by topography, the sign for the inequality (58.8) reflects the fact that topography is stationary in the rest frame but it moves in the direction opposite to the reference flow when viewed in the frame following the reference flow. This inequality can be considered a causality condition and it is central to the phase functions encountered in the following.[2]

The no-flow bottom kinematic boundary condition for the full nonlinear flow takes the form (Section 19.6.1)

$$w = \boldsymbol{u} \cdot \nabla \eta_\flat \quad \text{at } z = \eta_\flat(x, y). \tag{58.9}$$

Inserting the velocity decomposition (58.1) and the bottom topography,

$$z = \overline{\eta_\flat} + \eta'_\flat(x, y), \tag{58.10}$$

leads to

$$w' = (\boldsymbol{u}' + \boldsymbol{u}_\mathsf{R}) \cdot \nabla(\overline{\eta_\flat} + \eta'_\flat) = (\boldsymbol{u}' + \boldsymbol{u}_\mathsf{R}) \cdot \nabla \eta'_\flat \approx \boldsymbol{u}_\mathsf{R} \cdot \nabla \eta'_\flat \quad \text{at } z = 0, \tag{58.11}$$

where the approximation arises from dropping the relatively small term, $\boldsymbol{u}' \cdot \nabla \eta'_\flat$.

58.2.3 Galilean transformation to the moving flow's reference frame

Following the shallow water case from Section 56.2.2, we transform to the moving frame of the constant reference flow by introducing the boosted (moving reference frame) coordinates

$$\overline{t} = t \quad \text{and} \quad \overline{\boldsymbol{x}} = \boldsymbol{x} - \boldsymbol{u}_\mathsf{R} \, t \quad \text{and} \quad \overline{\boldsymbol{v}} = \boldsymbol{v} - \boldsymbol{u}_\mathsf{R}. \tag{58.12}$$

Observers in the rest frame see the topography at rest and the reference flow moving with velocity, $\boldsymbol{u}_\mathsf{R}$. In contrast, observers in the boosted reference frame see the topography moving with velocity $-\boldsymbol{u}_\mathsf{R}$ whereas the reference flow is at rest. Since the flow is constant in space and time, the two observers are inertial, so the transformation between the two reference frames is Galilean (Section 17.5). Following the discussion in Section 17.5, the Galilean transformation (58.12) leads to the transformed differential operators

$$\partial_{\overline{t}} = \partial_t + \boldsymbol{u}_\mathsf{R} \cdot \nabla \quad \text{and} \quad \overline{\nabla} = \nabla, \tag{58.13}$$

and the corresponding transformation of the linearized governing equations (58.5a)-(58.5d)

$$\partial_{\overline{t}} \boldsymbol{u}' + f_\circ \, \hat{\boldsymbol{z}} \times \boldsymbol{u}' = -\overline{\nabla}_\mathsf{h} \varphi' \tag{58.14a}$$

[2] We are considering the steady state flow where one generally has time symmetry. However, keeping in mind the transient situation where time symmetry is broken, we here break time symmetry through acknowledging a directionality to the reference flow (left to right) and by insisting that the forcing angular frequency, ω_R, is positive.

$$\partial_{\bar{t}} w' = -\partial_{\bar{z}} \varphi' + b' \tag{58.14b}$$

$$\partial_{\bar{t}} b' = -w' \, N_{\mathsf{R}}^2 \tag{58.14c}$$

$$\overline{\nabla} \cdot \boldsymbol{v}' = 0. \tag{58.14d}$$

Notice how transformation to the moving frame removed advection by the reference flow from the horizontal velocity equation.

58.2.4 Free space dispersion relation with moving reference flow

Before considering the case of a lower boundary, we here establish some basic results for waves moving in a uniform flow in free space. For that purpose, note that equations (58.14a)-(58.14d) are mathematically identical to the linear equations (57.17a)-(57.17d) that apply to the case of zero reference flow, only here with the time derivative computed in the boosted reference frame, $\partial_{\bar{t}}$, rather than the rest frame time derivative, ∂_t. Consequently, when assuming a constant reference state buoyancy frequency, the equation for the vertical velocity in the boosted reference frame is given by equation (57.144) with boosted coordinates

$$(\partial_{\bar{t}\bar{t}} \, \overline{\nabla}^2 + N_{\mathsf{R}}^2 \, \overline{\nabla_{\mathsf{h}}^2} + f^2 \, \partial_{\bar{z}\bar{z}}) \, w' = 0. \tag{58.15}$$

In the absence of any boundaries, the phase function for linear waves is written[3]

$$\boldsymbol{k} \cdot \boldsymbol{x} - \omega \, t = \boldsymbol{k} \cdot (\overline{\boldsymbol{x}} + \boldsymbol{u}_{\mathsf{R}} \, t) - \omega \, t = \boldsymbol{k} \cdot \overline{\boldsymbol{x}} - (\omega - \boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}) \, \bar{t} = \boldsymbol{k} \cdot \overline{\boldsymbol{x}} - \overline{\omega} \, \bar{t}, \tag{58.16}$$

where the final equality introduced[4]

$$\overline{\omega} = \omega - \boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}, \tag{58.17}$$

which relates the angular frequency in the boosted frame, $\overline{\omega}$, to that in the rest frame, ω. The frequency shift, $-\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}$, is known as the *Doppler shift*, which vanishes when the phase is directed orthogonal to the reference flow, $\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k} = 0$. Furthermore, the boosted frame's angular frequency, $\overline{\omega}$, vanishes for waves whose Doppler shift satisfies $\omega = \boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}$. For these waves, the boosted reference frame rides along a fixed wave and so there is no propagation within this reference frame.

Critical levels

Plugging the free wave ansatz,

$$w' = \widetilde{w} \, \mathrm{e}^{\mathrm{i} \, (\boldsymbol{k} \cdot \overline{\boldsymbol{x}} - \overline{\omega} \, \bar{t})}, \tag{58.18}$$

into the vertical velocity equation (58.15) leads to the dispersion relation

$$\overline{\omega}^2 = (\omega - \boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k})^2 = N_{\mathsf{R}}^2 \cos^2 \gamma + f_{\mathsf{o}}^2 \sin^2 \gamma = [(N_{\mathsf{R}} \, \boldsymbol{k}_{\mathsf{h}})^2 + (f_{\mathsf{o}} \, k_z)^2] / |\boldsymbol{k}|^2. \tag{58.19}$$

This is a straightforward extension of the frequency from the rest frame value, ω, to the moving frame.

[3] Throughout this book we are working with particle and wave speeds that are far smaller than the speed of light, thus enabling the use of Galilean space-time rather than Lorentz space-time. Hence, we do not encounter the special relativistic effects from length contraction, and so there are no changes to the wavelength when moving to the Galilean boosted reference frame. Consequently, movement to the Galilean boosted reference frame leaves the wavevector, $\boldsymbol{k}$, unchanged.

[4] We introduced the same angular frequency relation in equation (56.38) for shallow water waves generated by flow over topography.

Wave energy propagates according to the group velocity, which we compute from the wavevector gradient

$$\nabla_{\boldsymbol{k}}\overline{\omega}^2 = 2\,\overline{\omega}\,\nabla_{\boldsymbol{k}}\overline{\omega} = 2\,\overline{\omega}\,(\nabla_{\boldsymbol{k}}\omega - \boldsymbol{u}_{\mathsf{R}}) = 2\,\overline{\omega}\,(\boldsymbol{c}_{\mathsf{g}} - \boldsymbol{u}_{\mathsf{R}}), \tag{58.20}$$

where $\boldsymbol{c}_{\mathsf{g}} = \nabla_{\boldsymbol{k}}\omega$ is the group velocity (57.161) as measured in the rest frame, and $\boldsymbol{c}_{\mathsf{g}} - \boldsymbol{u}_{\mathsf{R}}$ is that in the moving frame. Computing $\nabla_{\boldsymbol{k}}\overline{\omega}^2$ yields

$$\boldsymbol{c}_{\mathsf{g}} - \boldsymbol{u}_{\mathsf{R}} = \frac{(N_{\mathsf{R}}^2 - f^2)\,k_z}{\overline{\omega}\,|\boldsymbol{k}|^4}\,(k_z\,\boldsymbol{k}_{\mathsf{h}} - |\boldsymbol{k}_{\mathsf{h}}|^2\,\hat{\boldsymbol{z}}). \tag{58.21}$$

It is particularly revealing to consider gravity waves with $f_{\mathsf{o}} = 0$, in which we find the vertical component to the group velocity

$$\hat{\boldsymbol{z}} \cdot \boldsymbol{c}_{\mathsf{g}} = -(\omega - \boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k})\,k_z/|\boldsymbol{k}|^2. \tag{58.22}$$

The group velocity slows down, and halts, as the wave frequency approaches $\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}$. Although derived here for a constant reference flow, this equation holds to leading order for gently varying reference flows using WKBJ methods as in Section 58.4. In such cases we can find the vertical component of the group velocity vanish at certain *critical levels*, which are levels where waves can deposit their energy to the mean flow.

58.2.5 Wavenumbers for stationary inertial-gravity waves

Now consider the case of a monochromatic bottom (mountains) as depicted in Figure 58.1, with bottom topography of the form

$$\eta'_{\mathsf{b}} = \eta_{\mathsf{o}}\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}_{\mathsf{b}}\cdot\boldsymbol{x}} = \eta_{\mathsf{o}}\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_{\mathsf{b}}\cdot\overline{\boldsymbol{x}} - \omega_{\mathsf{R}}\,\overline{t})}. \tag{58.23}$$

The topography is static in the rest frame, whereas it is a traveling plane wave in the boosted frame with angular frequency $\omega_{\mathsf{R}} = -\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}_{\mathsf{b}} \geq 0$ given from equation (58.8). In the presence of topography, the waves are not free in all three directions. Rather, they must satisfy the bottom boundary condition (58.11), which takes on the following form for a monochromatic mountain range

$$w'(z=0) = \boldsymbol{u}_{\mathsf{R}} \cdot \nabla\eta'_{\mathsf{b}} = \mathrm{i}\,(\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}_{\mathsf{b}})\,\eta'_{\mathsf{b}} = -\mathrm{i}\,\omega_{\mathsf{R}}\,\eta'_{\mathsf{b}}. \tag{58.24}$$

For waves that are stationary in the rest frame ($\omega = 0$ so that $\overline{\omega} = \omega_{\mathsf{R}}$), we satisfy the boundary condition (58.24) by setting the vertical velocity to

$$w' = -\mathrm{i}\,\omega_{\mathsf{R}}\,\eta_{\mathsf{o}}\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_{\mathsf{b}}\cdot\overline{\boldsymbol{x}} + k_z\,\overline{z} - \omega_{\mathsf{R}}\,\overline{t})} = -\mathrm{i}\,\omega_{\mathsf{R}}\,\eta_{\mathsf{o}}\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_{\mathsf{b}}\cdot\boldsymbol{x} + k_z\,z)}, \tag{58.25}$$

which has a real part given by

$$w' = \omega_{\mathsf{R}}\,\eta_{\mathsf{o}}\sin(\boldsymbol{k}_{\mathsf{b}} \cdot \boldsymbol{x} + k_z\,z). \tag{58.26}$$

Notably, the horizontal wavevector is set by the topography,

$$\boldsymbol{k}_{\mathsf{h}} = \boldsymbol{k}_{\mathsf{b}}. \tag{58.27}$$

With constant N_{R}, we can use the stationary form of the dispersion relation (58.19),

$$\overline{\omega}^2 = \omega_{\mathsf{R}}^2 = (\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k})^2 = N_{\mathsf{R}}^2\cos^2\gamma + f_{\mathsf{o}}^2\sin^2\gamma = [(N_{\mathsf{R}}\,|\boldsymbol{k}_{\mathsf{h}}|)^2 + (f_{\mathsf{o}}\,k_z)^2]/|\boldsymbol{k}|^2, \tag{58.28}$$

to find the squared vertical wavenumber for the stationary inertia-gravity waves (again, $\boldsymbol{k}_{\mathsf{h}} = \boldsymbol{k}_{\mathsf{b}}$

via equation (58.27))

$$k_z^2 = \frac{|\boldsymbol{k}_\mathsf{b}|^2 \, (N_\mathsf{R}^2 - \omega_\mathsf{R}^2)}{\omega_\mathsf{R}^2 - f_\circ^2}, \tag{58.29}$$

with the vertical wavenumber either real or imaginary according to

$$k_z^2 = \begin{cases} < 0 & \text{if } \omega_\mathsf{R}^2 < f_\circ^2 \\ > 0 & \text{if } f_\circ^2 < \omega_\mathsf{R}^2 < N_\mathsf{R}^2 \\ < 0 & \text{if } \omega_\mathsf{R}^2 > N_\mathsf{R}^2. \end{cases} \tag{58.30}$$

The cases with $k_z^2 < 0$ lead to stationary waves that are oscillating in the horizontal yet exponentially trapped in the vertical, much like the surface gravity waves studied in Chapter 52 or the edge waves studied in 54.5. In contrast, with $k_z^2 > 0$ there are stationary waves extending throughout the vertical. The regime of vertically extended stationary waves is given by

$$2\pi / N_\mathsf{R} < \Lambda_\mathsf{b} / U < 2\pi / f_\circ, \tag{58.31}$$

where

$$\Lambda_\mathsf{b} = 2\pi / |\boldsymbol{k}_\mathsf{b}| \tag{58.32}$$

is the topography's wavelength. In the atmosphere, typical values for the reference state are $N_\mathsf{R} = 10^{-2}$ s^{-1}, $U = 10$ m s^{-1}, and $f_\circ = 10^{-4}$ s^{-1}, in which case there are vertically extended inertia-gravity waves for mountains having wavelengths within the range

$$2\pi \, U / N_\mathsf{R} < \Lambda_\mathsf{b} < 2\pi \, U / f_\circ \implies 2\pi \times 10^3 \text{ m} < \Lambda_\mathsf{b} < 2\pi \times 10^5 \text{ m}. \tag{58.33}$$

For the deep ocean we take $N_\mathsf{R} = 10^{-3}$ s^{-1}, $U = 10^{-1}$ m s^{-1} (barotropic tidal speeds), and $f_\circ = 10^{-4}$ s^{-1}, so that there are vertically extended stationary inertia-gravity waves for undersea mountains having wavelengths within the range

$$2\pi \times 10^2 \text{ m} < \Lambda_\mathsf{b} < 2\pi \times 10^3 \text{ m}. \tag{58.34}$$

These numbers are only meant to give an impression of the approximate scales of mountain forcing that generate vertically extended internal inertia-gravity waves. One key point is the roughly one order smaller scales for the ocean relative to the atmosphere.

58.2.6 Stationary mountain waves with $f_\circ^2 < \omega_\mathsf{R}^2 < N_\mathsf{R}^2$

For $f_\circ^2 < \omega_\mathsf{R}^2 < N_\mathsf{R}^2$, we have stationary inertia-gravity waves with $k_z^2 > 0$ according to equation (58.29). As the reference flow interacts with the mountains at the lower boundary, internal inertia-gravity waves propagate energy upwards according to the group velocity. As seen in Section 57.5.10, an upward group velocity means a downward phase velocity, so that we take the negative root from equation (58.29)

$$k_z = -|\boldsymbol{k}_\mathsf{b}| \sqrt{\frac{N_\mathsf{R}^2 - \omega_\mathsf{R}^2}{\omega_\mathsf{R}^2 - f_\circ^2}} = -|k_z| < 0, \tag{58.35}$$

which renders the stationary vertical velocity in the wave[5]

$$w' = -\mathrm{i} \, \omega_\mathsf{R} \, \eta_\circ \, \mathrm{e}^{\mathrm{i} \, (\boldsymbol{k}_\mathsf{b} \cdot \boldsymbol{x} - |k_z| \, z)}. \tag{58.36}$$

[5]In equation (58.35), and elsewhere in this chapter, we find it useful to introduce the absolute value around a wavenumber in order to clearly expose the sign of the wavenumber. Doing so can greatly help in capturing the proper phase relations for the waves.

For the specific case of zonal reference flow, $\boldsymbol{u}_{\mathsf{R}} = U\,\hat{\boldsymbol{x}}$ with $U > 0$, we have $\boldsymbol{k}_{\mathsf{b}} = -|\boldsymbol{k}_{\mathsf{b}}|\,\hat{\boldsymbol{x}}$, so that

$$\omega_{\mathsf{R}} = -\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}_{\mathsf{b}} = U\,|\boldsymbol{k}_{\mathsf{b}}| \implies w' = -\mathrm{i}\,U\,|\boldsymbol{k}_{\mathsf{b}}|\,\eta_{\circ}\,\mathrm{e}^{-\mathrm{i}\,(|\boldsymbol{k}_{\mathsf{b}}|\,x + |k_z|\,z)}, \tag{58.37}$$

which has real part

$$w' = \widetilde{w}\sin(|\boldsymbol{k}_{\mathsf{b}}|\,x + |k_z|\,z) = -U\,|\boldsymbol{k}_{\mathsf{b}}|\,\eta_{\circ}\sin(|\boldsymbol{k}_{\mathsf{b}}|\,x + |k_z|\,z), \tag{58.38}$$

where we defined the vertical velocity amplitude

$$\widetilde{w} = -U\,|\boldsymbol{k}_{\mathsf{b}}|\,\eta_{\circ}. \tag{58.39}$$

Evidently, the vertical velocity amplitude is directly related to the reference flow magnitude, the topography wavenumber, and the topography amplitude.

To determine polarization relations for the other fields, we can return to those derived earlier for the free waves in Section 58.2.4, specializing to the case with $\omega = \omega_{\mathsf{R}}$. Alternatively, we can set $\partial_t = 0$ in the linear governing equations (58.5a)-(58.5d). This work is considered in Exercise 58.1 and follows a method similar to that taken for stationary mountain gravity waves in Section 58.2.7.

58.2.7 Stationary mountain waves with $0 < \omega_{\mathsf{R}}^2 < N_{\mathsf{R}}^2$

We now specialize to $f_{\circ} = 0$, such as appropriate for mountain waves that are small enough laterally to not feel the impacts from Coriolis. Also, continue to assume a zonal reference flow, $\boldsymbol{u}_{\mathsf{R}} = U\,\hat{\boldsymbol{x}}$ with $U > 0$ and $\boldsymbol{k}_{\mathsf{b}} = -|\boldsymbol{k}_{\mathsf{b}}|\,\hat{\boldsymbol{x}}$. The vertical velocity is still given by equation (58.38)

$$w' = -U\,|\boldsymbol{k}_{\mathsf{b}}|\,\eta_{\circ}\sin(|\boldsymbol{k}_{\mathsf{b}}|\,x + |k_z|\,z), \tag{58.40}$$

yet here with the angular frequency for stationary waves given by

$$\omega_{\mathsf{R}} = N_{\mathsf{R}}\,|\boldsymbol{k}_{\mathsf{b}}|/|\boldsymbol{k}| = U\,|\boldsymbol{k}_{\mathsf{b}}| \implies U = N_{\mathsf{R}}/|\boldsymbol{k}|, \tag{58.41}$$

and the vertical wavenumber corresponding to an upward directed group velocity

$$k_z = -|\boldsymbol{k}_{\mathsf{b}}|\sqrt{(N_{\mathsf{R}}/\omega_{\mathsf{R}})^2 - 1} = -\sqrt{(N_{\mathsf{R}}/U)^2 - |\boldsymbol{k}_{\mathsf{b}}|^2} < 0. \tag{58.42}$$

As discussed in Exercise 58.2, the frequency ratio,

$$\mathrm{Fr}(|\boldsymbol{k}_{\mathsf{b}}|) = \frac{\omega_{\mathsf{R}}}{N_{\mathsf{R}}} = \frac{U\,|\boldsymbol{k}_{\mathsf{b}}|}{N_{\mathsf{R}}}, \tag{58.43}$$

can be considered a wavenumber dependent Froude number. Inserting this Froude number into equation (58.42) yields

$$k_z = -|\boldsymbol{k}_{\mathsf{b}}|\sqrt{\mathrm{Fr}^{-2} - 1}, \tag{58.44}$$

so that the Froude number distinguishes vertically propagating stationary gravity waves ($\mathrm{Fr} < 1$) from vertically evanescent waves ($\mathrm{Fr} > 1$).

Lines of constant phase

For the vertical propagating waves ($\mathrm{Fr} < 1$), the vertical velocity (58.40) is constant along phase lines that satisfy

$$|\boldsymbol{k}_{\mathsf{b}}|\,x + |k_z|\,z = \text{constant}. \tag{58.45}$$

These phase lines have a slope

$$\frac{\mathrm{d}z}{\mathrm{d}x} = -|\boldsymbol{k}_\mathrm{b}|/|k_z|, \tag{58.46}$$

which indicates that the phase lines slope up to the left such as depicted in Figure 58.2. Evidently, the phase lines tilt into the reference flow.

Polarization relations

The polarization relations for the stationary waves are determined by the steady linear governing equations (58.5a)-(58.5d) with $f_\circ = 0$ and $\partial_t = 0$

$$(\boldsymbol{u}_\mathrm{R} \cdot \nabla)\boldsymbol{u}' = -\nabla_\mathrm{h}\varphi' \qquad \text{steady linearized horizontal velocity equation} \tag{58.47a}$$
$$(\boldsymbol{u}_\mathrm{R} \cdot \nabla)w' = -\partial_z\varphi' + b' \qquad \text{steady linearized vertical velocity equation} \tag{58.47b}$$
$$(\boldsymbol{u}_\mathrm{R} \cdot \nabla)b' = -w'\, N_\mathrm{R}^2 \qquad \text{steady linearized buoyancy equation} \tag{58.47c}$$
$$\nabla \cdot \boldsymbol{v}' = 0 \qquad \text{continuity for velocity fluctuations.} \tag{58.47d}$$

All motion is in the x-z plane, so that the continuity equation (58.47d) gives the zonal velocity

$$u' = -(|k_z|/|\boldsymbol{k}_\mathrm{b}|)\, w' \Longrightarrow u'\, \frac{\mathrm{d}z}{\mathrm{d}x} = w' \quad \text{and} \quad u' = U\, |k_z|\, \eta_\circ \sin(|\boldsymbol{k}_\mathrm{b}|\, x + |k_z|\, z), \tag{58.48}$$

where we used the slope relation (58.46). The steady buoyancy equation (58.47c) yields

$$U\, \partial_x b' = N_\mathrm{R}^2\, U\, |\boldsymbol{k}_\mathrm{b}|\, \eta_\circ \sin(|\boldsymbol{k}_\mathrm{b}|\, x + |k_z|\, z) \Longrightarrow b' = -\eta_\circ\, N_\mathrm{R}^2 \cos(|\boldsymbol{k}_\mathrm{b}|\, x + |k_z|\, z). \tag{58.49}$$

Likewise, the steady horizontal velocity equation (58.47a) gives the wave pressure

$$\varphi' = -U\, u' = -\eta_\circ\, |k_z|\, U^2 \sin(|\boldsymbol{k}_\mathrm{b}|\, x + |k_z|\, z). \tag{58.50}$$

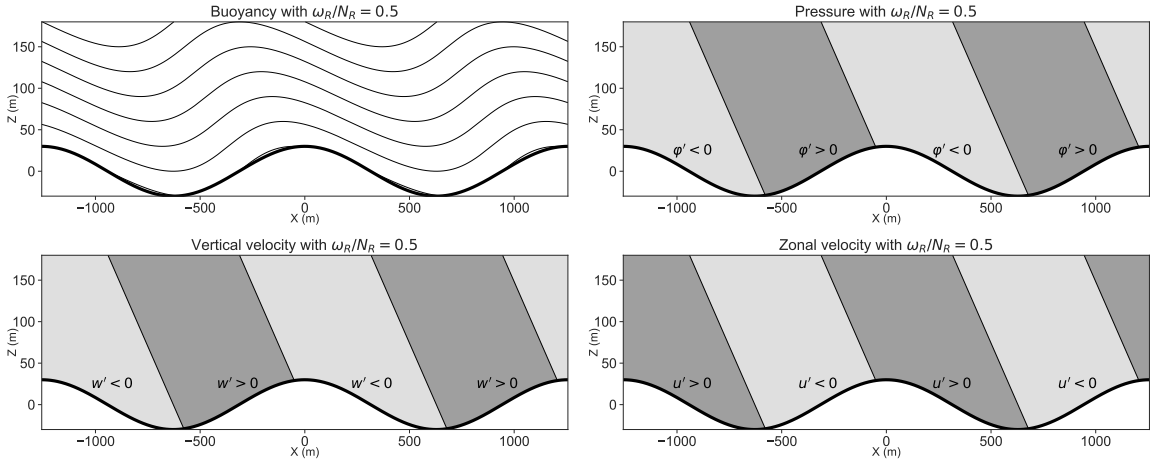

FIGURE 58.2: Stationary mountain gravity waves generated by an eastward reference flow, $\boldsymbol{u}_\mathrm{R} = U\,\hat{\boldsymbol{x}}$, over monochromatic topography. We set the parameters according to ocean values, with $\eta_\circ = 30$ m, $U = 0.1$ m s^{-1}, $N_\mathrm{R} = 10^{-3}$ s^{-1}, and $\Lambda_\mathrm{b} = 2\pi \times 200$ m, so that $\omega_\mathrm{R}/N_\mathrm{R} = 0.5$. Top left panel: contours of the buoyancy field, $b = b_\mathrm{R} + b'$, with $b_\mathrm{R} = N_\mathrm{R}^2\, z$ and $b' = -\eta_\circ\, N_\mathrm{R}^2 \cos(|\boldsymbol{k}_\mathrm{b}|\, x + |k_z|\, z)$ from equation (58.49). Top right panel: perturbation pressure field, $\varphi' = -U\, u' = U\, w'\, |k_z|/|\boldsymbol{k}_\mathrm{b}|$, from equation (58.50). Lower left panel: the vertical velocity anomaly, $w' = -U\, |\boldsymbol{k}_\mathrm{b}|\, \eta_\circ \sin(|\boldsymbol{k}_\mathrm{b}|\, x + |k_z|\, z)$ from equation (58.40). Lower right panel: the zonal velocity anomaly, $u' = -|k_z|/|\boldsymbol{k}_\mathrm{b}|\, w'$ from equation (58.48). The color scale is set to highlight just the sign of the field. The phase shift, whereby high pressures are on the windward side of the mountains and low pressures on the lee side, leads to a topographic pressure form stress acting on the fluid according to equation (58.51).

Wave induced topographic form stress

In Figure 58.2 we illustrate the buoyancy, pressure, vertical velocity, and zonal velocity within a stationary gravity wave for a particular set of parameters. Note the phase lines that are tilted into the mean flow with the positive pressure perturbation on the upwind side of the mountains. This orientation is reflective of the general discussion surrounding Figure 28.8 when studying pressure form stress acting between the fluid and the solid lower boundary. From that discussion we know that a positive pressure anomaly on the upwind side of a mountain renders an eastward form stress from the fluid to the solid, and a corresponding (through Newton's third law) westward topographic form stress directed from the solid to the fluid.

From the discussion in Section 28.2.2, we write the topographic form stress acting on the fluid as $-p \nabla \eta_\mathrm{b}$. The pressure is evaluated at the solid-fluid boundary for the nonlinear case, whereas for linear waves we evaluate the topographic form stress at $z = 0$, with a phase average yielding

$$\langle -\varphi' \, \partial_x \eta_\mathrm{b} \rangle = -U^2 \, \eta_\mathrm{o}^2 \, |\boldsymbol{k}_\mathrm{b}| \, |k_z|/2. \tag{58.51}$$

This westward topographic form stress acts from the solid onto the fluid, with a corresponding eastward form stress of the same magnitude from the fluid to the solid. The stress is directly related to the square of the reference flow speed and the square of the topography amplitude. It is also linearly related to the vertical wavenumber of the gravity wave and the vertical wavenumber of the topography. Since the stress is directed contrary to the reference flow direction, it is commonly referred to as a *mountain drag*.

Wave energy flux

From Section 57.5.14 we know that the energy flux carried by a gravity wave is given by $\boldsymbol{v}' \, \varphi'$. For stationary mountain waves in the x-z plane we have

$$\boldsymbol{v}' \, \varphi' = -(\hat{\boldsymbol{x}} \, u' + \hat{\boldsymbol{z}} \, w') \, U \, u' = \frac{U \, w' \, w' \, |k_z|}{|\boldsymbol{k}_\mathrm{b}|^2} \, (-|k_z| \, \hat{\boldsymbol{x}} + |\boldsymbol{k}_\mathrm{b}| \, \hat{\boldsymbol{z}}). \tag{58.52}$$

Now the group velocity for internal gravity waves is given by equation (57.71), which takes on the following form for the forced stationary waves

$$\boldsymbol{c}_\mathrm{g} = \frac{N_\mathsf{R} \, k_z}{|\boldsymbol{k}|^3 \, |\boldsymbol{k}_\mathrm{b}|} \, (k_z \, \boldsymbol{k}_\mathrm{b} - |\boldsymbol{k}_\mathrm{b}|^2 \, \hat{\boldsymbol{z}}) \tag{58.53a}$$

$$= \frac{N_\mathsf{R} \, |k_z|}{|\boldsymbol{k}|^3} \, (-|k_z| \, \hat{\boldsymbol{x}} + |\boldsymbol{k}_\mathrm{b}| \, \hat{\boldsymbol{z}}) \tag{58.53b}$$

$$= \frac{U \, |k_z|}{|\boldsymbol{k}|^2} \, (-|k_z| \, \hat{\boldsymbol{x}} + |\boldsymbol{k}_\mathrm{b}| \, \hat{\boldsymbol{z}}), \tag{58.53c}$$

where the second equality set $\boldsymbol{k}_\mathrm{b} = -|\boldsymbol{k}_\mathrm{b}| \, \hat{\boldsymbol{x}}$ and $k_z = -|k_z| < 0$, and the third equality set $U = N_\mathsf{R}/|\boldsymbol{k}|$ from equation (58.41). Next, we make use of equation (57.101) to write the mechanical energy within the stationary internal gravity wave

$$\mathcal{K}' + \mathcal{A}' = \langle w' \, w' \rangle \, |\boldsymbol{k}|^2/|\boldsymbol{k}_\mathrm{b}|^2 = \tfrac{1}{2} \, \eta_\mathrm{o}^2 \, U^2 \, |\boldsymbol{k}|^2 = \tfrac{1}{2} \, \eta_\mathrm{o}^2 \, N_\mathsf{R}^2, \tag{58.54}$$

which then brings the phase averaged energy flux to the standard form holding for a linear wave

$$\langle \boldsymbol{v}' \, \varphi' \rangle = \boldsymbol{c}_\mathrm{g} \, (\mathcal{K}' + \mathcal{A}'). \tag{58.55}$$

58.2.8 Trapped mountain waves with $\omega_{\mathsf{R}} > N_{\mathsf{R}}$

For the case with mountain forcing at a frequency greater than buoyancy frequency, $\omega_{\mathsf{R}} > N_{\mathsf{R}}$, the vertical wavenumber becomes imaginary

$$k_z = \mathrm{i}\sqrt{|\boldsymbol{k}_{\mathsf{b}}|^2 - (N_{\mathsf{R}}/U)^2} = \mathrm{i}\,|k_z|, \tag{58.56}$$

which yields a wave solution that is exponentially decaying away from the mountains (see equation (58.36) and remember that $\boldsymbol{k}_{\mathsf{b}} = -|\boldsymbol{k}_{\mathsf{b}}|\,\hat{\boldsymbol{x}}$ and $\omega_{\mathsf{R}} = U\,|\boldsymbol{k}_{\mathsf{b}}| > 0$)

$$w' = -\mathrm{i}\,\omega_{\mathsf{R}}\,\eta_{\mathsf{o}}\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}_{\mathsf{b}}\cdot\boldsymbol{x} - |k_z|\,z} \xrightarrow{\text{Re}} -U\,|\boldsymbol{k}_{\mathsf{b}}|\,\eta_{\mathsf{o}}\sin(|\boldsymbol{k}_{\mathsf{b}}|\,x)\,\mathrm{e}^{-|k_z|\,z}. \tag{58.57}$$

We refer to these fluctuations as *vertically evanescent* or *vertically trapped* gravity waves. The corresponding zonal velocity, buoyancy, and pressure fields are

$$u' = U\,|k_z|\,\eta_{\mathsf{o}}\cos(|\boldsymbol{k}_{\mathsf{b}}|\,x)\,\mathrm{e}^{-|k_z|\,z} \tag{58.58a}$$

$$b' = -\eta_{\mathsf{o}}\,N_{\mathsf{R}}^2\cos(|\boldsymbol{k}_{\mathsf{b}}|\,x)\,\mathrm{e}^{-|k_z|\,z} \tag{58.58b}$$

$$\varphi' = -U^2\,|k_z|\,\eta_{\mathsf{o}}\cos(|\boldsymbol{k}_{\mathsf{b}}|\,x)\,\mathrm{e}^{-|k_z|\,z}. \tag{58.58c}$$

Zero energy propagation and zero topographic form stress

Since the vertical velocity (58.57) and pressure (58.58c) are $\pi/2$ radians out of phase, vertically trapped waves generate no vertical propagation of phase averaged wave energy

$$\langle w'\,\varphi'\rangle = 0. \tag{58.59}$$

Likewise, there is no topographic form stress since there is no phase shift between the topography and the pressure

$$\langle \varphi'\,\partial_x \eta_{\mathsf{b}}\rangle = 0. \tag{58.60}$$

Limit where $\omega_{\mathsf{R}} \gg N_{\mathsf{R}}$

The case of $\omega_{\mathsf{R}} \gg N_{\mathsf{R}}$ corresponds to large topographic frequency and/or small buoyancy frequency. In this limit the vertical wavenumber has a magnitude $|k_z| \approx |\boldsymbol{k}_{\mathsf{b}}|$ so that N_{R} drops out from the system. This case corresponds to the surface gravity waves studied in Chapter 52 where stratification was completely ignored. In that case, as well as here, the exponential trapping is determined by the horizontal wavenumber, $|\boldsymbol{k}_{\mathsf{b}}|$. Furthermore, in the case with vertical length scales, H, such that $|k_z|\,H \approx |\boldsymbol{k}_{\mathsf{b}}|\,H \ll 1$, then the vertical velocity becomes a linear function of z. This case corresponds to the shallow water inertia-gravity waves studied in Section 56.2

Comments on exponential trapping

As discussed in Section 57.5.8, forcing a stratified fluid at a frequency greater than the buoyancy frequency does not lead to propagating internal gravity waves. For the case of mountain gravity waves, we see that exponential trapping arises when the topographic forcing has a frequency, ω_{R}, greater than the maximum frequency of the buoyancy oscillations, N_{R}. In this case, motion induced by the forcing is too fast for fluid particles to exhibit buoyancy oscillations. The result is fluid particles largely following whatever displacements are imposed on them by the external forcing, with exponential damping when moving away from the forcing and with fluid particles in phase with the forcing. In this case, no propagating internal gravity waves are formed, and energy imparted to the fluid stays local to the topographic forcing.

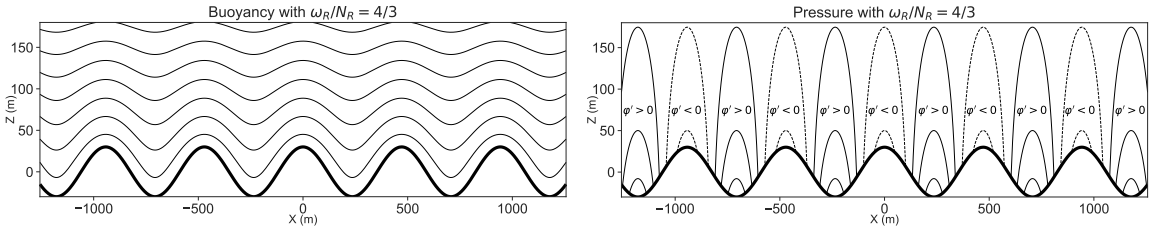

FIGURE 58.3: Stationary trapped mountain gravity waves generated by an eastward reference flow, $\boldsymbol{u}_{\mathsf{R}} = U\,\hat{\boldsymbol{x}}$, over monochromatic topography. We set the parameters according to ocean values, with $\eta_{\circ} = 30$ m, $U = 0.1$ m s^{-1}, $N_{\mathsf{R}} = 10^{-3}$ s^{-1}, and $\Lambda_{\mathsf{b}} = 2\pi \times 75$ m (we used the larger wavelength of $\Lambda_{\mathsf{b}} = 2\pi \times 200$ m in Figure 58.2), so that $\omega_{\mathsf{R}}/N_{\mathsf{R}} = 4/3$. These waves are exponentially trapped near the topography with e-folding scale $|k_z|^{-1} = 1/\sqrt{(N_{\mathsf{R}}/U)^2 - |\boldsymbol{k}_{\mathsf{b}}|^2} \approx 110$ m. Left panel: contours of the buoyancy field, $b = b_{\mathsf{R}} + b'$, with $b_{\mathsf{R}} = N_{\mathsf{R}}^2\, z$ and $b' = -\eta_{\circ}\, N_{\mathsf{R}}^2 \cos(|\boldsymbol{k}_{\mathsf{b}}|\, x)\, \mathrm{e}^{-|k_z|\, z}$ from equation (58.58c). Right panel: perturbation pressure field, $\varphi' = -U^2\, |\boldsymbol{k}_{\mathsf{b}}|\, \eta_{\circ} \cos(|\boldsymbol{k}_{\mathsf{b}}|\, x)\, \mathrm{e}^{-|k_z|\, z}$ from equation (58.58c). Note how the pressure is anomously high over the valleys (solid contours with $\varphi' > 0$) and low over the crests (dashed contours with $\varphi' < 0$). We chose the horizontal extent to be the same as in Figure 58.2, thus emphasizing how the smaller scale topography in this figure can lead to exponentially trapped waves, whereas the larger scale topography in Figure 58.2 allows for vertical propagation. Since there is no phase shift with height for the vertically trapped waves, there is no topographic form stress, which we see in equation (58.60).

58.2.9 Comments on the phenomenology

Gravity waves are ubiquitous in the ocean and atmosphere, with flow over topography one of the key means for generating such waves. As seen in this section, the flow speed, $U > 0$, and mountain wavenumber, $|\boldsymbol{k}_{\mathsf{b}}|$, together define the angular frequency for the forcing, $\omega_{\mathsf{R}} = U\,|\boldsymbol{k}_{\mathsf{b}}| > 0$. This forcing generates propagating gravity waves if $\omega_{\mathsf{R}} < N_{\mathsf{R}}$, or evanescent (trapped) gravity waves if $\omega_{\mathsf{R}} > N_{\mathsf{R}}$. That is, fast flow and/or high wavenumber mountains produce gravity waves that are trapped next to the mountain, whereas slower flow or lower wavenumber mountains generate gravity waves that propagate vertically.

Consider the case of an atmosphere with $N_{\mathsf{R}} = 10^{-2}$ s^{-1} and $U = 10$ m s^{-1}. Propagating gravity waves are generated for mountains with a horizontal wavelength ($|\boldsymbol{k}_{\mathsf{b}}| = 2\pi/\Lambda$) larger than $\Lambda = 2\pi \times 10^3$ m. For the deep ocean, with $N_{\mathsf{R}} = 10^{-3}$ m and $U = 10^{-2}$ m s^{-1}, propagating gravity waves are generated for abyssal mountains with wavelengths larger than $\Lambda = 2\pi \times 10^1$ m. These numbers suggest that all topographic features larger than a minimal scale will generate gravity waves. However, there is an upper bound on the scale imposed by the Coriolis parameter. Namely, for large enough scales the flow feels the Coriolis acceleration, thus requiring us to recall from Section 57.9.1 that propagating inertia-gravity waves have a dispersion relation (57.147)

$$\omega^2 = N_{\mathsf{R}}^2 \cos^2\gamma + f^2 \sin^2\gamma \implies f^2 < \omega^2 < N_{\mathsf{R}}^2, \tag{58.61}$$

where we here assume the Coriolis frequency is less than the buoyancy frequency. Hence, the condition for an upper bound on the forcing frequency, set by the buoyancy frequency, is coupled to a lower bound set by the Coriolis frequency. For the atmosphere at middle latitudes with $|f| = 10^{-4}$ s^{-1}, we find $2\pi \times 10^3$ m $< \Lambda < 2\pi \times 10^5$ m, whereas the ocean requires $2\pi \times 10^1$ m $< \Lambda < 2\pi \times 10^2$ m.

58.3 Gravity waves from a Lorentzian mountain

In this section we examine stationary mountain waves resulting from constant zonal flow, $\boldsymbol{u}_{\mathsf{R}} = U\,\hat{\boldsymbol{x}}$, moving over arbitrary (x-dependent) topography. This analysis extends our study of waves emanating from flow over monochromatic topography considered in Section 58.2. To handle arbitrary topography, we make use of Fourier analysis from Chapter 8 by exploiting the zonal symmetry of the reference flow and geometry. For pedagogy, we find it especially useful to

carefully step through the formulation, with a particular realization given by a mountain in the shape of a Lorentzian function.

58.3.1 Mathematical formulation using Fourier methods

Following our discussion in Section 8.3, we here introduce the Fourier transform and inverse Fourier transform for the bottom topography, velocity, buoyancy, and pressure. Furthermore, from our discussion of causality in Section 56.2.5, and with the reference flow $\boldsymbol{u}_{\mathsf{R}} = U\,\hat{\boldsymbol{x}}$ with $U > 0$, we build in causality by only considering $k_x \leq 0$, so that the forcing frequency is non-negative

$$\omega_{\mathsf{R}} = -\boldsymbol{u}_{\mathsf{R}} \cdot \boldsymbol{k}_{\mathsf{b}} = -U\,k_x \geq 0 \implies k_x \leq 0. \tag{58.62}$$

These considerations lead to the Fourier transform pairs

$$\widehat{\eta}_{\mathsf{b}}(k_x) = \int_{-\infty}^{\infty} \eta'_{\mathsf{b}}(x)\,\mathrm{e}^{-\mathrm{i}\,k_x\,x}\,\mathrm{d}x \qquad \eta'(x) = \frac{1}{2\pi}\int_{-\infty}^{0} \widehat{\eta}_{\mathsf{b}}(k_x)\,\mathrm{e}^{\mathrm{i}\,k_x\,x}\,\mathrm{d}k_x \tag{58.63a}$$

$$\widehat{u}(k_x,z) = \int_{-\infty}^{\infty} u'(x,z)\,\mathrm{e}^{-\mathrm{i}\,k_x\,x}\,\mathrm{d}x \qquad u'(x,z) = \frac{1}{2\pi}\int_{-\infty}^{0} \widehat{u}(k_x,z)\,\mathrm{e}^{\mathrm{i}\,k_x\,x}\,\mathrm{d}k_x \tag{58.63b}$$

$$\widehat{w}(k_x,z) = \int_{-\infty}^{\infty} w'(x,z)\,\mathrm{e}^{-\mathrm{i}\,k_x\,x}\,\mathrm{d}x \qquad w'(x,z) = \frac{1}{2\pi}\int_{-\infty}^{0} \widehat{w}(k_x,z)\,\mathrm{e}^{\mathrm{i}\,k_x\,x}\,\mathrm{d}k_x \tag{58.63c}$$

$$\widehat{b}(k_x,z) = \int_{-\infty}^{\infty} b'(x,z)\,\mathrm{e}^{-\mathrm{i}\,k_x\,x}\,\mathrm{d}x \qquad b'(x,z) = \frac{1}{2\pi}\int_{-\infty}^{0} \widehat{b}(k_x,z)\,\mathrm{e}^{\mathrm{i}\,k_x\,x}\,\mathrm{d}k_x \tag{58.63d}$$

$$\widehat{\varphi}(k_x,z) = \int_{-\infty}^{\infty} \varphi'(x,z)\,\mathrm{e}^{-\mathrm{i}\,k_x\,x}\,\mathrm{d}x \qquad \varphi'(x,z) = \frac{1}{2\pi}\int_{-\infty}^{0} \widehat{\varphi}(k_x,z)\,\mathrm{e}^{\mathrm{i}\,k_x\,x}\,\mathrm{d}k_x, \tag{58.63e}$$

where we only perform the x direction Fourier transform since the domain has a lower boundary and so is not symmetric in z. The hatted Fourier transform fields have an extra length dimension relative to their $\boldsymbol{x}$-space partners.

Now write the stationary linear equations (58.47a)-(58.47d) using the reference flow, $\boldsymbol{u}_{\mathsf{R}} = U\,\hat{\boldsymbol{x}}$,

$$U\,\partial_x u' = -\partial_x \varphi' \tag{58.64a}$$

$$U\,\partial_x w' = -\partial_z \varphi' + b' \tag{58.64b}$$

$$U\,\partial_x b' = -w'\,N_{\mathsf{R}}^2 \tag{58.64c}$$

$$\partial_x u' + \partial_z w' = 0, \tag{58.64d}$$

where we set $v' = 0$ and $\partial_y = 0$. Operating on these equations with $\int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\,k_x\,x}$, and assuming all boundary terms vanish, brings about the Fourier space equations

$$U\,\widehat{u} = -\widehat{\varphi} \tag{58.65a}$$

$$\mathrm{i}\,k_x\,U\,\widehat{w} = -\partial_z \widehat{\varphi} + \widehat{b} \tag{58.65b}$$

$$\mathrm{i}\,k_x\,U\,\widehat{b} = -\widehat{w}\,N_{\mathsf{R}}^2 \tag{58.65c}$$

$$\mathrm{i}\,k_x\,\widehat{u} + \partial_z \widehat{w} = 0, \tag{58.65d}$$

along with the Fourier space version of the linearized bottom boundary condition (58.11)

$$\widehat{w}(k_z, z=0) = \mathrm{i}\,k_x\,U\,\widehat{\eta}(k_x). \tag{58.66}$$

58.3.2 Wave solution in (k_x, z)-space

To satisfy the bottom kinematic boundary condition (58.66), we follow the approach from Section 58.2.5 used for the monochromatic topography by writing

$$\widehat{w} = \mathrm{i}\, k_x\, U\, \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\, k_z\, z}. \tag{58.67}$$

The vertical wavenumber is determined through use of the stationary gravity wave dispersion relation as in Section 58.2.7

$$k_z = -\sqrt{(N_\mathsf{R}/U)^2 - k_x^2}. \tag{58.68}$$

The negative sign ensures that $k_z < 0$ for long horizontal waves with $k_x < N_\mathsf{R}/U$, thus ensuring that gravity wave energy, which follows the group velocity, propagates vertically upward (away from the mountains), thus satisfying causality. The Fourier space continuity equation (58.65d) leads to the zonal velocity Fourier transform

$$\widehat{u} = -\mathrm{i}\, k_z\, U\, \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\, k_z\, z}, \tag{58.69}$$

which, with the pressure equation (58.65a), leads to

$$\widehat{\varphi} = \mathrm{i}\, k_z\, U^2\, \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\, k_z\, z}. \tag{58.70}$$

Finally, we make use of the buoyancy equation (58.65c) to find

$$\widehat{b} = \frac{\mathrm{i}\, \widehat{w}\, N_\mathsf{R}^2}{U\, k_x} = -N_\mathsf{R}^2\, \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\, k_z\, z}. \tag{58.71}$$

58.3.3 Wave solution in (x, z)-space

Making use of the inverse Fourier transforms from equations (58.63a)-(58.63e) renders the (x, z)-space expressions

$$\eta'(x) = \frac{1}{2\pi} \int_{-\infty}^{0} \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\, k_x\, x}\, \mathrm{d}k_x \tag{58.72a}$$

$$u'(x,z) = \frac{-\mathrm{i}\, U}{2\pi} \int_{-\infty}^{0} k_z\, \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\,(k_x\, x + k_z\, z)}\, \mathrm{d}k_x \tag{58.72b}$$

$$w'(x,z) = \frac{\mathrm{i}\, U}{2\pi} \int_{-\infty}^{0} k_x\, \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\,(k_x\, x + k_z\, z)}\, \mathrm{d}k_x \tag{58.72c}$$

$$b'(x,z) = \frac{-N_\mathsf{R}^2}{2\pi} \int_{-\infty}^{0} \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\,(k_x\, x + k_z\, z)}\, \mathrm{d}k_x \tag{58.72d}$$

$$\varphi'(x,z) = \frac{\mathrm{i}\, U^2}{2\pi} \int_{-\infty}^{0} k_z\, \widehat{\eta}_\mathsf{b}\, \mathrm{e}^{\mathrm{i}\,(k_x\, x + k_z\, z)}\, \mathrm{d}k_x. \tag{58.72e}$$

Again, the vertical wavenumber is given by equation (58.68), in terms of the horizontal wavenumber and the prescribed background stratification and reference flow speed. Evidently, stationary gravity waves with relatively low horizontal wavenumber ($k_x^2 < (N_\mathsf{R}/U)^2$) are vertically propagating ($k_z^2 > 0$), whereas higher horizontal wavenumber waves are exponentially trapped next to the mountains ($k_z^2 < 0$).

58.3.4 Lorentzian topography

Consider the case of topography given by the *Lorentzian* form

$$\eta_{\mathsf{b}}'(x) = \frac{\eta_{\circ}\,\ell^2}{x^2+\ell^2} = \frac{\eta_{\circ}}{1+(x/\ell)^2}, \tag{58.73}$$

where $\ell > 0$ is a length scale and $\eta_{\circ} > 0$ is an amplitude. The Fourier transform of the Lorentzian topography is given by

$$\widehat{\eta}_{\mathsf{b}}(k_x) = \pi\,\eta_{\circ}\,\ell\,\mathrm{e}^{-|k_x|\,\ell}. \tag{58.74}$$

When $\ell \to 0$, the topography sharpens in x-space whereas the k_x-space distribution broadens, with the high $|k_x|$ waves exponentially trapped near the mountain ($k_z^2 < 0$). Conversely, when $\ell \to \infty$, the topography flattens in x-space whereas the k_x-space distribution sharpens around $k_x = 0$, with such long horizontal waves vertically propagating ($k_z^2 > 0$).

Pressure in vertically propagating stationary waves

Getting the signs correct for the inverse Fourier transform can be a bit tricky, so let us work through the case of pressure with some care. First consider the case of vertically propagating stationary waves so that

$$k_z^2 > 0 \quad \text{and} \quad k_z = -\sqrt{(N_{\mathsf{R}}/U)^2 - k_x^2} < 0, \tag{58.75}$$

in which the pressure equation (58.72e) takes the form

$$\varphi'_{\text{prop}}(x,z) = \frac{\mathrm{i}\,U^2}{2\pi}\int_{-\infty}^{0} k_z(k_x)\,\widehat{\eta}_{\mathsf{b}}(k_x)\,\mathrm{e}^{\mathrm{i}\,(k_x\,x + k_z\,z)}\,\mathrm{d}k_x \tag{58.76a}$$

$$= \frac{\mathrm{i}\,U^2}{2\pi}\int_{0}^{\infty} k_z(-k_x)\,\widehat{\eta}_{\mathsf{b}}(-k_x)\,\mathrm{e}^{\mathrm{i}\,(-k_x\,x + k_z\,z)}\,\mathrm{d}k_x \tag{58.76b}$$

$$= \frac{\mathrm{i}\,U^2}{2\pi}\int_{0}^{\infty} k_z(k_x)\,\widehat{\eta}_{\mathsf{b}}(k_x)\,\mathrm{e}^{\mathrm{i}\,(-k_x\,x + k_z\,z)}\,\mathrm{d}k_x, \tag{58.76c}$$

where the final step noted that k_z is an even function of k_x, as is $\widehat{\eta}_{\mathsf{b}}(k_x)$ for the Lorentzian topography according to equation (58.74). Next make use of causality with $k_z = -|k_z| < 0$, so that

$$\varphi'_{\text{prop}}(x,z) = -\frac{\mathrm{i}\,U^2}{2\pi}\int_{0}^{\infty} |k_z|\,\widehat{\eta}_{\mathsf{b}}\,\mathrm{e}^{-\mathrm{i}\,(k_x\,x + |k_z|\,z)}\,\mathrm{d}k_x. \tag{58.77}$$

Assuming the Fourier transform of the topography is real (as for the Lorentzian in equation (58.74)), and taking the real part of the pressure field, renders the vertically propagating pressure

$$\varphi'_{\text{prop}}(x,z) = -\frac{U^2}{2\pi}\int_{0}^{\infty} |k_z|\,\widehat{\eta}_{\mathsf{b}}\sin(|k_x|\,x + |k_z|\,z)\,\mathrm{d}k_x, \tag{58.78}$$

which accords with equation (58.50) found for a monochromatic topography. Finally, we insert the Fourier transform (58.74) to have

$$\varphi'_{\text{prop}}(x,z) = -\frac{U^2\,\eta_{\circ}\,\ell}{2}\int_{0}^{N_{\mathsf{R}}/U} |k_z|\,\mathrm{e}^{-|k_x|\,\ell}\sin(|k_x|\,x + |k_z|\,z)\,\mathrm{d}k_x, \tag{58.79}$$

where we cutoff the upper limit in recognition that $|k_x < N_{\mathsf{R}}/U$ for vertically propagating waves.

Pressure in vertically trapped waves

With an imaginary vertical wavenumber,

$$k_z^2 < 0 \quad \text{and} \quad k_z = \mathrm{i}\sqrt{k_x^2 - (N_\mathsf{R}/U)^2} = \mathrm{i}\,|k_z|, \tag{58.80}$$

the pressure equation (58.72e) takes the form

$$\varphi'_{\text{trap}}(x,z) = -\frac{U^2}{2\pi}\int_{-\infty}^{0} |k_z(k_x)|\,\widehat{\eta}_\mathsf{b}(k_x)\,\mathrm{e}^{\mathrm{i}\,k_x\,x - |k_z|\,z}\,\mathrm{d}k_x \tag{58.81a}$$

$$= -\frac{U^2}{2\pi}\int_{0}^{\infty} |k_z(-k_x)|\,\widehat{\eta}_\mathsf{b}(-k_x)\,\mathrm{e}^{-\mathrm{i}\,k_x\,x - |k_z|\,z}\,\mathrm{d}k_x \tag{58.81b}$$

$$= -\frac{U^2}{2\pi}\int_{0}^{\infty} |k_z(k_x)|\,\widehat{\eta}_\mathsf{b}(k_x)\cos(k_x\,x)\,\mathrm{e}^{-|k_z|\,z}\,\mathrm{d}k_x, \tag{58.81c}$$

where the final step took the real part and made use of $|k_z(-k_x)| = |k_z(k_x)|$, as well as $\widehat{\eta}_\mathsf{b}(-k_x) = \widehat{\eta}_\mathsf{b}(k_x)$ and its reality. This expression for the trapped pressure accords with equation (58.58c) for the case of monochromatic topography. Making use of the Fourier transform (58.74) renders

$$\varphi'_{\text{trap}}(x,z) = -\frac{U^2\,\eta_\circ\,\ell}{2}\int_{N_\mathsf{R}/U}^{\infty} |k_z|\,\cos(k_x\,x)\,\mathrm{e}^{-|k_z|\,z}\,\mathrm{d}k_x, \tag{58.82}$$

where we set the lower limit to N_R/U in recognition that the waves are trapped with $|k_x| > N_\mathsf{R}/U$.

Summary expression for the pressure field

Bringing the two pieces together yields the pressure field

$$\varphi'(x,z) = -\frac{U^2\,\eta_\circ\,\ell}{2}\int_{0}^{N_\mathsf{R}/U} |k_z|\,\mathrm{e}^{-|k_x|\,\ell}\sin(|k_x|\,x + |k_z|\,z)\,\mathrm{d}k_x$$
$$- \frac{U^2\,\eta_\circ\,\ell}{2}\int_{N_\mathsf{R}/U}^{\infty} |k_z|\,\cos(k_x\,x)\,\mathrm{e}^{-|k_z|\,z}\,\mathrm{d}k_x. \tag{58.83}$$

We provide two examples in Figure 58.4, one with a relatively sharp mountain and one that is broader. Note that the sharp mountain exhibits oscillatory features on the lee side of the mountain, which are referred to as *lee waves*.

58.4 Gravity waves in gently varying stratification

In Section 57.5 and 57.6 we assumed a constant background buoyancy frequency, N_R, thus enabling us to study plane internal gravity waves. However, for geophysical fluids it is common for reference state stratification to be a function of the vertical, $N_\mathsf{R}(z)$. Indeed, such vertical dependence was considered in Sections 57.2, 57.3, and 57.4 when studying properties of the linear Boussinesq equations before specializing to plane waves in Sections 57.5 and 57.6. In this section we make use of the WKBJ approximation also used for acoustic waves in Section 51.9 (see Chapter 50 for a more general discussion), here using it to study internal gravity waves in the presence of $N_\mathsf{R}(z)$. Our fundamental assumption is that the background reference density, which is static, displays vertical variations over a vertical scale that is much larger than the vertical wavelength of the gravity waves. This scale separation is essential to use WKBJ methods.

We can anticipate the basic results of this analysis by noting that if a propagating internal gravity wave, with frequency $\omega < N_\mathsf{R}$, moves into a region where $\omega > N_\mathsf{R}$, then it can no longer propagate. Instead, it becomes an exponentially damped or *evanescent* wave. In this case, the

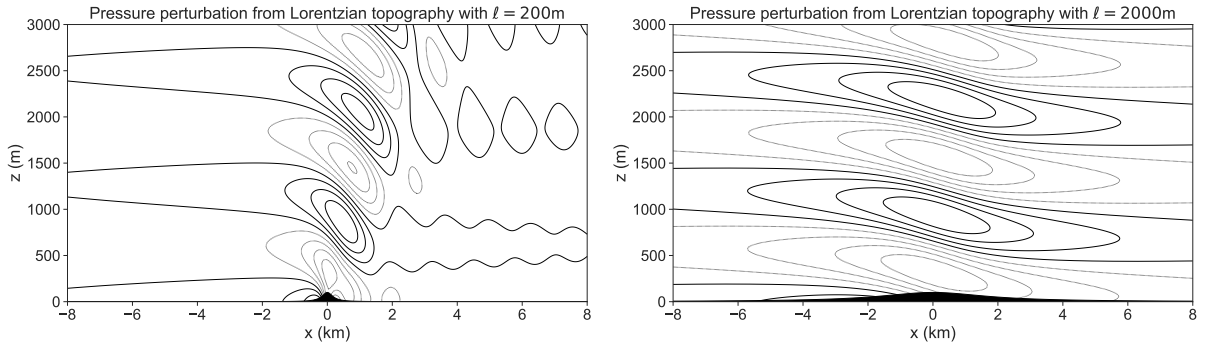

FIGURE 58.4: Stationary gravity waves over a Lorentzian mountain as seen in the pressure field, and as generated with buoyancy frequency, $N = 0.005\,\mathrm{s}^{-1}$, reference flow speed $U = 1\,\mathrm{m\,s}^{-1}$ (flow from left to right), and topographic amplitude, $\eta_\circ = 100$ m. The left panel makes use of the Lorentzian mountain (58.73) with $\ell = U/N = 200$ m, whereas the right panel uses $\ell = 10\,U/N = 2000$ m. Dotted contours depict negative pressure anomalies (such as those adjacent to the mountain) and solid contours are positive anomalies. The pressure field resulting from the relatively sharp mountain (left panel) exhibits oscillatory features on the lee side of the mountain, which are referred to as *lee waves*. These solutions were generated using a trapezoidal numerical integration to compute the integrals in equation (58.83).

propagating wave can reflect back to regions where propagation is available. Alternatively, if the region of evanescence is narrow, then the wave can tunnel through such regions.

58.4.1 The two length scale assumption

We introduced the WKBJ formalism in Section 51.9 for acoustic waves moving in a fluid with a spatially dependent equilibrium density. For internal gravity waves we consider the somewhat simpler case with vertical variations in the background density stratification, rather than the fully three dimensional variations considered for acoustic waves. We thus introduce the length scale for vertical variations in the stably stratified background density field

$$L \equiv |\partial_z \rho_\mathsf{R}/\rho_\mathsf{R}|^{-1} = (\rho_\circ\, N_\mathsf{R}^2/(g\,\rho_\mathsf{R}))^{-1}. \tag{58.84}$$

We assume that the internal gravity waves have a phase that has a vertical wavevector component that is a function of vertical position, $k_z = k_z(z)$, which satisfies the following scaling

$$L \gg |k_z|^{-1} \Longrightarrow |k_z| \gg \rho_\circ\, N_\mathsf{R}^2/(g\,\rho_\mathsf{R}). \tag{58.85}$$

This assumption means that we are concerned with a vertical length scale of the waves, as measured by $|k_z(z)|^{-1}$, that is much smaller than the length scale, L. Furthermore, we assume that the vertical variations of k_z^{-1} occur over the length scale L, so that

$$\left|\mathrm{d}k_z^{-1}/\mathrm{d}z\right| = |k_z\,L|^{-1} \ll 1. \tag{58.86}$$

In addition to having k_z now a function of vertical, we allow the wave amplitude to slowly vary with z. Writing $A(z)$ for that amplitude we assume, as for $k_z(z)$, that

$$|\mathrm{d}A/\mathrm{d}z| = |A/L|, \tag{58.87}$$

which implies that

$$|A^{-1}\,\mathrm{d}^2A/\mathrm{d}z^2| = L^{-2} \ll k_z^2. \tag{58.88}$$

58.4.2 The wave equation with the WKBJ ansatz

The wave equation (57.40) for the vertical velocity holds for $N_{\mathsf{R}}(z)$, so we focus our WKBJ analysis on that equation, rewritten here in the form

$$(\partial_{tt}\,\nabla^2 + N_{\mathsf{R}}^2\,\nabla_{\mathsf{h}}^2)\,w' = \partial_{tt}\partial_{zz}w' + (\partial_{tt} + N_{\mathsf{R}}^2)\,\nabla_{\mathsf{h}}^2 w' = 0. \tag{58.89}$$

Recall the plane wave ansatz (57.54) assumed for constant background density, which for the vertical velocity is given by

$$w'(\boldsymbol{x},t) = \widetilde{w}\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)} = (\widetilde{w}\,\mathrm{e}^{\mathrm{i}\,k_z\,z})\,\mathrm{e}^{\mathrm{i}\,(k_x\,x+k_y\,y-\omega\,t)} \quad \text{for constant } N_{\mathsf{R}}. \tag{58.90}$$

For the case with $N_{\mathsf{R}}(z)$ we generalize this ansatz to the form

$$w'(\boldsymbol{x},t) = A(z)\,\mathrm{e}^{\mathrm{i}\,(k_x\,x+k_y\,y+\sigma(z)-\omega\,t)} \quad \text{for vertically varying } N_{\mathsf{R}}(z), \tag{58.91}$$

with the real amplitude, $A(z)$, and real phase, $\sigma(z)$, each of which are to be determined. For the ansatz (58.91), we took a horizontal wavevector, $\boldsymbol{k}_{\mathsf{h}} = k_x\,\hat{\boldsymbol{x}} + k_y\,\hat{\boldsymbol{y}}$, and angular frequency, ω, just as for the constant N_{R} waves. This form is motivated by the geometric optics results in Section 50.3. Namely, when following a ray, a wavevector component is constant if the background structure is constant in its corresponding direction, and the angular frequency is constant if the background state is time independent. Given that the only spatial dependence of the background state is in the vertical, it is only the vertical wavenumber that has a vertical dependence.

Making use of the WKBJ wave ansatz (58.91) in the wave equation (58.89) leads to the following expressions

$$\partial_{zz}w'/w' = A^{-1}\,\partial_{zz}A - (\mathrm{d}\sigma/\mathrm{d}z)^2 + \mathrm{i}\,[\mathrm{d}^2\sigma/\mathrm{d}z^2 + 2\,A^{-1}\,(\mathrm{d}\sigma/\mathrm{d}z)\,(\mathrm{d}A/\mathrm{d}z)] \tag{58.92a}$$

$$\nabla_{\mathsf{h}}^2 w'/w' = -|\boldsymbol{k}_{\mathsf{h}}|^2 \tag{58.92b}$$

$$\partial_{tt}w'/w' = -\omega^2, \tag{58.92c}$$

which brings the wave equation (58.89) to the form

$$\left[\partial_{zz} + k_z^2(z)\right] w' = 0, \tag{58.93}$$

where we defined

$$k_z^2(z) = \frac{|\boldsymbol{k}_{\mathsf{h}}|^2\,(N_{\mathsf{R}}^2(z) - \omega^2)}{\omega^2}. \tag{58.94}$$

This expression for $k_z(z)$ is identical to the case with a constant N_{R} (see equation (57.67)), only now it holds with $N_{\mathsf{R}}(z)$ a function of vertical position. Equation (58.93) generalizes equation (57.70) that holds when N_{R} is a spatial constant.

58.4.3 WKBJ solution for the vertical velocity

Making use of equation (58.92a) for $\partial_{zz}w'$ in equation (58.94), and setting the real and imaginary parts to zero, leads to

$$k_z^2 - (\mathrm{d}\sigma/\mathrm{d}z)^2 = A^{-1}\,\mathrm{d}^2A/\mathrm{d}z^2 \tag{58.95a}$$

$$\mathrm{d}^2\sigma/\mathrm{d}z^2 + 2\,A^{-1}\,(\mathrm{d}\sigma/\mathrm{d}z)\,(\mathrm{d}A/\mathrm{d}z) = 0. \tag{58.95b}$$

Recall the amplitude scaling (58.88), which says that $A^{-1}\,\mathrm{d}^2A/\mathrm{d}z^2 \ll k_z^2$. Equation (58.95a) thus leads to the vertical phase function

$$\mathrm{d}\sigma/\mathrm{d}z = k_z \implies \sigma(z) = \int_{z_0}^{z} k_z(z')\,\mathrm{d}z'. \tag{58.96}$$

The vertical position, z_0, is generally ignored since it results only in an overall shift in the phase. Equation (58.95b) can be written in the form of a total derivative

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[A\left(\frac{\mathrm{d}\sigma}{\mathrm{d}z}\right)^{1/2}\right] = 0, \tag{58.97}$$

which means that the wave amplitude is related to the vertical wavenumber via

$$A \propto (\mathrm{d}\sigma/\mathrm{d}z)^{-1/2} = |k_z|^{-1/2}. \tag{58.98}$$

Bringing the pieces together leads to the WKBJ solution for the vertical velocity component

$$w'(\boldsymbol{x},t) = C\,|k_z|^{-1/2}\,\mathrm{e}^{\mathrm{i}\,(k_x\,x + k_y\,y + \sigma(z) - \omega\,t)}. \tag{58.99}$$

Assuming the constant C is real leads to

$$w'(\boldsymbol{x},t) = C\,|k_z|^{-1/2}\,\cos(k_x\,x + k_y\,y + \sigma(z) - \omega\,t) \tag{58.100a}$$

$$k_z(z) = (|\boldsymbol{k}_\mathsf{h}|/\omega)\,\sqrt{N_\mathsf{R}^2(z) - \omega^2} \tag{58.100b}$$

$$\sigma(z) = \int^{z} k_z(z')\,\mathrm{d}z' \tag{58.100c}$$

$$\omega = N_\mathsf{R}(z)\cos\gamma(z) \tag{58.100d}$$

$$C\ [=]\ L^{1/2}/T. \tag{58.100e}$$

In equation (58.100b) for the vertical component to the wavevector, we exposed its z dependence along with that for the buoyancy frequency, $N_\mathsf{R}(z)$. However, recall that the angular frequency, ω, and the horizontal wavevector, $\boldsymbol{k}_\mathsf{h}$, are both spatially independent. Consequently, equation (58.100d) means that the angle, $\gamma(z)$, changes as the buoyancy frequency changes in order to keep $N_\mathsf{R}(z)\cos\gamma(z)$ constant, with this property an essential feature of the wave guides discussed in Section 58.4.5. Furthermore, note that the vertical wavenumber, k_z, becomes imaginary in regions where $\omega^2 > N_\mathsf{R}^2(z)$. So if a propagating wave enters such a region of relatively low vertical stratification, then it becomes *evanescent*, which means that the wave exponentially decays when moving into the region. This behavior is exemplified by the wave guide discussed in Section 58.4.5.

58.4.4 Structure of an internal gravity wave

The WKBJ expressions (58.100a)-(58.100e) are sufficient to construct the full structure of an internal gravity wave moving through a region with non-constant background stratification. To do so requires making use of the linear relations from Section 57.4 in a manner similar to what we did in Section 57.5 for plane waves with N_R constant. We start with equation (57.17c) that relates buoyancy and vertical velocity via

$$\partial_t b' = -w'\,N_\mathsf{R}^2. \tag{58.101}$$

Time integrating the vertical velocity in equation (58.100a) leads to the buoyancy field

$$b' = \mathrm{i}\, C\, N_{\mathsf{R}}^2/(\omega\,|k_z|^{1/2})\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}_{\mathsf{h}}\cdot\boldsymbol{x}+\sigma(z)-\omega\,t)}, \tag{58.102}$$

where

$$\boldsymbol{k}_{\mathsf{h}}\cdot\boldsymbol{x} = k_x\,x + k_y\,y. \tag{58.103}$$

For the horizontal velocity we use the non-divergence condition, $\nabla\cdot\boldsymbol{v}' = 0$ (Section 57.5.2), as well as the vanishing vertical component to the relative vorticity, $\partial_x v' = \partial_y u'$ (Section 57.5.3), to find

$$\boldsymbol{u}' = -\frac{C\,\boldsymbol{k}_{\mathsf{h}}}{|2\,k_z|^{1/2}\,|\boldsymbol{k}_{\mathsf{h}}|^2}\big[(k_z^{-1}\,\partial_z k_z)\sin(\boldsymbol{k}_{\mathsf{h}}\cdot\boldsymbol{x}+\sigma(z)-\omega\,t) + 2\,k_z\cos(\boldsymbol{k}_{\mathsf{h}}\cdot\boldsymbol{x}+\sigma(z)-\omega\,t)\big]. \tag{58.104}$$

58.4.5 Wave packets within a wave guide

We here highlight a particularly special property of internal gravity waves moving in a region with vertically varying stratification. This property results from having the angular frequency remain constant within the dispersion relation (58.100d). Again, the constancy of the angular frequency follows from our discussion of geometric optics in Section 50.3, with the angular frequency of a wave a space-time constant if the base state is static. For the angular frequency to remain constant within a varying $N_{\mathsf{R}}(z)$ requires the phase angle, $\gamma(z)$, to compensate. For example, if a wave packet moves from a region of large vertical stratification to a region with small stratification, then $\gamma(z)$ must get smaller in magnitude so to keep ω constant. At some point if $N_{\mathsf{R}}(z)$ continues to get smaller then $\gamma(z)$ will vanish, $\gamma = 0$, which means that the waves only have a vertical wavenumber. So what happens beyond that point?

To answer this question recall equation (57.71) for the group velocity, which can be written in the form

$$\boldsymbol{c}_{\mathsf{g}} = \frac{N_{\mathsf{R}}\,k_z}{|\boldsymbol{k}|^3\,|\boldsymbol{k}_{\mathsf{h}}|}\,(k_z\,\boldsymbol{k}_{\mathsf{h}} - |\boldsymbol{k}_{\mathsf{h}}|^2\,\hat{\boldsymbol{z}}) = \frac{N_{\mathsf{R}}\,k_z}{|\boldsymbol{k}|^2}\,(\widehat{\boldsymbol{k}_{\mathsf{h}}}\sin\gamma - \hat{\boldsymbol{z}}\cos\gamma), \tag{58.105}$$

where $\widehat{\boldsymbol{k}_{\mathsf{h}}} = \boldsymbol{k}_{\mathsf{h}}/|\boldsymbol{k}_{\mathsf{h}}|$ is the unit vector pointing in the direction of the horizontal wavector. As the wave becomes horizontal to compensate for the reduced $N_{\mathsf{R}}(z)$, the group velocity vanishes, which we already noted by equation (57.75) for the group velocity magnitude. Yet the second form of equation (58.105) reveals that the horizontal component to the group velocity vanishes before the vertical component. Hence, as the wave packet approaches the region of weak stratification its ray forms a vertical cusp as the packet stalls. Since the packet cannot propagate into a region with $\omega^2 > N_{\mathsf{R}}^2$, which is a region of evanescence, then the wave reflects back into the region where $\omega^2 < N_{\mathsf{R}}^2$. If the propagation region with $\omega^2 < N_{\mathsf{R}}^2$ sits between two regions with weak stratification with $\omega^2 > N_{\mathsf{R}}^2$, then the bounded relatively high stratification region forms a *wave guide* for the internal gravity waves. We depict an idealized example of a wave guide in Figure 58.5.

We can compute an analytic expression for the wave packet ray (i.e., its trajectory) as it rises to a *turning level*, at $z = z_{\mathsf{t}}$, defined as the level where $N_{\mathsf{R}}(z = z_{\mathsf{t}}) = \omega$. We do so by taking a Taylor series for the squared buoyancy frequency for points close to the turning level

$$N_{\mathsf{R}}^2(z) \approx N_{\mathsf{R}}^2(z_{\mathsf{t}}) + (\mathrm{d}N_{\mathsf{R}}/\mathrm{d}z)\,(z - z_{\mathsf{t}}) = \omega^2 - |\mathrm{d}N_{\mathsf{R}}/\mathrm{d}z|\,(z - z_{\mathsf{t}}) = \omega^2 + |\mathrm{d}N_{\mathsf{R}}/\mathrm{d}z|\,(z_{\mathsf{t}} - z), \tag{58.106}$$

where we note that N_{R}^2 is a decreasing function as z increases towards z_{t}, which means that $\mathrm{d}N_{\mathsf{R}}^2/\mathrm{d}z = -|\mathrm{d}N_{\mathsf{R}}^2/\mathrm{d}z|$. Assuming the packet is moving in the x-z plane, we obtain the ray equation from the group velocity (58.105) and the dispersion relation (58.100b)

$$\frac{\mathrm{d}z}{\mathrm{d}x} = -\frac{|\boldsymbol{k}_{\mathsf{h}}|}{k_z} = -\frac{\omega}{\sqrt{N_{\mathsf{R}}^2 - \omega^2}} = -\frac{\omega}{\sqrt{|\mathrm{d}N_{\mathsf{R}}^2/\mathrm{d}z|\,(z_{\mathsf{t}} - z)}}. \tag{58.107}$$

We integrate along the ray as the packet moves from a point (x, z) to the turning level at (x_t, z_t) (see Figure 58.5), which yields the expression for the ray trajectory

$$(z_t - z)^{3/2} = \frac{(3\,\omega/2)\,(x_t - x)}{\sqrt{|\mathrm{d}N_R^2/\mathrm{d}z|}} \Longrightarrow z_t - z = \left[\frac{(3\,\omega/2)\,(x_t - x)}{\sqrt{|\mathrm{d}N_R^2/\mathrm{d}z|}}\right]^{2/3}. \tag{58.108}$$

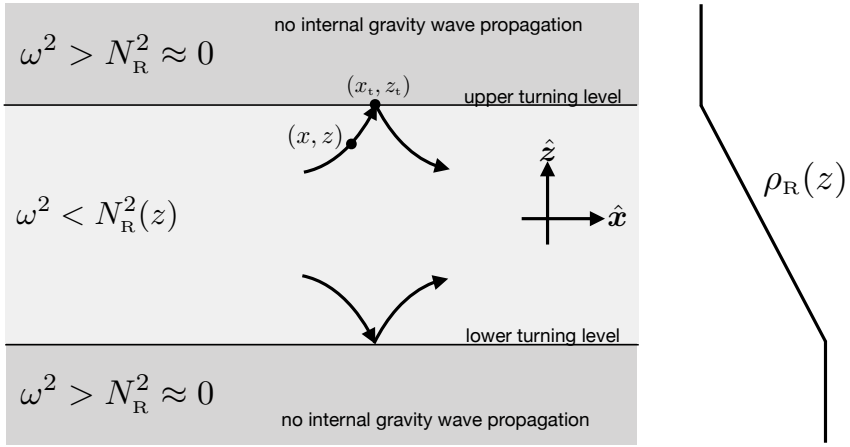

FIGURE 58.5: A waveguide for internal gravity waves, here depicted by two low stratification regions ($N_R^2 \approx 0$) bounding a higher stratification region ($N_R^2 > 0$). The density profile on the right provides an idealized realization of such a guide. The levels where $N_R = \omega$ are referred to as *turning levels*. We depict sample rays approaching and leaving the turning levels, with the rays computed from the group velocity and dispersion relation. For example, a ray approaching the upper turning is computed from (x, t) to (x_t, zt), with the cusp-like trajectory given by equation (58.108).

58.4.6 Comments and further study

See Lecture 9 of *Pedlosky* (2003) or Section 7.5 of *Vallis* (2017) for similar presentations. Note that there remains ongoing research to understand details of what happens to internal gravity waves when they reach a turning level. For an ocean application, concerning how gravity waves interact with the upper ocean boundary layer, see *Shakespeare et al.* (2021).

58.5 Exercises

EXERCISE 58.1: POLARIZATION RELATIONS FOR STATIONARY INERTIA-GRAVITY WAVES ON A MEAN FLOW

Following the discussion in Section 58.2.6, determine the polarization relations for stationary inertia-gravity waves in the presence of a constant reference flow, $\boldsymbol{u}_R = U\,\hat{\boldsymbol{x}}$ and with $\omega_R = -\boldsymbol{u}_R \cdot \boldsymbol{k}_b > 0$. Assume $f_o^2 < \omega_R^2 < N_R^2$ so that the waves extend throughout the vertical. Write expressions for u', v', w', b', and φ' in terms of the vertical velocity amplitude, $\widetilde{w}$, as given by equation (58.39). Confirm that setting $f_o = 0$ reduces the intertia-gravity results to the gravity wave case derived in Section 58.2.7.

EXERCISE 58.2: MOUNTAIN GRAVITY WAVE FROUDE NUMBER BASED ON FREQUENCIES

Consider the non-dimensional *Froude number* for forced mountain gravity waves ($f_o = 0$)

$$\mathrm{Fr} = \frac{|\boldsymbol{u}_R \cdot \boldsymbol{k}_b|}{N_R} = \frac{\omega_R}{N_R}, \tag{58.109}$$

which is the ratio of the forcing frequency (from flow over the monochromatic mountains) to the buoyancy frequency.

(a) Write the squared vertical wavenumber (58.42) for mountain gravity waves in terms of Fr.

(b) Write Fr as the ratio of two time scales. Provide an interpretation for why mountain waves are vertically trapped when one of those time scales is greater than the other, and vertically propagating for the alternative.

Hint: see Section 5.4.2 of *Sutherland* (2010) for a discussion of this non-dimensional number. The second part of this exercise is mostly meant to be answered in words.

EXERCISE 58.3: MECHANICAL ENERGY OF A TRAPPED MOUNTAIN GRAVITY WAVE

We studied the energetics of propagating mountain gravity waves in Section 58.2.7. Here we consider the energetics of trapped mountain waves.

(a) Compute the mechanical energy for the trapped mountain gravity waves from Section 58.2.8.

(b) Compute the phase averaged mechanical energy.

(c) Evaluate the phase averaged mechanical energy at the ground (approximated by $z = 0$ in the linear theory), and compare this energy to the phase averaged mechanical energy in a propagating mountain wave.

Part XI

Flow instabilities

Part X of this book is concerned with small amplitude wave fluctuations that move on the background of a prescribed exact solution to the fluid equations. For example, in studying acoustic waves in Chapter 51, the background state is static and uniform, whereas when studying internal gravity waves in Chapter 57, the background is static yet stably stratified according to gravity. In each of these cases, the background state is stable to small perturbations so that the wave fluctuations do not lead to waves of growing amplitude. In Part XI of the book we examine conditions required to ensure stability of background flow states, or conversely, what properties of the background state are necessary (and sometimes sufficient) to support instabilities.

What enables an instability?

As noted in Section 2 of the authoritative book by *Drazin and Reid* (2004), flow instabilities occur when a disturbance leads to the disequilibrium of forces within the fluid, and with this disequilibrium enabling the disturbance to grow. We explore numerous mechanisms for the growth of disturbances that manifest positive feedbacks energized by the background state. Examples include the kinetic energy that supports shear instability, the potential energy that supports baroclinic instability, and the angular momentum that supports centrifugal instability. A central goal of instability theory is to develop a physical understanding and mathematical recipe to determine what constitutes an unstable flow state. Furthermore, a flow state might be unstable, but not all disturbances "tickle" the instability. This situation motivates the study of conditions required of the disturbance for it to manifest the instability.

We focus on mechanisms that lead to a variety of geophysical flow instabilities, and in so doing develop associated mathematical analysis methods. Instabilities are the norm for geophysical flows rather than the exception, and they play a fundamental role in establishing properties of planetary circulations in both the atmosphere and ocean. Furthermore, most of the instabilities occuring in geophysical fluids are primarily understood in the absence of viscous dissipation, thus prompting us to focus exclusively on the inviscid equations.

Distinguishing two classes of flow instabilities

We distinguish two general classes of fluid flow instabilities: *local* (or *parcel*) instabilities and *global* (or *wave*) instabilities. Local/parcel instabilities afford a local necessary and sufficient condition to determine whether the background flow state is unstable. For example, in the study of gravitational instability (in the absence of surface tension), we can measure the local squared buoyancy frequency: if $N^2 < 0$ then the fluid is gravitationally unstable at the location where $N^2 < 0$. The study of symmetric instabilities in Chapter 59 explores a broader class of local instabilities, in which angular momentum and potential vorticity are central to determining stability conditions. Stability conditions are generally derived by considering an imagined displacement of a fluid parcel within the environment of the prescribed background state. If the forces acting on the parcel lead to furthering the displacement, then that signals a positive feedback indicating that the background state is unstable. The result of such local instabilities is a catastrophic breakdown of the background state without concern for any special space and/or time scale for the breakdown.

Global/wave instabilities arise from the interference of waves that lead to mutually constructive positive feedbacks, thus constituting the *wave resonance* interpretation of such instabilities. The stability analysis is generally referred to as the *method of normal modes*. We do not seek the most general solution to the linearized equations. Instead we ask if a single wave can go unstable, and if so then what properties of such waves enable the instability to manifest? Determining properties of the unstable waves (e.g., the most unstable wavelength, wave velocity, and the growth rate) requires solving an eigenvalue problem where boundary conditions often play a fundamental role. Shear instabilities of Chapter 61 and baroclinic instabilities of Chapter 62

are canonical examples of this sort of instability. Operationally, the means to reveal a global instability is similar to that used to study linear waves in Part X of this book. Namely, we determine a dispersion relation for small amplitude fluctuations, only now allowing the possibility of the wave frequency or wavevector to be complex. Temporally unstable waves occur with a complex wave frequency and real wavevector, whereas spatial instabilities arise with real wave frequency and complex wavevector. Finally, observe that local instabilities can be considered wave instabilities in which all waves are unstable.

Flow instabilities lead to a stable end state

Flow instabilities are energized by the background state and, through the process of creating the instability and allowing it to grow to a nonlinear stage, act to eliminate the source for the instability. For example, the catastrophic vertical motion of a gravitationally unstable fluid column serves to remove the potential energy source of the instability, with the resulting equilibrium state gravitationally stable. In geophysical fluids, there are external forces (ultimately arising from solar heating, geothermal heating, or astronomical tides) that return the background state to an unstable condition, thus allowing for the fluid to undergo a multitude of successive instabilities. Through such successive instabilities, or further secondary instabilities that feed off the primary instability, the fluid generally evolves into an extremely complex state of linear and nonlinear waves, instabilities, and turbulence. The resulting fluid flow is comprised of a wide suite of space and time scales whose mathematical description requires methods from statistics and stochastics. We do not pursue the study of wave turbulence or fully developed turbulence in this book, but do appreciate that instabilities are the central means for geophysical fluids to transition into a turbulent state. Hence, understanding the mechanisms for flow instabilities offers insights into the nature of the associated turbulence.

We do not examine the effects of instabilities on the background state

Throughout this study, we do not examine evolution of the prescribed background state. Ignoring changes to the background state is a sensible assumption when studying the motion of stable linear waves, whose amplitudes remain bounded and so offer only a tiny perturbation to the background state. However, for unstable flows, the assumption of a fixed background proves untenable when fluctuations become large enough to engage flow nonlinearities and thus to nontrivially impact the background state. It is for this reason that our analysis focuses exclusively on the early stages of an instability, whereby small amplitude assumptions allow for a focus on linear mechanisms leading to growth of a disturbance, rather than enable the rich complexities of interactions (some stable and some unstable) between the disturbance and an evolving background state.

Seek out visualizations of flow instabilities to help develop understanding

This video from Prof. Mollo-Christensen provides an insightful introduction to the topic of fluid mechanical instabilities. This and many other videos from laboratory studies and numerical simulations offer useful, if not essential, visual impressions to complement the somewhat intricate mathematical analysis in this part of the book.

Chapter 59

SYMMETRIC FLOWS

In this chapter we study the stability of fluid flows exhibiting either axial symmetry (e.g., rotating fluid column) or spatial symmetry in one horizontal direction (e.g., f-plane geostrophic fronts). This analysis supports the study of frontal features in geophysical fluids, where a front is a region of strong buoyancy gradients that leads to a jet-like geostrophic flow. Because of the assumed symmetry in the base flow state and the perturbation, the instabilities in this chapter are generically referred to as *symmetric instabilities*. However, the terminology is not universal, with flavors of symmetric instability often referred to as *centrifugal*, *inertial*, and *symmetric*.

We make use of three methods for stability analysis in this chapter. One consists of an energetic approach due to Rayleigh (*energetic stability analysis*); one is Lagrangian and considers force balances acting on a test fluid parcel (*parcel stability analysis*); and one is Eulerian and considers wave perturbations (*modal stability analysis*). For the instabilities considered in this chapter, each method leads to the same stability condition, which is here measured by local properties of the flow so that we refer to the method as *local stability* analysis. As part of the analysis we make use of material invariants, such as angular momentum, potential momentum, buoyancy, and potential vorticity. We restrict attention to the f-plane since that allows us to make use of potential momentum as a material invariant. It is notable that the flows considered in this chapter generally exhibit secondary overturning circulations, with such circulations studied here using the rudiments of *semi-geostrophy*.

Energetic and parcel methods probe the base state flow by perturbing test fluid parcels. A test parcel is assumed to have no impact on the flow state itself, meaning that the pressure field remains unchanged even as the parcel is moved. In effect, the test fluid parcel stability analysis makes the tacit assumption that pressure responses to a perturbation can be neglected for the purpose of detecting an unstable flow state. Ignoring the impacts on pressure is consistent with the notion of a test fluid element introduced in Section 17.2.5.[1] However, we questioned that approach when studying buoyancy in Section 30.11, where we computed the pressure response to the perturbation and found that the response has an important impact on the effective buoyancy felt by a finite fluid region. Acknowledging this limitation motivates us to complement the parcel approach with an Eulerian linear stability analysis using plane waves. This approach is dynamically consistent, and yet it works within the limitations of the linearized equations.

READER'S GUIDE FOR THIS CHAPTER

We make use of the shallow water system from Chapters 35 and 36, in particular the study of angular momentum in Section 36.8 (see also Section 27.5). We also assume an understanding of geostrophic flow as studied in Chapter 31, as well as the continuously stratified Boussinesq ocean from Chapter 29.

Gravitational instability is the canonical local instability and it is signaled by $N^2 < 0$.

[1] Since the concern here is with perfect fluids, the test fluid element from Section 17.2.5 is the same as a test fluid parcel.

However, we do not consider gravitational instability in this chapter, with this instability introduced in Chapter 30 when studying buoyancy, and Chapter 60 when studying the Rayleigh-Taylor instability.

59.1 Loose threads

- Work through symmetric instability in two shallow water layers. Does it work? Do we need to have mixing of the layers?
- Write the full oscillator equation for (59.75), including Δx and Δz motion.
- Energy analysis for each instability as per Chapter 8 of *Smyth and Carpenter* (2019), who use a modal approach and linearize the equations. Include energetics of gravitational instability.
- Maximum growth rate for symmetric instability in chapter 8 of *Smyth and Carpenter* (2019).
- Include more in Section 59.9.7 concerning stable and unstable symmetric fronts.
- More closely connect the ageostrophic overturning from Section 59.9 to symmetric instability. Make the case that the overturning is either stable or unstable, with the unstable form leading to symmetric instability.
- More about the growth of the squared buoyancy gradient in equation (59.170). Can that equation be written in a more revealing manner?
- Pursue the coordinate transformation from *Hoskins* (1975), in which case the discussion of semi-geostrophy could form a separate chapter.
- What is the potential vorticity for the linearized perturbations in Section 59.8?

59.2 Instabilities in this chapter

The instabilities studied in this chapter are termed *local* since they are detected through a local condition that yields a necessary and sufficient condition for instability. The physical features of the flow instabilities considered here are quite similar, thus making it convenient to study them together. For centrifugal and horizontal inertial instabilities, we develop the stability conditions using both energetic and parcel analysis methods. For symmetric instability we use the parcel and modal methods.

59.2.1 Summary of the instabilities studied in this chapter

Before diving into the details, we here offer a summary of the instabilities studied in this chapter.

Centrifugal instability of cyclostrophic balanced flow

Consider an equilibrium flow state under inviscid cyclostrophic balance. As studied in Section 32.5, cyclostrophic balance arises when pressure and centrifugal accelerations are balanced, with centrifugal accelerations arising from curvature in the fluid particle trajectory. The angular momentum is materially invariant when the equilibrium state is rotationally symmetric, as in an ideal circular vortex or a rotating circular tank (Section 36.8). Flow stability can be probed by horizontally displacing a rotationally symmetric circular ring of fluid parcels, with each parcel retaining its original angular momentum. If the parcels are displaced to a position where pressure and centrifugal accelerations further support the displacement, then the base state is unstable to centrifugal instability.

Horizontal inertial instability of f-plane geostrophic flow

Consider an equilibrium flow state in a barotropic fluid under inviscid geostrophic balance on an f-plane, whereby pressure and Coriolis accelerations are balanced (Chapter 31). The potential momentum is materially invariant when the equilibrium state is symmetric in a horizontal direction, as in a zonally or meridionally symmetric f-plane front. Flow stability is probed by horizontally displacing a symmetric line of fluid parcels, with each parcel retaining its original potential momentum. If the parcels are displaced to a position where pressure and Coriolis accelerations further support the displacement, then the base state is unstable to horizontal inertial instability.

Isentropic inertial instability (symmetric instability) for f-plane flow

Consider an equilibrium flow state under inviscid f-plane geostrophic balance in a baroclinic fluid. Potential momentum in the direction of the front as well as buoyancy are materially invariant when the base state is symmetric in a horizontal direction. Flow stability of the base flow is probed by isentropically displacing a symmetric line of fluid parcels, with each parcel retaining its original potential momentum and buoyancy. If the parcels are displaced to a position where pressure and Coriolis accelerations further support the displacement, then the base state is unstable to isentropic inertial instability, which we call *symmetric* instability.

59.2.2 Nature of the base state and the perturbations

For the study of centrifugal instability, we make use of the shallow water model from Chapters 35 and 36, whereas we consider the continuously stratified Boussinesq ocean (Chapter 29) for the horizontal and isentropic inertial instabilities. When the fluid is continuosly stratified and inviscid, all motion occurs along isentropes. However, when probing for centrifugal or horizontal inertial instabilities using parcel arguments, we examine stability to perturbations along geopotential surfaces. Such horizontal displacements generally cross isentropic surfaces in a baroclinic fluid. The isentropic inertial instability analysis in Section 59.6 maintains the adiabatic nature of displacements when probing for instabilities. Even so, these perturbations do not maintain a materially invariant potential vorticity. So what is it about these perturbations that makes them relevant to stability analysis?

The stability thought experiment using test fluid parcels assumes the parcels maintain their materially invariant property (e.g., buoyancy, angular momentum, potential momentum) as they probe stability of the surrounding fluid flow. That is the nature of the test parcels, as they do not directly interact with nor alter the surrounding fluid environment. Local flow stability is examined by having test parcels cross surfaces of constant materially invariant properties. For example, gravitational stability is probed by test parcels moving across buoyancy surfaces (Section 30.6). Likewise, entering the *wedge of instability* for symmetrically unstable flow requires a test parcel to leave its constant buoyancy and constant potential momentum surfaces (Section 59.6).

59.2.3 Comments

Section 7.1 of *Holton and Hakim* (2013) distinguishes between *parcel* and *wave* instabilities. Analogously, *Cushman-Roisin and Beckers* (2011) use the terms *local* and *global*. Canonical examples of global instabilities are Kelvin-Helmholtz and baroclinic. We are not concerned with those instabilities in this chapter. Rather, the three instabilities considered here are examples of parcel or local instabilities.

Because of the rather close similarities between centrifugal and inertial instability, the oceanographic literature often uses the term centrifugal instability when referring to the inertial

instability considered here (e.g., see *Thomas et al.* (2013) and *McWilliams* (2016)). However, we do not follow that usage since the inertial instability in this chapter is *not* associated with centrifugal accelerations. Rather, inertial instability is associated with Coriolis accelerations. We choose to follow the terminology of the atmospheric literature as detailed in the texts by *Holton and Hakim* (2013) and *Markowski and Richardson* (2010), which also follows the fluid mechanics terminology used by *Drazin and Reid* (1981). So in brief, we use the term *centrifugal instability* for an axisymmetric base state in cyclostrophic balance, and *inertial instability* for a two-dimensional base state in geostrophic balance.

59.3 Centrifugal instability of cyclostrophic flow

Consider flow of a single shallow water fluid layer in a rotating cylindrical tank with rotation about its vertical axis.[2] Throughout this analysis we assume all flow features maintain rotational symmetry (Figure 59.1). Hence, all dynamical fields are a spatial function only of the radial distance from the rotational axis (*axisymmetric*). We are interested in questions concerning flow stability as a function of the radial distribution of the angular momentum per mass, $l^z(r)$. In particular, we examine stability of *cyclostrophically balanced* flow, defined by flow whose radial acceleration vanishes so that the radial pressure gradient balances the centrifugal acceleration (Section 32.5). Furthermore, we examine stability under perturbations that also maintain axial symmetry. We find that such cyclostrophic flow is stable to rotationally symmetric perturbations so long as the squared angular momentum increases radially outward. This system provides a pedagogical introduction to the stability of rotating vortices in the ocean and atmosphere, and it establishes analysis methods we later use for inertial and symmetric instabilities arising in two-dimensional frontal regions. The stability condition for angular momentum is reflected in observed stable vortices in both the atmosphere and ocean.

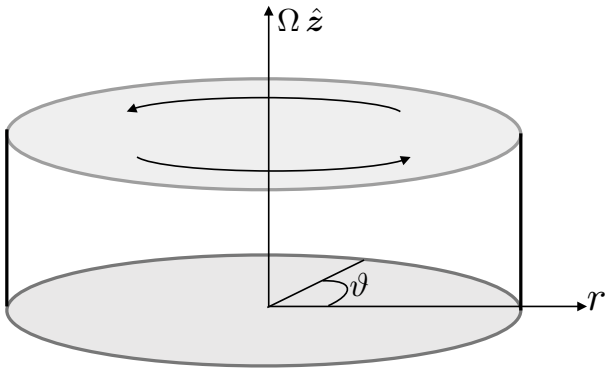

FIGURE 59.1: Rotating tank of shallow water fluid used to discuss centrifugal instability. We make use of cylindrical-polar coordinates from Section 4.22 to describe the flow. All flow features are assumed to be rotationally symmetric, including both the cyclostrophic balanced state and perturbations relative to the balanced state.

The centrifugal instability described here does *not* rely on baroclinic structure. Rather, it arises from the imbalances between centrifugal and pressure forces along a geopotential surface.[3] By using the shallow water fluid to study this instability, we directly connect to Section 36.8,

[2] The same ideas can be formulated for rotating Couette flow, in which fluid is placed between two rotating cylinders. We prefer the shallow water tank since it is a system considered elsewhere in this book as a laboratory model for rotating fluid mechanics.

[3] One may conceive of centrifugal instability in a baroclinic flow where parcel displacements maintain their angular momentum and buoyancy. That analysis would lead to isentropic centrifugal instability, which is directly analogous to the isentropic inertial instability discussed in Section 59.6. See *Buckingham et al.* (2021) for a discussion of this system.

where we studied angular momentum in a rotating tank of shallow water fluid.

59.3.1 Equations of motion

We studied the angular momentum of this rotating shallow water system in Section 36.8, where we made use of a rotating reference frame and polar coordinates (r, ϑ) (Section 4.22) measured in the rotating frame. Here, r is the radial position from the rotational axis and ϑ is the azimuthal angle measured counter-clockwise from the rotating x-axis. We furthermore derived the acceleration in cylindrical-polar coordinates in Exercise 13.3. Making use of those results allows us to write down the horizontal components to the inviscid velocity equation as well as the thickness equation

$$\mathrm{D}v^r/\mathrm{D}t = -g\,\partial_r\eta + r^{-3}\,(l^z)^2 \tag{59.1a}$$

$$\mathrm{D}l^z/\mathrm{D}t = -g\,\partial_\vartheta\eta \tag{59.1b}$$

$$r\,\partial_t\eta = -\partial_r(h\,r\,v^r) - \partial_\vartheta(h\,v^\vartheta). \tag{59.1c}$$

In these equations, h is the layer thickness and η is the free surface height for the shallow water layer (see Figure 35.1). The radial and azimuthal velocity components are given by

$$v^r = \mathrm{D}r/\mathrm{D}t \quad \text{and} \quad v^\vartheta = r\,\mathrm{D}\vartheta/\mathrm{D}t, \tag{59.2}$$

and the angular momentum per mass computed about the rotation axis (the z-axis) is

$$l^z = \hat{\boldsymbol{z}}\cdot[\boldsymbol{r}\times(\boldsymbol{u}+\boldsymbol{U}_{\text{rigid}})] = r\,(v^\vartheta + r\,\Omega). \tag{59.3}$$

Material evolution of the radial velocity (equation (59.1a)) is affected by the radial pressure gradient plus centrifugal acceleration, whereas the material evolution of angular momentum (equation (59.1b)) is affected by angular gradients in the pressure field as realized by angular gradients in the free surface.

We consider equilibrium states where the radial acceleration vanishes. Such states are said to be in *cyclostrophic balance*, whereby the radial pressure gradient balances the centrifugal acceleration

$$\mathrm{D}v^r/\mathrm{D}t = 0 \Longrightarrow g\,\partial_r\eta = (v^\vartheta + r\,\Omega)^2/r = r^{-3}\,(l^z)^2 \qquad \text{cyclostrophic balance.} \tag{59.4}$$

Is cyclostrophically balanced flow stable? To answer this question we examine the more restricted problem of stability of rotational symmetric flow, and with perturbations also assumed to be rotationally symmetric. Rotational symmetry also means that all flow fields are a function only of the radial direction. As such, angular momentum is materially constant

$$\partial_\vartheta\eta = 0 \Longrightarrow \mathrm{D}l^z/\mathrm{D}t = 0. \tag{59.5}$$

This constraint on the flow plays a fundamental role in the stability analysis.

59.3.2 Elements of angular momentum

Consider a spinning top in a gravitational field, in which conservation of angular momentum (holding in the absence of friction) keeps the top upright. Yet in the presence of friction, the angular momentum is dissipated so that the top eventually falls. There is an analog with a rotating fluid. Namely, we find that a state of zero angular momentum leads to centrifugal instability. To develop this result we study basic properties for angular momentum in the rotating tank.

Rigid-body motion

A fluid in rigid-body motion has $v^\vartheta = 0$ and angular momentum per mass

$$l^z_{\text{rigid-body}} = r^2\,\Omega. \tag{59.6}$$

Evidently, the magnitude of the angular momentum increases as the square of the radial distance. In the following we find it more convenient to use the square of the angular momentum (as it appears in the radial velocity equation (59.1a)), which also increases radially for the rigid-body motion

$$\frac{\mathrm{d}[l^z(r)]^2}{\mathrm{d}r} = 4\,r^3\,\Omega^2 > 0. \tag{59.7}$$

We will find that flow is centrifugally unstable if the square of its angular momentum is a decreasing function of its radial distance. Such unstable configurations adjust through *centrifugal instability* towards a configuration with squared angular momentum that increases radially. The instability is termed "centrifugal" since it is the centrifugal acceleration that "throws outward" the fluid if its squared angular momentum decreases radially, thus bringing the fluid back into a stable state. More precisely, a flow where the angular momentum decreases outward has pressure gradients that cannot balance the centrifugal acceleration from the outward movement of angular momentum conserving fluid parcels.

Zero angular momentum flow

Consider a non-rotating tank with zero flow, so that the angular momentum is zero. In a perfect fluid the angular momentum of each fluid parcel remains zero, even if we start the tank rotating. That is, for a perfect fluid with zero angular momentum, the tank simply rotates but the fluid remains at rest in the inertial reference frame. To generate non-zero angular momentum for the fluid requires friction between the rotating tank and fluid. After sufficient time, friction transfers angular momentum from the tank walls throughout the fluid, thus leading to a steady state flow in rigid-body motion. Upon reaching the steady rigid-body flow, there are no strains in the fluid and thus no viscous stresses to impart friction (Section 25.8).

In a flow with zero angular momentum, the relative angular velocity is given by

$$l^z = 0 \implies v^\vartheta = -r\,\Omega, \tag{59.8}$$

so that the flow is anti-cyclonic (i.e., directed counter to the tank's rotation). Furthermore, the zero angular momentum flow has the relative vorticity

$$l^z = 0 \implies \zeta = \frac{1}{r}\frac{\mathrm{d}(r\,v^\vartheta)}{\mathrm{d}r} = -2\,\Omega. \tag{59.9}$$

That is, the relative vorticity is anti-cyclonic with a Rossby number

$$l^z = 0 \implies \mathrm{Ro} = \zeta/(2\,\Omega) = -1. \tag{59.10}$$

As we show in the following, the $l^z = 0$ flow is the onset point for centrifugal instability. Again, we conceive of this flow as analogous to a rotating top that falls over (goes unstable) when its angular momentum vanishes.

Establishing zero angular momentum flow

It is relatively simple to establish rigid-body motion of a fluid in a tank; all it takes is sufficient time for transients to relax and friction to fully transfer momentum from the tank walls throughout the fluid. For the complement task, consider a rigid-body flow that is subjected to

an irreversible force that brings the fluid to zero angular momentum. The question we ask in our stability analysis is not concerned with details of how such forces arise. Instead, we are interested in what happens to the flow when it reaches zero angular momentum.

59.3.3 Energetic stability analysis

As first introduced by Rayleigh, we consider a thought experiment in which two adjacent equal mass circular fluid rings are swapped, one originating from radial position $r = r_1$ and the other at $r = r_2 = r_1 + \Delta r$ (see Figure 59.2). Furthermore, assume that the radial velocity vanishes so that the kinetic energy of the rings is due only to their rotational motion. If swapping the rings decreases the kinetic energy in the base state, then the released kinetic energy can be used to fuel an instability.[4] In this case we say that the flow is *centrifugally unstable*, with this name used since it is the centrifugal acceleration from the circular parcel trajectory that promotes the instability. In general, any curved flow will be exposed to centrifugal instability if swapping parcels reduces the kinetic energy of the base state while maintaining constant angular momentum.

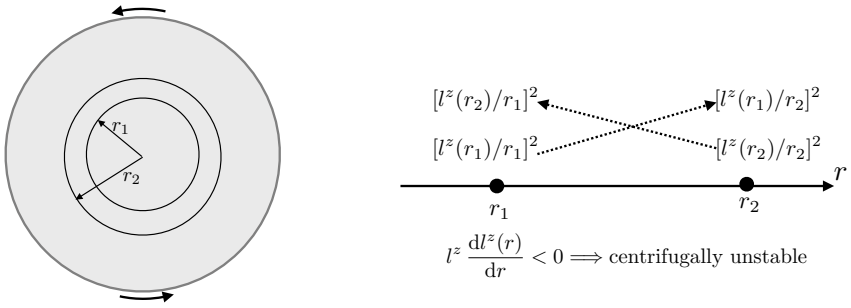

FIGURE 59.2: Illustrating Rayleigh's energetic method for centrifugal instability. The initial configuration defines two rings of fluid at radii r_1 and $r_2 = r_1 + \Delta r$, as shown in the left panel, with the two rings having a combined kinetic energy per mass $2\,E_{\text{init}} = [l^z(r_1)/r_1]^2 + [l^z(r_2)/r_2]^2$. Swapping the two rings while maintaining a constant angular momentum (and assuming nothing else changes) leads to the swapped kinetic energy per mass, $2\,E_{\text{swap}} = [l^z(r_1)/r_2]^2 + [l^z(r_2)/r_1]^2$. If $E_{\text{swap}} - E_{\text{init}} < 0$ then energy is released upon the swap and the rotationally symmetric flow is centrifugally unstable. Energy is released upon swapping fluid rings if the angular momentum condition (59.15) is satisfied: $\mathrm{d}[l^z(r)]^2/\mathrm{d}r < 0$.

With no radial flow, kinetic energy only arises from angular motion so that a ring of mass $\delta m = \rho\,\delta V$ and radius r_1 has kinetic energy

$$E(r_1) = (\delta m/2)\,[v^\vartheta(r_1) + r_1\,\Omega]^2 = (\delta m/2)\,[l^z(r_1)/r_1]^2. \tag{59.11}$$

The initial kinetic energy for the two rings is thus given by the sum

$$E_{\text{init}} = (\delta m/2)\,\big([l^z(r_1)/r_1]^2 + [l^z(r_2)/r_2]^2\big). \tag{59.12}$$

The equilibrium state and the perturbation each maintain rotational symmetry. Hence, when swapping their radial positions, the rings each maintain their respective angular momentum. But by changing radial positions their kinetic energy changes, thus leading to the kinetic energy of the swapped state

$$E_{\text{swap}} = (\delta m/2)\,\big([l^z(r_1)/r_2]^2 + [l^z(r_2)/r_1]^2\big). \tag{59.13}$$

The difference in energy is given by

$$E_{\text{swap}} - E_{\text{init}} = (\delta m/2)\,\big([l^z(r_2)]^2 - [l^z(r_1)]^2\big)\big(r_1^{-2} - r_2^{-2}\big). \tag{59.14}$$

[4] Gravitational potential energy plays no role here, as we are swapping fluid rings at the same vertical position.

Since $r_2 = r_1 + \Delta r > r_1$, we have a release of kinetic energy ($E_{\text{swap}} - E_{\text{init}} < 0$) if the squared angular momentum decreases upon moving outward

$$\frac{\mathrm{d}[l^z(r)]^2}{\mathrm{d}r} = 2\, l^z(r)\, \frac{\mathrm{d}l^z(r)}{\mathrm{d}r} < 0 \implies \text{necessary + sufficient for centrifugally unstable flow.} \tag{59.15}$$

Recall from equation (59.7) that the angular momentum of rigid-body flow is an increasing function of radius. Hence, the instability condition (59.15) signals a distinctively non-rigid-body angular momentum configuration. We can consider a thought experiment in which a stable flow (one where $\mathrm{d}[l^z(r)]^2/\mathrm{d}r > 0$) is somehow forced towards a centrifugally unstable state with $\mathrm{d}[l^z(r)]^2/\mathrm{d}r < 0$. A vanishing angular momentum at a particular radius, $l^z = 0$, is a sufficient condition to ensure $\mathrm{d}[l^z(r)]^2/\mathrm{d}r = 0$ at that radius. Evidently, if the angular momentum of the cyclostrophic flow is reduced toward zero, the fluid will go centrifugally unstable upon reaching just below zero angular momentum.

59.3.4 Instability condition in terms of absolute vorticity

The angular momentum condition (59.15) is the traditional way to write the necessary and sufficient condition for centrifugal instability. However, to anticipate the role of vorticity found in the case of inertial and symmetric instability, we rewrite the stability condition (59.15) in terms of absolute vorticity. For this purpose, introduce the vertical component of the relative vorticity,

$$\zeta = \frac{1}{r}\frac{\mathrm{d}(r\, v^\vartheta)}{\mathrm{d}r}, \tag{59.16}$$

and thus write the angular velocity as the radial integral of the radius weighted vorticity

$$v^\vartheta = \frac{1}{r}\int_0^r r'\, \zeta(r')\, \mathrm{d}r'. \tag{59.17}$$

This result allows us to write the angular momentum (59.3) in terms of the absolute vorticity

$$l^z = \Omega\, r^2 + \int_0^r r'\, \zeta(r')\, \mathrm{d}r' = \int_0^r r'\, (\zeta(r') + 2\,\Omega)\, \mathrm{d}r' = \int_0^r r'\, \zeta_{\mathsf{a}}(r')\, \mathrm{d}r'. \tag{59.18}$$

This equation allows us to write the stability condition (59.15) in the form

$$\frac{\mathrm{d}[l^z(r)]^2}{\mathrm{d}r} = 2\, l^z\, \frac{\mathrm{d}l^z(r)}{\mathrm{d}r} = 2\, r\, \zeta_{\mathsf{a}}(r) \int_0^r r'\, \zeta_{\mathsf{a}}(r')\, \mathrm{d}r' < 0 \implies \text{centrifugally unstable.} \tag{59.19}$$

For $\mathrm{d}[l^z(r)]^2/\mathrm{d}r < 0$ at a particular radius, r, and thus for the cyclostrophic flow to be unstable, requires the absolute vorticity at that radius to have the opposite sign to the integral of the radius weighted absolute vorticity from the origin to r. Since $r \geq 0$, a necessary condition for the instability is for the absolute vorticity to have a sign change somewhere within the region $0 \leq r$.

59.3.5 Parcel stability analysis

As a complement to the energetic stability analysis of Section 59.3.3, we here study the force balance in the radial momentum equation. This analysis shows that an unstable angular momentum profile corresponds to a situation where the outward centrifugal acceleration is stronger than the radially inward pressure gradient acceleration, thus allowing for the fluid parcel to be "thrown" outward.

We again assume rotational symmetry so that the angular momentum is a material invariant, and assume the base state is in cyclostrophic balance. As such, the radial momentum equation

(59.1a) leads to

$$0 = -g\,\partial_r \overline{\eta} + r^{-3}\,(\overline{l^z})^2, \tag{59.20}$$

with the overline denoting the cyclostrophic base state. Subtracting this equilibrium flow from the full momentum equation (59.1a) leads to an equation for radial acceleration of perturbations about the equilibrium state

$$\frac{\mathrm{D}v^r}{\mathrm{D}t} = -g\,\frac{\partial \eta'}{\partial r} + r^{-3}\left[(l^z)^2 - (\overline{l^z})^2\right], \tag{59.21}$$

where

$$\eta' = \eta - \overline{\eta} \tag{59.22}$$

is the perturbation surface height. We focus now on the difference in squared angular momentum, with questions about the perturbation pressure gradient, $-g\,\partial\eta'/\partial r$, falling outside the parcel method of stability analysis.

Probing stability by perturbing the radius of a circular fluid ring

Consider a perturbation realized by moving a constant mass circular fluid ring outward from its initial equilibrium state at radius r to a radius $r + \Delta r$. During expansion of the ring, its angular momentum remains constant due to the rotational symmetry, so that

$$(l^z)^2(r + \Delta r) = (l^z)^2(r) = (\overline{l^z})^2(r), \tag{59.23}$$

where the second equality holds since we are starting the ring from its cyclostrophic initial condition (59.20). To determine the radial acceleration at $r + \Delta r$ appearing on the right hand side of the radial velocity equation (59.21), we compute

$$(l^z)^2(r + \Delta r) - (\overline{l^z})^2(r + \Delta r) = (\overline{l^z})^2(r) - (\overline{l^z})^2(r + \Delta r) \approx -\Delta r\,\frac{\mathrm{d}(\overline{l^z})^2(r)}{\mathrm{d}r}, \tag{59.24}$$

so that the equation (59.21) evaluated at $r + \Delta r$ is

$$\frac{\mathrm{D}v^r}{\mathrm{D}t} = -g\,\frac{\partial \eta'}{\partial r} - \frac{\Delta r}{(r + \Delta r)^3}\,\frac{\mathrm{d}(\overline{l^z})^2(r)}{\mathrm{d}r}. \tag{59.25}$$

We thus see that if the squared angular momentum decreases upon moving the ring to a larger radius, then the second right hand side term in equation (59.25) provides a positive radial acceleration, thus supporting the initial outward perturbation. Ignoring the possibility for the perturbation pressure gradient, $-g\partial\eta'/\partial r$, to counter-act the acceleration, we are left with the same instability condition (59.15) derived using energetic arguments.

Describing the instability mechanism

When the fluid is in cyclostrophic balance, the radial pressure gradient acceleration (which is pointing radially inward) balances the centrifugal acceleration (which is pointing radially outward) as per equation (59.20). When a constant mass fluid ring is perturbed outward, from r to $r + \Delta r$, it carries its angular momentum, $\overline{l^z}(r)$, to the new location. This displaced ring is generally not in cyclostrophic balance with the pressure gradient at the new position. That is, the centrifugal acceleration of the displaced ring does not equal the pressure gradient of the new position

$$\underbrace{(r + \Delta r)^{-3}\,[\overline{l^z}(r)]^2}_{\text{centrifugal of displaced ring}} \quad \neq \quad \underbrace{g\frac{\partial \overline{\eta}(r + \Delta r)}{\partial r}}_{\text{pressure gradient at } r + \Delta r} \tag{59.26}$$

If the centrifugal acceleration of the displaced ring is greater than the local pressure gradient acceleration, then the ring will continue to move outward. That is, the outward centrifugal acceleration at the new location is greater than the inward pressure gradient so that the fluid ring is flung further outward. This process characterizes a centrifugally unstable state, and it occurs if the squared angular momentum decreases when moving radially outward, as per equation (59.15). Conversely, if the local pressure gradient is greater than the centrifugal acceleration of the dispaced ring, then the ring returns to its original radius and exhibits stable centrifugal oscillations.

Centrifugal oscillations

Ignoring the perturbation pressure gradient, and introducing a squared centrifugal angular frequency,

$$\sigma^2(r) \equiv \frac{1}{(r+\Delta r)^3} \frac{\mathrm{d}(\overline{l^z})^2(r)}{\mathrm{d}r}, \tag{59.27}$$

leads to the free oscillator equation for the fluctuation of a fluid ring from its equilibrium radial position

$$\frac{\mathrm{D}^2\Delta r}{\mathrm{D}t^2} + \sigma^2 \Delta r = 0, \tag{59.28}$$

where $u^r = \mathrm{D}(\Delta r)/\mathrm{D}t$ is the radial velocity of a fluid parcel relative to its equilibrium radial position. For stable cases with $\sigma^2 > 0$, the ring exhibits harmonic centrifugal oscillations around the equilibrium radius with period $2\pi/\sigma$. In contrast, for the unstable case with $\sigma^2 < 0$, then Δr grows exponentially.

59.3.6 Stability condition in terms of the surface height

The equilibrium angular momentum and free surface height are related by the cyclostrophic balance (59.20). So rather than focusing on the angular momentum, we can develop an equivalent stability condition in terms of radial derivatives of the free surface height. For this purpose, write the difference in angular momentum

$$(\overline{l^z})^2(r) - (\overline{l^z})^2(r+\Delta r) = g\,[r^3\,\mathrm{d}\overline{\eta}(r)/\mathrm{d}r - (r+\Delta r)^3\,\mathrm{d}\overline{\eta}(r+\Delta r)/\mathrm{d}r], \tag{59.29}$$

and then perform a Taylor series

$$\begin{aligned} F(r+\Delta r) &\equiv (r+\Delta r)^3\,\mathrm{d}\overline{\eta}(r+\Delta r)/\mathrm{d}r && \text{(59.30a)}\\ &\approx F(r) + \Delta r\,\mathrm{d}F(r)/\mathrm{d}r && \text{(59.30b)}\\ &= r^3\,\mathrm{d}\overline{\eta}(r)/\mathrm{d}r + \Delta r\,\mathrm{d}[r^3\,\mathrm{d}\overline{\eta}/\mathrm{d}r]/\mathrm{d}r, && \text{(59.30c)} \end{aligned}$$

which renders

$$(\overline{l^z})^2(r) - (\overline{l^z})^2(r+\Delta r) \approx -g\,\Delta r \frac{\mathrm{d}}{\mathrm{d}r}\left[r^3 \frac{\mathrm{d}\overline{\eta}}{\mathrm{d}r}\right]. \tag{59.31}$$

The radial momentum equation (59.25) thus takes the form

$$\frac{\mathrm{D}v^r}{\mathrm{D}t} = -g\frac{\partial \eta'}{\partial r} - \frac{g\,\Delta r}{(r+\Delta r)^3}\frac{\mathrm{d}}{\mathrm{d}r}\left[r^3\frac{\mathrm{d}\overline{\eta}}{\mathrm{d}r}\right]. \tag{59.32}$$

We are thus led to the instability condition written in terms of the surface height in the cyclostrophically balanced base state

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[r^3\frac{\mathrm{d}\overline{\eta}}{\mathrm{d}r}\right] < 0 \Longrightarrow \text{centrifugally unstable.} \tag{59.33}$$

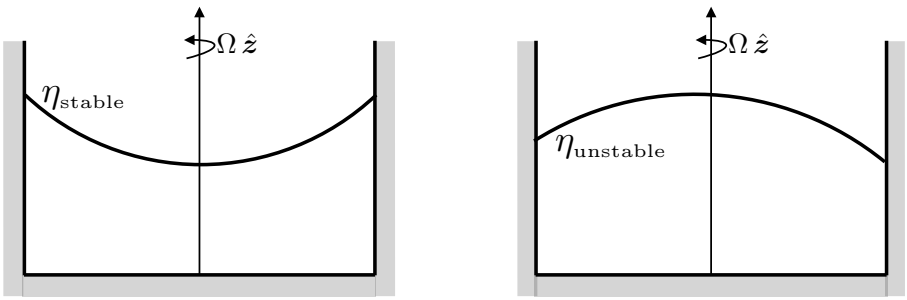

FIGURE 59.3: Example free surface heights for a shallow water layer in a rotating tank. The left panel exhibits a free surface height that is stable to centrifugal instability, whereas the right is unstable, with stability determined by the condition (59.33). The stable configuration approximates the parabolic profile that is realized for a rigid-body flow as in equation (59.35). The unstable profile has its layer thickness decrease with increasing radius, so that the radial pressure gradient acceleration cannot balance the centrifugal acceleration.

A particular example of a centrifugally unstable free surface configuration is the decreasing function

$$\overline{\eta} = \eta_0 - a\, r^b \implies \left[r^3\, \frac{\mathrm{d}\overline{\eta}}{\mathrm{d}r} \right] = -a\, b\, (2+b)\, r^{b+1}, \tag{59.34}$$

with η_0 the free surface height at the origin, b a dimensionless constant, and a having dimensions so that $a\, r^b$ has dimensions of length. Furthermore, we require with $a\, b > 0$, and $b > -2$. Recall that the free surface is parabolic when the fluid is in rigid-body motion, as given by equation (27.103)

$$\overline{\eta} = \eta_0 + \Omega^2\, r^2/(2\, g_{\mathrm{e}}) \implies \left[r^3\, \frac{\mathrm{d}\overline{\eta}}{\mathrm{d}r} \right] = 4\, \Omega^2\, r^3/g_{\mathrm{e}} > 0, \tag{59.35}$$

which is stable.

59.3.7 Comments and further study

Chapter 3 of *Drazin and Reid* (1981) is the canonical reference for centrifugal instability, where they provide a stability analysis including both axisymmetric and non-axisymmetric perturbations. In our treatment, we also made use of the parcel arguments from Section 3.2 of *Markowski and Richardson* (2010). Furthermore, *Markowski and Richardson* (2010) comment on the perturbation pressure gradient in equation (59.25), emphasizing that parcel stability arguments generally ignore changes to the pressure gradient. Stated otherwise, a parcel analysis concerns the equilibrium angular momentum profile and its contribution to movement away from equilibrium. It is not concerned with back reaction from pressure perturbations associated with movement of parcels or fluid rings. A fuller treatment generally requires analysis beyond the parcel framework. Section 11.6 of *Kundu et al.* (2016) presents centrifugal instability in the context of viscous Couette flow, which is the flow of fluid between two rotating co-axial cylinders.

For a laboratory realization of centrifugal instability, see this video from the UCLA spin lab. The laboratory technique spins up a fluid to rigid-body motion in a tank, and then quickly reduces the rotation rate to induce $\mathrm{d}[l^z(r)]^2/\mathrm{d}r < 0$. The instability manifests as roll vorticies aligned along the tank wall, with the character of the vorticies a function of $\mathrm{d}[l^z(r)]^2/\mathrm{d}r$ and other parameters.

59.4 Potential momentum on the f-plane

A front is a region of enhanced lateral gradients in the buoyancy field (baroclinic front) or sea level (shallow water front). These fronts generally have corresponding currents (jets) arising from geostrophic balance (when off-equator). Figure 59.4 illustrates a baroclinic front that

is symmetric in the zonal direction so that the buoyancy field is only a function of latitude, depth, and time, $b = b(y, z, t)$. We likewise assume that all other fields possess zonal symmetry, including pressure and velocity. Fronts can generally be oriented in any direction. Furthermore, there is rotational symmetry on the f-plane so that we can orient the horizontal coordinate axes as desired. In later sections we study the stability of fronts. Here, we establish some basic properties of *potential momentum*, which proves central to the stability analysis.

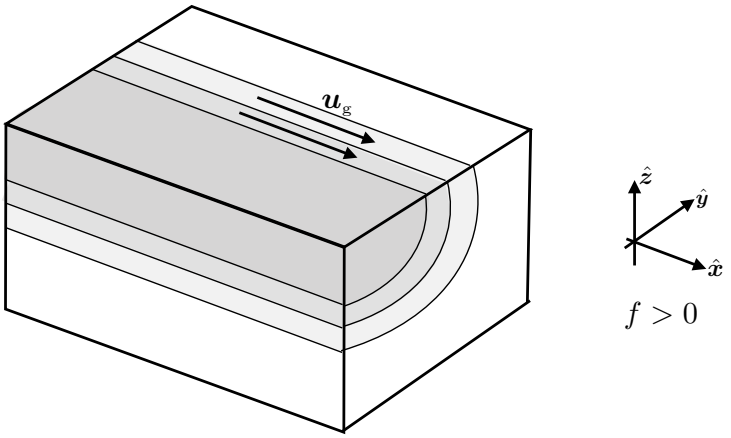

FIGURE 59.4: Example of a zonally symmetric baroclinic frontal region, showing iso-buoyancy surfaces with $b = b(y, z, t)$. With $\partial b/\partial y < 0$ as drawn, the corresponding zonal thermal wind shear, $f\,\partial u_g/\partial z = -\partial b/\partial y > 0$, is eastward for a northern hemisphere front; i.e., stronger eastward flow with increasing height (see Section 31.4.3).

59.4.1 Linear momentum and potential momentum

The horizontal linear momentum per mass for a perfect Boussinesq ocean on an f-plane evolves according to (see Section 29.1.6)

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_h \varphi. \tag{59.36}$$

Since f is a constant, this equation can be written

$$\frac{\mathrm{D}\boldsymbol{M}}{\mathrm{D}t} = -\nabla_h \varphi, \tag{59.37}$$

where we introduced the *potential momentum* per mass

$$\boldsymbol{M} \equiv \boldsymbol{u} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{x} = (u - f\,y)\,\hat{\boldsymbol{x}} + (v + f\,x)\,\hat{\boldsymbol{y}}, \tag{59.38}$$

and noted that $\boldsymbol{v} = \mathrm{D}\boldsymbol{x}/\mathrm{D}t$. Notably, the potential momentum remains materially invariant in directions where the horizontal pressure gradient vanishes. We described the potential momentum for a point particle in Section 14.3, and here make use of it to study the stability of certain f-plane fluid flows.

Materially constant zonal potential momentum

For the zonally aligned buoyancy front illustrated in Figure 59.4, we assume all fields are independent of the zonal direction so that

$$\partial_x \varphi = 0. \tag{59.39}$$

A vanishing zonal pressure gradient means that the zonal potential momentum per mass is a material invariant

$$\mathrm{D}M^x/\mathrm{D}t = 0 \quad \text{where } M^x \equiv u - f\,y. \tag{59.40}$$

This material invariance greatly constrains the flow. For example, consider a fluid parcel at an initial latitude y_0 with zonal velocity u_0. Movement of the parcel to a new latitude leads to the equality

$$u_0 - f y_0 = u_1 - f\,y_1, \tag{59.41}$$

so that the zonal velocity at the new latitude is given by

$$u_1 = u_0 - f(y_0 - y_1). \tag{59.42}$$

Motivating the name potential momentum

Although *absolute momentum* or *geostrophic momentum* are more commonly used in the literature, we prefer the term *potential momentum* as motivated by the same reasoning used for potential temperature (Section 23.3), potential density (Section 30.3.4), and potential vorticity (Section 39.3.2). Namely, the zonal potential momentum identifies that amount of zonal linear momentum per mass (i.e., the velocity) that a parcel would acquire if moved from an arbitrary latitude y_1, to a reference latitude, y_0. More specifically, inverting equation (59.42) we see that

$$u_0 = M^x(y_1) + f y_0. \tag{59.43}$$

Hence, the quantity $M^x(y_1)$ is the extra zonal momentum per mass available at the reference latitude, y_0, upon moving a parcel from y_1 to y_0. We thus see that the potential momentum is a material invariant in the way that potential temperature is for a perfect fluid. Furthermore, as seen in Section 59.5, meridional gradients of M^x measure the *inertial* stability of a flow configuration in a manner directly analogous to how vertical gradients of potential temperature (or buoyancy) measure gravitational stability.

Meridional potential momentum

There are occasions when a front exhibits meridional symmetry, in which case the perfect Boussinesq equations take the form

$$\mathrm{D}u/\mathrm{D}t = fv - \partial_x\varphi \tag{59.44a}$$
$$\mathrm{D}v/\mathrm{D}t = -fu. \tag{59.44b}$$

In this case the meridional potential momentum is materially invariant

$$\mathrm{D}M^y/\mathrm{D}t = 0 \quad \text{where} \quad M^y \equiv v + fx. \tag{59.45}$$

59.4.2 Zonal potential momentum on a β-plane

The f-plane is rotationally invariant about the rotational axis. Correspondingly, we can write the momentum equation in the form (59.37), thus exposing the potential momentum. Material invariance for potential momentum holds along the symmetry direction of an arbitrarily oriented symmetric front.

The β-plane is not rotationally invariant. Rather, it only maintains symmetry along lines of constant latitude (zonal directions). Consequently, only zonally oriented symmetric fronts maintain material invariance of zonal potential momentum. To see this property, write the zonal

momentum equation in the form

$$\partial_t u + v\,\partial_y u + w\,\partial_z u - f\,v = 0, \tag{59.46}$$

where we assumed zonal symmetry ($\partial_x = 0$). Now write the Coriolis parameter in the form

$$\Gamma = f_\circ\, y + \beta\, y^2/2 \Longrightarrow f = \mathrm{d}\Gamma/\mathrm{d}y, \tag{59.47}$$

so that the zonal momentum equation takes the form

$$\partial_t(u - \Gamma) + v\,\partial_y(u - \Gamma) + w\,\partial_z(u - \Gamma) = 0. \tag{59.48}$$

Evidently, $M^x = u - \Gamma$ is materially invariant for this zonally symmetric front.

59.4.3 Further reading

See Section 14.4 for more discussion of potential momentum as it concerns a point particle. The term *absolute momentum* follows the arguments given on page 51 of *Markowski and Richardson* (2010).

59.5 Horizontal inertial instability of geostrophic fronts

We now examine stability of an f-plane geostrophically balanced front for an inviscid Boussinesq fluid. The analysis of centrifugal instability in Section 59.3 is closely followed, with rotational symmetry replaced by along-front symmetry and angular momentum replaced by potential momentum. We consider both the Rayleigh energetic stability analysis and the parcel analysis. Furthermore, the perturbations maintain symmetry in the along-front direction, so perturbations consist of a horizontally displaced row of parcels oriented along the front. Stability to more general perturbations, such as those that are not symmetric along the front, is not addressed here.

The results of our analysis are rotationally invariant since the f-plane is rotationally invariant. Hence, we choose to orient the coordinate system based on convenience whereby the x-axis is the along front axis and the y-axis is across the front (as in Figure 59.4). Furthermore, their relative orientation is chosen in the usual righthand sense, so that $\hat{\boldsymbol{x}} \times \hat{\boldsymbol{y}} = \hat{\boldsymbol{z}}$, where $\hat{\boldsymbol{z}}$ is anti-parallel to gravity.

Although we make use of a continuously stratified Boussinesq fluid, the inertial instability considered in this section is not associated with baroclinicity. Rather, as for the centrifugal case in Section 59.3, it is associated with stability of an equilibrium state to horizontal displacements along geopotential surfaces. In a continuously stratified adiabatic fluid, horizontal displacements generally cross isentropic surfaces and so comprise irreversible perturbations. So long as the associated mixing of momentum is negligible, we can still make use of material invariance of potential momentum. We return to this point when studying isentropic inertial (symmetric) instability in Section 59.6, in which perturbations are along sloped buoyancy surfaces rather than geopotential surfaces.

59.5.1 Equations of motion relative to the geostrophic equilibrium state

The horizontal momentum equation for an inviscid Boussinesq fluid on an f-plane is given by (see Section 29.1)

$$\mathrm{D}\boldsymbol{u}/\mathrm{D}t + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_{\!\mathrm{h}}\varphi. \tag{59.49}$$

In the presence of along-front symmetry, an exact solution to the horizontal momentum equation is given by along-front geostrophic flow and zero flow across the front

$$u_{\rm g} = -f^{-1}\,\partial_y\varphi \quad \text{and} \quad v = 0 \quad \text{and} \quad \partial_x\varphi = 0. \tag{59.50}$$

We examine the stability of this exact equilibrium base state[5] to perturbations aligned with the front. To study evolution of the perturbations relative to the base state, subtract the base state solution from the full momentum equation (59.49) to render

$$\mathrm{D}u/\mathrm{D}t = f\,v \tag{59.51a}$$
$$\mathrm{D}v/\mathrm{D}t = f\,(u_{\rm g} - u). \tag{59.51b}$$

We continue to assume along-front symmetry in the perturbation so that there is no along-front pressure gradient ($\partial_x\varphi = 0$) in equation (59.51a). Equation (59.51b) says that across-front accelerations are determined by deviations from geostrophy of the along-front velocity, and equation (59.51a) says that along-front accelerations are determined by the Coriolis acceleration arising from a non-zero across-front velocity.

Following the treatment of potential momentum in Section 14.3, we write the along-front momentum equation (59.51a) as the material time derivative of the along-front potential momentum per mass

$$M^x = u - fy, \tag{59.52}$$

bringing the suite of perturbation equations to

$$\mathrm{D}M^x/\mathrm{D}t = 0 \tag{59.53a}$$
$$\mathrm{D}v/\mathrm{D}t = f(u_{\rm g} - u). \tag{59.53b}$$

Material invariance of the along-front potential momentum plays a fundamental role in the stability analysis, analogous to the role of angular momentum for centrifugal instability in Section 59.3. Finally, we can write the equations in terms of just M^x and v via

$$\mathrm{D}M^x/\mathrm{D}t = 0 \tag{59.54a}$$
$$\mathrm{D}v/\mathrm{D}t = f(M^x_{\rm g} - M^x). \tag{59.54b}$$

59.5.2 Stability analysis based on energetic arguments

We follow the energetic arguments given in Section 59.3.3 for centrifugal instability of cyclostrophic flow. Here, we ask whether the along-front geostrophic flow is stable to a swap of two along-front oriented rows that have the same geopotential. If the swap releases kinetic energy from the base state, then the base state flow is *inertially unstable* to an along-front symmetric perturbation. In that case, perturbations spontaneously initiate inertial instability to affect a return to an inertially stable state.

Instability condition

The kinetic energy per mass for the along-front geostrophic flow is given by

$$E = u_{\rm g}^2/2 = (M^x_{\rm g} + fy)^2/2, \tag{59.55}$$

[5] It is useful to confirm that $u_{\rm g} = -f^{-1}\,\partial_y\varphi$ and $v = 0$ are indeed exact solutions to equation (59.49).

where we replaced the geostrophic velocity with the geostrophic potential momentum through equation (59.52)

$$M^x_{\text{g}} = u_{\text{g}} - f\,y. \tag{59.56}$$

The kinetic energy per mass contained in two equal mass parcels at distinct meridional cross-front positions, $y = y_1$, and

$$y_2 = y_1 + (y_2 - y_1) = y_1 + \Delta y, \tag{59.57}$$

is given by

$$E_{\text{init}} = [M^x_{\text{g}}(y_1) + f y_1]^2/2 + [M^x_{\text{g}}(y_2) + f y_2]^2/2. \tag{59.58}$$

Swapping the parcels and making use of the invariance of potential momentum leads to the kinetic energy in the swapped state

$$E_{\text{swap}} = [M^x_{\text{g}}(y_1) + f\,y_2]^2/2 + [M^x_{\text{g}}(y_2) + f\,y_1]^2/2. \tag{59.59}$$

A bit of algebra leads to the difference in kinetic energy between the two states

$$E_{\text{swap}} - E_{\text{init}} = -f\,(y_2 - y_1)\,[M^x_{\text{g}}(y_2) - M^x_{\text{g}}(y_1)] = -f\,\Delta y\,\Delta M^x_{\text{g}}. \tag{59.60}$$

Now compute a Taylor series of the potential momentum, $M^x_{\text{g}}(y_2)$, relative to the across-front position, $y = y_1$,

$$M^x_{\text{g}}(y_2) \approx M^x_{\text{g}}(y_1) + (y_2 - y_1)\,\frac{\mathrm{d}M^x_{\text{g}}}{\mathrm{d}y}\bigg|_{y=y_1}, \tag{59.61}$$

which then leads to the energy difference

$$\begin{aligned} E_{\text{swap}} - E_{\text{init}} &= -f\,(\Delta y)^2\,\frac{\mathrm{d}M^x_{\text{g}}}{\mathrm{d}y} && \text{(59.62a)}\\ &= -f\,(\Delta y)^2\,(\partial_y u_{\text{g}} - f) && \text{(59.62b)}\\ &= f\,(\Delta y)^2\,(\zeta_{\text{g}} + f), && \text{(59.62c)} \end{aligned}$$

where

$$\zeta_{\text{g}} = -\partial_y u_{\text{g}} \tag{59.63}$$

is the vertical component to the geostrophic relative vorticity for the symmetric base state. Evidently, kinetic energy is released upon swapping the two rows if the following condition is satisfied

$$-f\,\partial_y M^x_{\text{g}} = f\,(\zeta_{\text{g}} + f) < 0 \Longrightarrow \text{inertial instability}. \tag{59.64}$$

The second instability condition says that the base state is unstable if the absolute geostrophic vorticity, $\zeta_{\text{g}} + f$, has an opposite sign to the planetary vorticity. This stability condition has a natural generalization to the case of symmetric instability considered in Sections 59.6 and 59.8.

Interpreting the instability condition

The first instability condition in equation (59.64) arises if the cross-front gradient of the geostrophic potential momentum has the same sign as the Coriolis parameter. To help understand this condition we examine the inertial stability of a base state with zero flow. Zero flow in a rotating reference frame corresponds to rigid-body motion with potential momentum $M^x_{\text{g}} = -fy$. For this base state, the inertial stability condition (59.64) is given by

$$-f\,(\partial M^x_{\text{g}}/\partial y) = f^2 > 0, \tag{59.65}$$

thus signaling the rigid-body flow is inertially stable. By contrast, we infer that an inertially unstable base state is rendered unstable by having an along-front flow that overcomes the stabilizing contribution to potential momentum from planetary rotation. This situation is directly analogous to the centrifugal instability studied in Section 59.3.

Summarizing the conditions for inertial instability

The instability condition (59.64) takes the following form for the northern and southern hemispheres. Again, the x-axis is oriented along the front and y-axis is across the front with $\hat{\boldsymbol{x}} \times \hat{\boldsymbol{y}} = \hat{\boldsymbol{z}}$ and $M^x_{\rm g} = u_{\rm g} - f\, y$

$$\text{northern hemisphere } (f > 0): \qquad \partial_y M^x_{\rm g} > 0 \qquad \zeta_{\rm g} < -|f| \qquad \partial_y u_{\rm g} > +|f| \tag{59.66a}$$

$$\text{southern hemisphere } (f < 0): \qquad \partial_y M^x_{\rm g} < 0 \qquad \zeta_{\rm g} > +|f| \qquad \partial_y u_{\rm g} < -|f|. \tag{59.66b}$$

In both hemispheres, instability arises when the relative geostrophic vorticity is anti-cyclonic and larger in magnitude than the cyclonic vorticity from planetary rotation. Under such conditions, inertial instability allows the flow to readjust toward a state of less extreme relative vorticity, thus returning the flow to a state with absolute vorticity dominated by planetary vorticity. Equivalently, inertial instability arises for flows where $\partial M^x_{\rm g}/\partial y > 0$ in the northern hemisphere and $\partial M^x_{\rm g}/\partial y < 0$ in the southern hemisphere, so that potential momentum of the geostrophic base state increases poleward.

59.5.3 Stability analysis based on parcel arguments

Following the analysis for centrifugal instability in Section 59.3.5, we here consider a parcel stability analysis to provide a force-balance interpretation of the inertial instability. For this purpose, return to the perturbation equations (59.53a) and (59.53b), again with the equilibrium base state of along-front geostrophic balance with zero motion in the across-front direction

$$f\, u_{\rm g} = -\partial_y \varphi. \tag{59.67}$$

We examine the stability of this geostrophic base state with respect to along-front perturbations of fluid parcels. For this purpose, imagine moving a row of fluid parcels from position y to a new position, $y + \Delta y$. As per the usual assumption of a parcel analysis, this move is assumed to have no impact on the surrounding fluid environment, including the pressure field.[6] In general, the displaced row of fluid parcels will not be in geostrophic balance at the new position, thus providing for a non-zero acceleration in the across-front direction. If the acceleration is directed back to the original position, then the base state is stable and displaced parcels exhibit inertial oscillations in the x-y plane. In contrast, the base state is inertially unstable if the net acceleration acts to further the initial displacement. Note that while the fluid parcels are moved meridionally, they will be displaced zonally due to the Coriolis acceleration. However, we focus attention on the meridional motion to determine whether the parcel accelerates further away from its initial latitude or returns. We illustrate facets of the stable and unstable situations in Figures 59.5 and 59.6, with details of these figures explained in the remainder of this section.

Mathematical formulation

Equation (59.53b) for the across-front motion is given by

$$\mathrm{D}v/\mathrm{D}t = f\,(u_{\rm g} - u). \tag{59.68}$$

[6] With this assumption, the pressure field remains in geostrophic balance with the unperturbed background geostrophic flow.

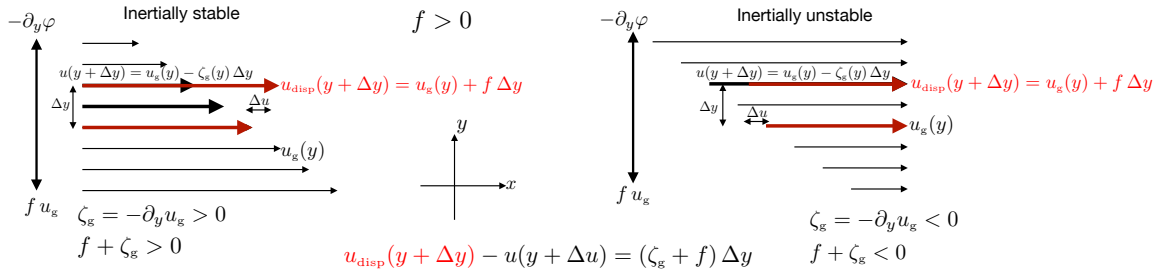

FIGURE 59.5: Schematics of an inertially stable (left panel) and inertially unstable (right panel) geostrophic base flow in the northern hemisphere. One of the red vectors is for the geostrophic velocity, $u_g(y)$, and the second for the velocity at a displaced position $u_{disp}(y+\Delta y)$. The displaced velocity is determined by conservation of zonal potential momentum, $u_{disp}(y+\Delta y) = u_g(y) + f\,\Delta y$, from equation (59.71). In the unperturbed flow, the eastward geostrophic velocity is generated by a northward pressure gradient acceleration that balances a southward Coriolis acceleration. The base state pressure gradient remains unchanged even as the fluid parcels are perturbed, with this assumption basic to the parcel method of stability analysis. At the displaced position we also show the base state velocity at the displaced position, $u(y+\Delta y) = u_g(y) + \partial_y u(y)\,\Delta y = u_g(y) - \zeta_g(y)\,\Delta y$. The difference between the displaced velocity and the base state velocity is $u_{disp}(y+\Delta y) - u(y+\Delta y) = (f+\zeta_g)\,\Delta y$. For the left panels, the flow has positive relative vorticity so that $\zeta_g + f > 0$ and the flow is inertially stable. In this case, the displaced parcel has a southward Coriolis acceleration larger than the local Coriolis, thus returning the row of fluid parcels back towards its initial latitude. For the right panel, the flow has negative relative geostrophic vorticity, and that vorticity is strong enough so that the absolute geostrophic vorticity is negative, $\zeta_g + f < 0$, in which case the flow is inertially unstable. In this case, the displaced parcel has a southward Coriolis acceleration smaller than the local Coriolis. Hence, the northward pressure gradient is strong enough to keep the parcel moving northward, away from its initial position, thus signaling a base state that is inertially unstable.

This equation holds everywhere, in particular at the displaced cross-front position, $y + \Delta y$. At this position, the right hand side has $u(y + \Delta y)$, which is the along-front velocity of the displaced parcel at the new position. Likewise, $u_g(y + \Delta y)$ is the geostrophic velocity at $y + \Delta y$ of the prescribed background flow. According to equation (59.67), the geostrophic velocity, $u_g(y+\Delta y)$, determines a Coriolis acceleration at the displaced position, $y+\Delta y$, with this Coriolis acceleration balanced by the cross-front pressure gradient, also evaluated at $y + \Delta y$.

To determine the sign of the cross-front acceleration in equation (59.68) acting on the displaced parcel at $y + \Delta y$, we make use of the material invariance of along-front potential momentum. This invariance means that each fluid parcel carries its potential momentum from the original position.[7] For example, the potential momentum of a fluid parcel initially at position y has the value given by the geostrophic base state at that latitude

$$M^x(y) = M^x_g(y) = u_g(y) - f\,y. \tag{59.69}$$

Material invariance means that the parcel retains this potential momentum as it moves to the new position, $y + \Delta y$. In turn, invariance of along-front potential momentum allows us to determine the along-front velocity of the parcel at the displaced position in terms of $u_g(y)$ (recall the procedure leading to equation (59.42))

$$\begin{aligned} M^x(y+\Delta y) &= u(y+\Delta y) - f\,(y+\Delta y) && \text{(59.70a)} \\ &= M^x(y) && \text{(59.70b)} \\ &= u_g(y) - f\,y, && \text{(59.70c)} \end{aligned}$$

which leads to

$$u(y+\Delta y) = u_g(y) + f\,\Delta y. \tag{59.71}$$

[7] We offer a cautionary remark about notation. Namely, f is a constant so that $f\,y$ is f times the latitude position y, and likewise for $f\,(y+\Delta y)$. In contrast, the zonal velocity, u, is a function of y, so that $u(y)$ and $u(y+\Delta y)$ represent the zonal velocity evaluated at the latitude positions y and $y+\Delta y$, respectively.

The cross-front acceleration (59.68) at the new latitude position thus takes the form

$$\frac{\mathrm{D}v(y+\Delta y)}{\mathrm{D}t} = f\,[u_{\mathrm{g}}(y+\Delta y) - u(y+\Delta y)] \tag{59.72a}$$

$$= f[u_{\mathrm{g}}(y+\Delta y) - u_{\mathrm{g}}(y) - f\,\Delta y] \tag{59.72b}$$

$$\approx f\Delta y\left[\frac{\partial u_{\mathrm{g}}}{\partial y} - f\right] \tag{59.72c}$$

$$= -f\,\Delta y\,(\zeta_{\mathrm{g}} + f). \tag{59.72d}$$

The initial displacement grows,

$$\frac{1}{\Delta y}\frac{\mathrm{D}v(y+\Delta y)}{\mathrm{D}t} > 0, \tag{59.73}$$

if the following instability condition holds

$$f\,(\zeta_{\mathrm{g}} + f) < 0 \Longrightarrow \text{inertially unstable}, \tag{59.74}$$

which is the same instability condition as found via the energetic arguments in Section 59.5.2.

Oscillations or exponential growth?

Let y be the arbitrary initial meridional position for a fluid parcel, and Δy the meridional position relative to y. The equation of motion (59.72d) can be written in terms of the relative position so that

$$\frac{\mathrm{d}^2\Delta y}{\mathrm{d}t^2} + f\,(\zeta_{\mathrm{g}} + f)\,\Delta y = 0. \tag{59.75}$$

If $f\,(\zeta_{\mathrm{g}} + f) < 0$ then Δy has an exponentially growing (and decaying) solution, thus indicating instability. For the alternative case with $f\,(\zeta_{\mathrm{g}} + f) > 0$ we expect to find inertial-like oscillations.

A quick derivation of the instability condition

The displaced parcel at $y+\Delta y$ has zonal velocity $u(y+\Delta y) = u_{\mathrm{g}}(y) + f\,\Delta y$ according to equation (59.71), which follows from the material conservation of zonal potential momentum. The velocity of the background geostrophic flow at $y+\Delta y$ is given by the Taylor series approximation relative to the flow at y (keeping terms up to first order):

$$u_{\mathrm{g}}(y+\Delta y) \approx u_{\mathrm{g}}(y) + \Delta y\,\partial_y u_{\mathrm{g}}(y) = u_{\mathrm{g}}(y) - \Delta y\,\zeta_{\mathrm{g}}(g). \tag{59.76}$$

The difference between these two zonal velocities is

$$u_{\mathrm{g}}(y+\Delta y) - u(y+\Delta y) = -(f+\zeta_{\mathrm{g}})\,\Delta y, \tag{59.77}$$

which recovers the inertial stability condition derived above.

Summary of the parcel argument

As summarized in Figures 59.5 and 59.6, at the initial location in the base state, a parcel under geostrophic balance has its Coriolis acceleration balanced by its pressure acceleration. However, the displaced parcel generally will not be in geostrophic balance at the new location, in which case its Coriolis acceleration does not balance the local pressure gradient. The parcel approach determines a stability condition based on whether the imbalance leads to an acceleration back towards its initial position (stable inertial oscillations) or further away (inertial instability). For the unstable case, the Coriolis acceleration of the displaced parcel at its new location cannot

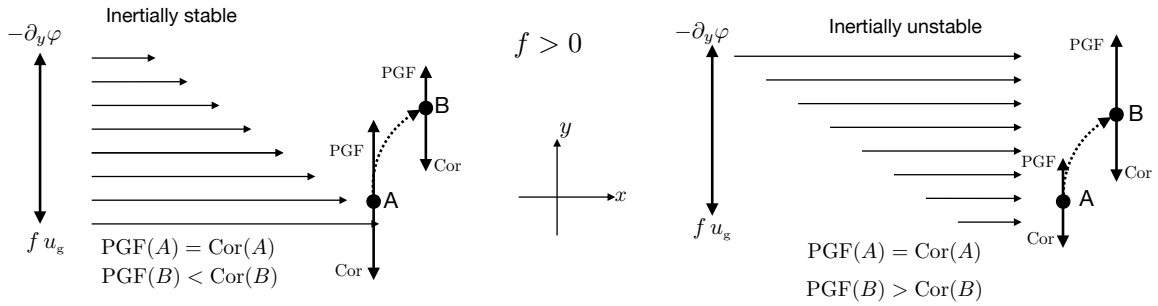

FIGURE 59.6: Further depiction of inertially stable geostrophic flow (left panel) and unstable geostrophic flow (right panel), complementing features presented in Figure 59.5. Here we show a fluid parcel starting at point A and displaced to point B, with the curved motion due to the zonal Coriolis acceleration that acts when the parcel is displaced in the meridional direction ($f > 0$). For the inertially stable case, the pressure gradient acceleration acting on the displaced parcel at point B is weaker than the parcel's Coriolis acceleration, so that the parcel exhibits stable inertial oscillations in the x-y plane. For the inertially ustable case, the pressure gradient acceleration acting on the parcel at point B is stronger than the parcel's Coriolis acceleration, so that the parcel continues to move further away and thus exhibits inertial instability.

match the local pressure gradient, thus causing the parcel to be thrust away from its initial latitude.

Along-front symmetry of both the base state and the perturbation ensures material invariance of along-front potential momentum. This invariance provides an explicit expression for the acceleration felt by the displaced parcel, thus determining a condition on stability of the base state to such symmetric perturbations. The method of analysis is directly analogous to that applied to the rotating tank of fluid in Section 59.3 for centrifugal instability, as well as for a vertical column of fluid in Section 30.4 for gravitational stability. We follow this procedure again in Section 59.6 for studying symmetric instability.

59.6 Symmetric instability and the $f\,Q < 0$ criteria

In this section we examine stability of a geostrophically balanced baroclinic front on an f-plane. We continue to assume the front is gravitationally stable ($N^2 > 0$) and that it exhibits along-front symmetry so that the along-front potential momentum is a material invariant (Figure 59.4). Different from the inertial instability case in Section 59.5, we here assume the fluid to be adiabatic so that Archimedean buoyancy is a second materially invariant property. We investigate stability of a geostrophically balanced along-front flow using the parcel method and make use of buoyancy as the vertical coordinate. We follow up this analysis in Section 59.8 with an Eulerian modal analysis. Both approaches reveal the fundamental importance of potential vorticity as a signature of symmetric instability. More precisely, the product, $f\,Q$, if negative, indicates a symmetrically unstable front.

59.6.1 Equations using buoyancy as the vertical coordinate

Given the adiabatic nature of the fluid, and the role of baroclinicity, we are motivated to use buoyancy as the vertical coordinate for a Boussinesq fluid as detailed in Section 66.2. That is, we consider symmetric displacements of parcels along a constant buoyancy surface. By construction, this displacement is neutral to gravitational instability since it occurs along a constant buoyancy surface. However, a displaced parcel could still find itself in an unstable position depending on the potential momentum of the local environment relative to the buoyancy surfaces. The analysis proceeds just like for the horizontal inertial instability of Section 59.5.3, yet with the displacements here being isentropic (constant buoyancy) rather than horizontal

(constant geopotential). We are thus motivated to refer to the ensuing instability as *isentropic inertial instability*, though note that it is more commonly referred to as *symmetric instability*.

With buoyancy as the vertical coordinate, the horizontal momentum equation is[8]

$$\mathrm{D}\boldsymbol{u}/\mathrm{D}t + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_{\mathrm{hb}} M \tag{59.78}$$

where ∇_{hb} is a horizontal gradient computed along constant buoyancy surfaces. Furthermore,

$$M = \varphi - b\,z \tag{59.79}$$

is the Montomery potential that contributes an acceleration via[9]

$$-\nabla_{\mathrm{hb}} M = -\nabla_{\mathrm{hb}} \varphi + b\,\nabla_{\mathrm{hb}} z. \tag{59.80}$$

The first term arises from pressure gradients and the second from geopotential gradients, both computed along constant buoyancy surfaces. In the presence of along-front symmetry, an exact solution to the horizontal momentum equation is given by along-front geostrophic flow and zero cross-front flow

$$u_{\mathrm{g}} = -\frac{1}{f\,\rho_\circ}\left[\frac{\partial M}{\partial y}\right]_b \quad \text{and} \quad v = 0 \quad \text{and} \quad \left[\frac{\partial M}{\partial x}\right]_b = 0. \tag{59.81}$$

We examine stability of this base state to perturbations that are symmetric in the along-front direction. Subtracting the exact equilibrium solution from the full momentum equation (59.49) leads to

$$\mathrm{D}u/\mathrm{D}t = fv \quad \text{and} \quad \mathrm{D}v/\mathrm{D}t = f(u_{\mathrm{g}} - u), \tag{59.82}$$

where we assume along-front symmetry thus allowing us to drop the along-front gradient of the Montgomery potential. Following the treatment in Sections 14.3 and 59.5.1, we write the along-front momentum equation as the material time derivative of the along-front potential momentum per mass, $M^x = u - fy$ (equation (59.52)), thus bringing the perturbation equations to

$$\mathrm{D}M^x/\mathrm{D}t = 0 \quad \text{and} \quad \mathrm{D}v/\mathrm{D}t = f\,(M^x_{\mathrm{g}} - M). \tag{59.83}$$

59.6.2 Parcel stability analysis

We follow the parcel analysis used for inertial instability in Section 59.5.3, starting with an equilibrium base state of along-front geostrophic balance with zero meridional motion and then examine the stability of this state to symmetric perturbations of fluid parcels along a constant buoyancy surface. For this purpose, imagine moving a row of fluid parcels from cross-front position y to position $y + \Delta y$ while maintaining a fixed buoyancy *and* fixed potential momentum. Furthermore, assume the displacement has no impact on the base state, which is the typical assumption of the parcel approach to stabilty analysis. In general, the displaced row of parcels will not be in geostrophic balance at the new position, thus providing for a non-zero cross-front acceleration at that displaced position. The sign of that acceleration determines stability of the flow to the symmetric perturbation.

At the new cross-front position, the meridional acceleration acting on the displaced parcels

[8] In Part XII of this book, we develop the mathematical and physical details for generalized vertical coordinates, such as buoyancy or isopycnal coordinates. In particular, the essential features of the ∇_{hb} gradient operator are provided in Figure 63.4. For purposes of the present chapter, one merely needs to know that ∇_{hb} provides a measure of the property gradients computed along constant buoyancy surfaces, and yet with ∇_{hb} still having only horizontal components: $\nabla_{\mathrm{hb}} = \hat{\boldsymbol{x}}\,(\partial/\partial x)_b + \hat{\boldsymbol{y}}\,(\partial/\partial y)_b$, where the b subscript means that the derivative is computed while holding b constant.

[9] Be careful to distinguish the Montgomery potential, M, in equation (59.79) from the zonal potential momentum, M^x, in equation (59.40).

is given by[10]

$$\frac{\mathrm{D}v(y+\Delta y)}{\mathrm{D}t} = f\,[M^x_{\mathrm{g}}(y+\Delta y) - M^x(y+\Delta y)], \tag{59.84}$$

where $M^x(y+\Delta y)$ is the potential momentum at $y+\Delta y$, and $M^x_{\mathrm{g}}(y+\Delta y)$ is the geostrophic potential momentum at $y+\Delta y$. To determine the sign of the acceleration acting on the displaced parcel, we make use of the material invariance of along-front potential momentum,

$$M^x(y+\Delta y) = M^x(y) = M^x_{\mathrm{g}}(y), \tag{59.85}$$

so that the meridional acceleration is

$$\frac{\mathrm{D}v(y+\Delta y)}{\mathrm{D}t} = f\left[\frac{\partial M^x_{\mathrm{g}}}{\partial y}\right]_b \Delta y. \tag{59.86}$$

Evidently, if $\Delta y > 0$ then the displacement is unstable if

$$f\left[\frac{\partial M^x_{\mathrm{g}}}{\partial y}\right]_b > 0 \Longrightarrow \text{symmetrically unstable geostrophic state.} \tag{59.87}$$

We can write this condition in terms of the absolute geostrophic vorticity by noting that

$$\left[\frac{\partial M^x_{\mathrm{g}}}{\partial y}\right]_b = \left[\frac{\partial u_{\mathrm{g}}}{\partial y}\right]_b - f = -(\widetilde{\zeta}_{\mathrm{g}} + f), \tag{59.88}$$

where $\widetilde{\zeta}_{\mathrm{g}}$ is the relative vorticity of the geostrophic flow computed on buoyancy surfaces (see Section 66.2)

$$\widetilde{\zeta}_{\mathrm{g}} = \left[\frac{\partial v_{\mathrm{g}}}{\partial x}\right]_b - \left[\frac{\partial u_{\mathrm{g}}}{\partial y}\right]_b, \tag{59.89}$$

with $v_{\mathrm{g}} = 0$ for this zonal geostrophic front. Evidently, we have arrived at the alternative expression of a symmetrically unstable geostrophic base flow

$$f\,(f + \widetilde{\zeta}_{\mathrm{g}}) < 0 \Longrightarrow \text{symmetrically unstable geostrophic state.} \tag{59.90}$$

Finally, we can introduce the Boussinesq Ertel potential vorticity in the form[11]

$$Q = (\boldsymbol{\omega} + f\,\hat{\boldsymbol{z}}) \cdot \nabla b = (\widetilde{\zeta} + f)\,N^2, \tag{59.91}$$

with $N^2 = \partial_z b > 0$ the squared buoyancy frequency for gravitationally stable flows. Bringing these results together leads to the equivalent expressions of the necessary and sufficient conditions for a geostrophic base flow to be symmetrically unstable

$$f\left[\frac{\partial M^x_{\mathrm{g}}}{\partial y}\right]_b > 0 \tag{59.92a}$$

$$f\,(\widetilde{\zeta}_{\mathrm{g}} + f) < 0 \tag{59.92b}$$

$$f\,Q_{\mathrm{g}} < 0. \tag{59.92c}$$

[10] We only expose the meridional coordinate dependence in equation (59.84), but note that the velocity and potential momentum are also a function of the vertical position and time.

[11] We derive equation (59.91) when studying potential vorticity in the Boussinesq ocean using buoyancy coordinates; see equation (66.38).

59.6.3 Geometric perspective on the instability condition

The instability condition (59.92b) is a direct translation of the inertial instability condition (59.74), swapping horizontal displacements with displacements along buoyancy surfaces. Likewise, the instability condition (59.92a) is directly analogous to the inertial instability condition (59.64), only here with displacement along a buoyancy surface rather than a geopotential. In the northern hemisphere, if one moves in the $+\hat{\boldsymbol{y}}$ direction on a constant buoyancy surface and encounters increasing values for the potential momentum, then the base state flow is symmetrically unstable. Conversely in the southern hemisphere, if one moves in $-\hat{\boldsymbol{y}}$ direction on a constant buoyancy surface and encounters increasing values for the potential momentum, then the base state flow is symmetrically unstable. We illustrate this situation in Figure 59.7.

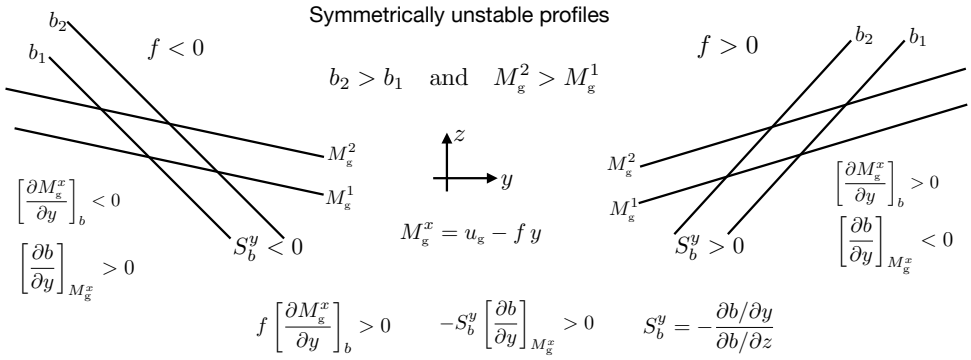

FIGURE 59.7: Example geostrophically balanced flow configurations that are symmetrically unstable; i.e., inertially unstable to a perturbation with symmetry along the front. We show example buoyancy surfaces and potential momentum surfaces for the southern hemisphere (left) and northern hemisphere (right). The instability conditions (59.99a) and (59.99b) are indicated on the respective panels. In both cases, surfaces of constant buoyancy are more steeply sloped than constant potential momentum surfaces. The x coordinate measures distance in the along-front direction and y measures distance in the cross-front direction, oriented so that $\hat{\boldsymbol{x}} \times \hat{\boldsymbol{y}} = \hat{\boldsymbol{z}}$ where $\hat{\boldsymbol{z}}$ is anti-parallel to gravity ($\hat{\boldsymbol{x}}$ is out of the page). A means to quickly judge whether a flow is symmetrically unstable is to note that the *wedge of instability* region between buoyancy and potential momentum surfaces provides a source of available potential energy. Symmetric instability can feed off the potential energy only when buoyancy surfaces are more steeply sloped than potential momentum surfaces.

As another way to write the instability condition (59.92a), make use of the expression (63.78b) to transform the derivative on buoyancy surfaces back to geopotential coordinates

$$\left[\frac{\partial M_{\mathrm{g}}^x}{\partial y}\right]_b = \left[\frac{\partial M_{\mathrm{g}}^x}{\partial y}\right]_z - \frac{\partial b/\partial y}{\partial b/\partial z}\frac{\partial M_{\mathrm{g}}^x}{\partial z} \tag{59.93a}$$

$$= (\partial b/\partial z)^{-1}\left[\frac{\partial M_{\mathrm{g}}^x}{\partial y}\frac{\partial b}{\partial z} - \frac{\partial M_{\mathrm{g}}^x}{\partial z}\frac{\partial b}{\partial y}\right] \tag{59.93b}$$

$$= -N^{-2}\,\hat{\boldsymbol{x}} \cdot (\nabla b \times \nabla M_{\mathrm{g}}^x). \tag{59.93c}$$

Similarly, we have

$$\left[\frac{\partial b}{\partial y}\right]_{M_{\mathrm{g}}^x} = (\partial M_{\mathrm{g}}^x/\partial z)^{-1}\left[\frac{\partial b}{\partial y}\frac{\partial M_{\mathrm{g}}^x}{\partial z} - \frac{\partial b}{\partial z}\frac{\partial M_{\mathrm{g}}^x}{\partial y}\right] \tag{59.94a}$$

$$= (\partial M_{\mathrm{g}}^x/\partial z)^{-1}\,\hat{\boldsymbol{x}} \cdot (\nabla b \times \nabla M_{\mathrm{g}}^x), \tag{59.94b}$$

which then leads to

$$\frac{(\partial b/\partial y)_{M_{\mathrm{g}}^x}}{\partial b/\partial z} = -\frac{(\partial M_{\mathrm{g}}^x/\partial y)_b}{\partial M_{\mathrm{g}}^x/\partial z}. \tag{59.95}$$

Furthermore, with $M^x_{\mathrm{g}} = u_{\mathrm{g}} - f\,y$ we have

$$\partial_z M^x_{\mathrm{g}} = \partial_z u_{\mathrm{g}} = -f^{-1}\,(\partial b/\partial y)_z, \tag{59.96}$$

so that

$$S^y_b\,(\partial b/\partial y)_{M^x_{\mathrm{g}}} = -f\,(\partial M^x_{\mathrm{g}}/\partial y)_b, \tag{59.97}$$

where we introduced the slope of the meridional buoyancy surface

$$S^y_b \equiv -\frac{\partial b/\partial y}{\partial b/\partial z}. \tag{59.98}$$

Use of the identity (59.97) in the instability condition (59.92a) leads to the equivalent expressions of a symmetrically unstable geostrophically balances state

$$f\left[\frac{\partial M^x_{\mathrm{g}}}{\partial y}\right]_b = -S^y_b\left[\frac{\partial b}{\partial y}\right]_{M^x_{\mathrm{g}}} > 0 \quad \Longrightarrow \text{symmetrically unstable} \tag{59.99a}$$

$$f\,N^2\left[\frac{\partial M^x_{\mathrm{g}}}{\partial y}\right]_b = \left[\frac{\partial b}{\partial y}\right]_z\left[\frac{\partial b}{\partial y}\right]_{M^x_{\mathrm{g}}} > 0 \Longrightarrow \text{symmetrically unstable.} \tag{59.99b}$$

Consider a configuration with buoyancy slopes rising to the north, so that the meridional buoyancy slope is positive, $S^y_b > 0$. Equation (59.99a) says that if the buoyancy decreases moving in the $+\hat{\boldsymbol{y}}$ direction while moving along constant potential momentum surfaces, then the flow is symmetrically unstable. Equivalently, equation (59.99b) says that if buoyancy has a meridional derivative of the same sign on both a constant z surface and a constant M^x_{g} surface, then the flow is symmetrically unstable. In Figure 59.7 we depict various properties of symmetrically unstable configurations.

59.7 Symmetric instability and the wedge of instability

We here formulate the stability of a symmetric front using geopotential vertical coordinate equations, thus serving as a complement to the analysis in Section 59.6 based on buoyancy as the vertical coordinate. Furthermore, we here focus on perturbations that lead to an instability if presented with a base flow state that is unstable. More precisely, we consider zonally symmetric perturbations (i.e., a row of fluid parcels) that carry buoyancy and zonal potential momentum from the initial position into a new position. The question is whether the displaced row of fluid parcels feels a net force that sends it back to where it came (stable perturbation), or if the force sends it further away (unstable perturbation). Through this analysis we show that flow configurations with buoyancy and potential momentum surfaces oriented as in Figure 59.7 admit unstable perturbations that probe the *wedge of instability* (see Figure 59.8). The existence of such perturbations is a signature of a symmetrically unstable background flow state.

59.7.1 Formulation of the basic equations

Take the inviscid Boussinesq equation (30.91b) as a starting point, here written as

$$\mathrm{D}M^x/\mathrm{D}t = 0 \quad \text{and} \quad \mathrm{D}v/\mathrm{D}t = f\,(M^x_{\mathrm{g}} - M^x) \quad \text{and} \quad \mathrm{D}w/\mathrm{D}t = -\partial_z\varphi + b. \tag{59.100}$$

The base state is assumed to be in geostrophic and hydrostatic balance, in which

$$\text{base flow state} \Longleftrightarrow \mathrm{D}\boldsymbol{v}/\mathrm{D}t = 0 \quad \text{and} \quad M^x = M^x_{\mathrm{g}} \quad \text{and} \quad \partial_z\varphi = b\,g. \tag{59.101}$$

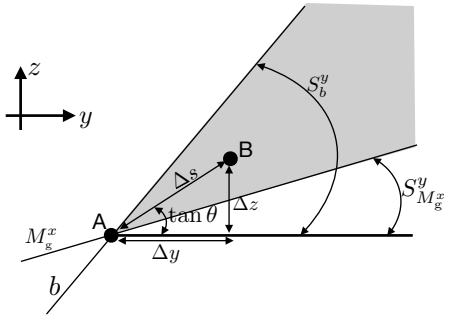
To examine stability of this base state, displace a row of fluid parcels from its original y-z position, (y_A, z_A), to a new position,

$$y_B = y_A + \Delta y \quad \text{and} \quad z_B = z_A + \Delta z, \tag{59.102}$$

such as depicted in Figure 59.8. Notably, the buoyancy and potential momentum at point (y_B, z_B) are distinct from those at (y_A, z_A). Importantly, the displacement materially preserves the buoyancy and potential momentum of the displaced row of parcels, so that

$$b_{\text{parcel}} = b(A) \quad \text{and} \quad M^x_{\text{parcel}} = M^x(A) = M^x_{\text{g}}(A). \tag{59.103}$$

At the displaced position, the row of parcels finds itself in a local environment where it feels a nonzero acceleration. Does this acceleration act to further the displacement (unstable perturbation) or return the row of parcels to its original position (stable perturbation)?



$$\tan\theta = \frac{\Delta z}{\Delta y}$$

$$S^y_b = \left[\frac{\Delta z}{\Delta y}\right]_b = -\frac{\partial b/\partial y}{\partial b/\partial z} = \frac{f\,\partial_z u_g}{N^2}$$

$$S^y_{M^x_g} = \left[\frac{\Delta z}{\Delta y}\right]_{M^x_g} = -\frac{\partial M^x_g/\partial y}{\partial M^x_g/\partial z} = \frac{\zeta_g + f}{\partial_z u_g}$$

FIGURE 59.8: Illustrating the parcel argument for symmetric instability, whereby we displace a zonally ($\hat{\boldsymbol{x}}$ points out of the page) symmetric row of parcels from A to B while retaining their buoyancy, $b(A)$, and potential momentum, $M^x(A) = M^x_{\text{g}}(A)$. We also depict the slope of the displacement, $\tan\theta = \Delta z/\Delta y$, the slope of the buoyancy surface, $S^y_b = (\Delta z/\Delta y)_b = f\,\partial_z u_{\text{g}}/N^2$, and slope of the potential momentum surface, $S^y_{M^x_{\text{g}}} = (\Delta y/\Delta z)_{M^x_{\text{g}}} = (\zeta_{\text{g}} + f)/\partial_z u_{\text{g}}$. When the buoyancy surface is sloped more steeply than the potential momentum surface, then that base state flow is subject to symmetrically unstable perturbations, with the unstable perturbations extending into the gray *wedge of instability*.

59.7.2 Assessing stability of the perturbation

To answer the above stability question, write the acceleration for the parcel displaced from point A to point B in the form

$$\frac{\mathrm{D}\boldsymbol{v}_{\text{parcel}}}{\mathrm{D}t} = f\,[M^x_{\text{g}}(B) - M^x_{\text{parcel}}]\,\hat{\boldsymbol{y}} + [b_{\text{parcel}} - \partial_z\varphi(B)]\,\hat{\boldsymbol{z}} \tag{59.104a}$$

$$= f\,[M^x_{\text{g}}(B) - M^x_{\text{parcel}}]\,\hat{\boldsymbol{y}} + [b_{\text{parcel}} - b(B)]\,\hat{\boldsymbol{z}}, \tag{59.104b}$$

where M^x_{g} and $\partial_z\varphi$ are taken from the base state at point B, and for the second equality we set the base state vertical pressure gradient equal to the buoyancy according to the hydrostatic balance, $\partial_z\varphi(B) = b(B)$. We are interested in whether this displacement leads to an acceleration of the parcel further in the direction of the displacement, beyond point B, in which case the base state is symmetrically unstable, otherwise it is stable.

To determine stability conditions, use material invariance of the potential momentum and buoyancy in the form of equation (59.103), thus leading to the parcel acceleration

$$\frac{\mathrm{D}\boldsymbol{v}_{\text{parcel}}}{\mathrm{D}t} = f\,[M^x_{\text{g}}(B) - M^x_{\text{g}}(A)]\,\hat{\boldsymbol{y}} + [b(A) - b(B)]\,\hat{\boldsymbol{z}}. \tag{59.105}$$

For orientation, let the unit vector in the direction of the displacement be written

$$\hat{\boldsymbol{s}} = \hat{\boldsymbol{y}} \cos\theta + \hat{\boldsymbol{z}} \sin\theta = \hat{\boldsymbol{y}} \, (\Delta y/\Delta s) + \hat{\boldsymbol{z}} \, (\Delta z/\Delta s), \tag{59.106}$$

where θ is the angle of the displacement with respect to the horizontal plane, and

$$\Delta s = \sqrt{(\Delta y)^2 + (\Delta z)^2}, \tag{59.107}$$

is the distance of the displacement (see Figure 59.8). Taking the $\hat{\boldsymbol{s}}$ projection of the parcel acceleration (59.105) leads to

$$\hat{\boldsymbol{s}} \cdot \frac{\mathrm{D}\boldsymbol{v}_{\text{parcel}}}{\mathrm{D}t} = f \, [M^x_{\text{g}}(B) - M^x_{\text{g}}(A)] \cos\theta - [b(B) - b(A)] \sin\theta. \tag{59.108}$$

Now expand the terms on the right hand side in a Taylor series, expressing values at point B in terms of those at point A, so that (keeping terms up to first order)

$$b(B) - b(A) = \partial_y b \, \Delta y + \partial_z b \, \Delta z = \Delta y \, (\partial_y b + \partial_z b \tan\theta) \tag{59.109a}$$

$$M^x_{\text{g}}(B) - M^x_{\text{g}}(A) = \partial_y M^x_{\text{g}} \, \Delta y + \partial_z M^x_{\text{g}} \, \Delta z = \Delta y \, (\partial_y M^x_{\text{g}} + \partial_z M^x_{\text{g}} \tan\theta), \tag{59.109b}$$

with terms on the right hand side evaluated at point A. These expansions bring the equation of motion (59.108) to

$$\hat{\boldsymbol{s}} \cdot \frac{\mathrm{D}\boldsymbol{v}_{\text{parcel}}}{\mathrm{D}t} = f \, \Delta y \, (\partial_y M^x_{\text{g}} + \partial_z M^x_{\text{g}} \tan\theta) \cos\theta - \Delta y \, (\partial_y b + \partial_z b \tan\theta) \sin\theta. \tag{59.110}$$

For a northward and upward perturbation as depicted in Figure 59.8, the symmetric perturbation is unstable if the right hand side of equation (59.110) is positive, which requires

$$f \, (\partial_y M^x_{\text{g}} + \partial_z M^x_{\text{g}} \tan\theta) \cos\theta > (\partial_y b + N^2 \tan\theta) \sin\theta, \tag{59.111}$$

which can be written in terms of the slope of the buoyancy surface, S^y_b, the slope of the potential momentum surface, $S^y_{M^x_{\text{g}}}$, and the slope of the perturbation, $\tan\theta$

$$f \, \partial_z M^x_{\text{g}} \, (\tan\theta - S^y_{M^x_{\text{g}}}) > \partial_z b \, (\tan\theta - S^y_b). \tag{59.112}$$

Finally, we make use of thermal wind

$$f \, \partial_z M^x_{\text{g}} = f \, \partial_z u_{\text{g}} = -\partial_y b, \tag{59.113}$$

so that the inequality (59.112) is

$$S^y_b \, (\tan\theta - S^y_{M^x_{\text{g}}}) > \tan\theta - S^y_b. \tag{59.114}$$

We now assume the following properties of the base state

$$S^y_b > 0 \quad \text{and} \quad S^y_{M^x_{\text{g}}} > 0 \quad \text{and} \quad \tan\theta > 0, \tag{59.115}$$

which correspond to the base state configuration in Figure 59.8. The inequality (59.114) yields the following condition for symmetric instability (as signaled by an acceleration in the direction of the displacement)

$$S^y_{M^x_{\text{g}}} < \tan\theta < S^y_b. \tag{59.116}$$

This slope condition means that a symmetric perturbation that falls within the wedge of instability in Figure 59.8 initiates a symmetric unstability. Conversely, perturbations that fall

outside of the wedge do not initiate a symmetric instability.

59.7.3 Symmetrically unstable while inertially and gravitationally stable

An alternative means to write the parcel acceleration equation (59.110) is given by

$$\hat{\boldsymbol{s}} \cdot \frac{\mathrm{D}\boldsymbol{v}_{\text{parcel}}}{\mathrm{D}t} = \Delta y \cos\theta \, [-f \, (f + \zeta_{\text{g}}) - N^2 \tan^2\theta + 2 \, f \, \partial_z u_{\text{g}} \tan\theta], \tag{59.117}$$

where we used $\partial_y M^x_{\text{g}} = -(f + \zeta_{\text{g}})$ and $\partial_z b = N^2$. The assumptions (59.115) are equivalent to (it is useful to prove this)

$$f \, (f + \zeta_{\text{g}}) > 0 \quad \text{and} \quad N^2 > 0, \tag{59.118}$$

which means the base state flow is stable to horizontal inertial instability and to gravitational instability. We thus find from equation (59.117) that the perturbation is unstable if

$$2 \, f \, \partial_z u_{\text{g}} \tan\theta > f \, (f + \zeta_{\text{g}}) + N^2 \tan^2\theta. \tag{59.119}$$

This instability condition is equivalent to the purely geometric form given by equation (59.116).

59.8 Symmetric instability and linear modal analysis

We now consider symmetric instability following the linear stability analysis of *Hoskins* (1974). This approach recovers the same stability condition as for the parcel method in Section 59.6. However, linear stability analysis offers added insights concerning the central role of Ertel potential vorticity and it provides further details of the instability. The mathematical analysis here also offers useful practice for the study of baroclinic instability in Chapter 62.

59.8.1 Geostrophic base state and the perturbation equations

Our goal is to examine the stability of a zonally symmetric geostrophic front to zonally symmetric perturbations. Whereas the base state for the study of gravity waves has zero baroclinicity, here we consider a geostrophic front with meridional (across-front) baroclinicity. Rather than the buoyancy coordinates used for the parcel stability analusis in Section 59.6.1, we here make use of geopotential vertical coordinates and linearize the Boussinesq ocean equations. The starting point for this development is the f-plane version of the perfect Boussinesq ocean equations from Section 29.1.6

$$\partial_t \boldsymbol{v} + (\boldsymbol{v} \cdot \nabla) \, \boldsymbol{v} + f \, \hat{\boldsymbol{z}} \times \boldsymbol{v} = -\nabla\varphi + b \, \hat{\boldsymbol{z}} \tag{59.120a}$$

$$\partial_t b + \boldsymbol{v} \cdot \nabla b = 0. \tag{59.120b}$$

Equations for the geostrophic base state

The equations describing the zonal geostrophic and hydrostatic base state are given by

$$f \, u_{\text{g}} = -\partial_y \varphi_{\text{g}} \quad \text{zonal flow in geostrophic balance} \tag{59.121a}$$

$$\partial_z \varphi_{\text{g}} = b_{\text{g}} \quad \text{hydrostatic balance} \tag{59.121b}$$

$$f \, \partial_z u_{\text{g}} = -\partial_y b_{\text{g}} \quad \text{thermal wind of zonal flow} \tag{59.121c}$$

$$\zeta_{\text{g}} = -\partial_y u_{\text{g}} \quad \text{relative vorticity.} \tag{59.121d}$$

The pressure field, $\varphi_{\text{g}}(y, z)$, has a meridional derivative that supports the zonal geostrophic flow, $u_{\text{g}}(y, z)$, and which is in hydrostatic balance with the base state buoyancy, $b_{\text{g}}(y, z)$. Combining geostrophy with the hydrostatic balance leads to the thermal wind shear in equation (59.121c).

Due to zonal symmetry, the only contribution to the relative vorticity comes from the meridional shear of the zonal geostrophic flow, $\zeta_{\mathrm{g}} = -\partial_y u_{\mathrm{g}}$. Ertel potential vorticity (Chapter 41) of the base state proves to be central to the stability conditions

$$Q_{\mathrm{g}} = (\omega_{\mathrm{g}} + f\,\hat{\boldsymbol{z}}) \cdot \nabla b_{\mathrm{g}} = N^2\,(f + \zeta_{\mathrm{g}}) - f\,(\partial_z u_{\mathrm{g}})^2, \tag{59.122}$$

where we made use of the thermal wind equation (59.121c) as well as the relative vorticity for the zonal geostrophic background flow

$$\omega_{\mathrm{g}} = \nabla \times \hat{\boldsymbol{x}}\, u_{\mathrm{g}} = \hat{\boldsymbol{y}}\, \partial_z u_{\mathrm{g}} - \hat{\boldsymbol{z}}\, \partial_y u_{\mathrm{g}} = -\hat{\boldsymbol{y}}\, f^{-1} \partial_y b_{\mathrm{g}} + \hat{\boldsymbol{z}}\, \zeta_{\mathrm{g}}. \tag{59.123}$$

Linearized perturbation equations

To develop perturbation equations, we decompose the flow into the geostrophic base state plus a perturbation. The perturbation is time dependent and ageostrophic, and, importantly, is assumed to retain the zonal symmetry of the base state

$$\boldsymbol{v}(y,z,t) = \boldsymbol{v}'(y,z,t) + \hat{\boldsymbol{x}}\, u_{\mathrm{g}}(y,z) \tag{59.124a}$$
$$\varphi(y,z,t) = \varphi'(y,z,t) + \varphi_{\mathrm{g}}(y,z) \tag{59.124b}$$
$$b(y,z,t) = b'(y,z,t) + b_{\mathrm{g}}(y,z). \tag{59.124c}$$

The linearized version of the velocity equation (59.120a) and buoyancy equation (59.120b) take the form

$$\partial_t u' = v'\,(f - \partial_y u_{\mathrm{g}}) - w'\,\partial_z u_{\mathrm{g}} \quad \text{zonal velocity} \tag{59.125a}$$
$$\partial_t v' = -f\,u' - \partial_y \varphi' \quad \text{meridional velocity} \tag{59.125b}$$
$$\partial_t w' = -\partial_z \varphi' + b' \quad \text{vertical velocity} \tag{59.125c}$$
$$\partial_t b' = -(v'\,\partial_y b_{\mathrm{g}} + w'\,\partial_z b_{\mathrm{g}}) \quad \text{buoyancy} \tag{59.125d}$$
$$\partial_y v' + \partial_z w' = 0 \quad \text{continuity.} \tag{59.125e}$$

Observe that the zonal velocity evolves according to the Coriolis acceleration plus the convergence of the advective flux of the base state geostrophic velocity

$$-v'\,\partial_y u_{\mathrm{g}} - w'\,\partial_z u_{\mathrm{g}} = -\nabla \cdot (\boldsymbol{v}'\,u_{\mathrm{g}}). \tag{59.126}$$

Likewise, the buoyancy evolves according to the convergence of the advective flux of the base state buoyancy

$$-(v'\,\partial_y b_{\mathrm{g}} + w'\,\partial_z b_{\mathrm{g}}) = -\nabla \cdot (\boldsymbol{v}'\,b_{\mathrm{g}}). \tag{59.127}$$

In both cases, the advection velocity arises from the non-divergent anomalous flow, $\boldsymbol{v}'$, with zonal symmetry meaning there is no contribution to the flux convergences from the anomalous zonal velocity, u'.

59.8.2 Inertia-vorticity oscillator equations

As in our study of buoyancy oscillations in Section 57.3 and inertia-gravity oscillations in Section 57.8, we here develop forced oscillator equations for the zonal and meridional velocity components. To do so, take a time derivative of the zonal velocity equation (59.125a) and then substitute the meridional velocity equation (59.125b) to find the zonal velocity oscillator equation

$$[\partial_{tt} + f\,(f + \zeta_{\mathrm{g}})]\,u' = -(f + \zeta_{\mathrm{g}})\,\partial_y \varphi' + \partial_z u_{\mathrm{g}}\,(\partial_z \varphi' - b'). \tag{59.128}$$

Similar manipulations lead to the forced oscillator equation for the meridional velocity

$$[\partial_{tt} + f\,(f + \zeta_{\rm g})]\,v' = f\,w'\,\partial_z u_{\rm g} - \partial_{ty}\varphi'. \tag{59.129}$$

The forcing functions on the right hand side of both equations (59.128) and (59.129) are generally nonzero. However, in their absence both the zonal and meridional velocity components satisfy a free oscillator equation with squared natural angular frequency, $f\,(f + \zeta_{\rm g})$. We refer to these as *inertia-vorticity* oscillations given the dual role of the Coriolis and vorticity for determining the oscillations. The motion is oscillatory if $f\,(f + \zeta_{\rm g}) > 0$, whereas it is exponentially growing if $f\,(f + \zeta_{\rm g}) < 0$. This stability condition for the oscillators is consistent with that found for the parcel stability analysis leading to equation (59.92a). To develop more insight into the nature of the instability for $f\,(f + \zeta_{\rm g}) < 0$, we next develop an equation for the overturning streamfunction in the meridional-vertical plane.

59.8.3 Ageostrophic overturning circulation streamfunction

The continuity equation (59.125e) means that the meridional-vertical circulation is non-divergent so that we can introduce a streamfunction for the perturbation flow

$$\boldsymbol{v}' = -\hat{\boldsymbol{x}} \times \nabla\psi \implies v' = \partial_z\psi \quad \text{and} \quad w' = -\partial_y\psi. \tag{59.130}$$

The perturbed fields are ageostrophic and are sometimes referred to as the *ageostrophic secondary circulation*, with this circulation described by the ageostrophic overturning circulation streamfunction, ψ. Based on the oscillator equations (59.128) and (59.129), we anticipate that the overturning circulation is unstable for $f\,(f + \zeta_{\rm g}) < 0$.

Zonal vorticity equation

Taking the z derivative of the meridional velocity equation (59.125b) and the y derivative of the vertical velocity equation (59.125c), and then subtracting, leads to the equation for the zonal component of the vorticity[12]

$$\partial_t(\partial_y w' - \partial_z v') - f\,\partial_z u' = \partial_y b', \tag{59.131}$$

which takes on the form using the overturning streamfunction

$$\partial_t(\partial_{yy} + \partial_{zz})\,\psi = -f\,\partial_z u' - \partial_y b'. \tag{59.132}$$

Further assumptions for the base state flow

To enable the next steps of the derivation, which makes use of a plane wave ansatz in Section 59.8.4, we make use of the following assumptions about the base state:

$$\zeta_{\rm g} = -\partial_y u_{\rm g} \quad \text{constant relative vorticity} \tag{59.133a}$$

$$f\,\partial_z u_{\rm g} = -\partial_y b_{\rm g} \quad \text{constant thermal wind shear} \tag{59.133b}$$

$$N^2 = \partial_z b_{\rm g} \quad \text{constant buoyancy frequency.} \tag{59.133c}$$

These assumptions are restrictive, and yet the resulting instabiliity calculation provides great insights into base state flow configurations that are more general.

[12]The zonal component of the perturbation vorticity is given by $\hat{\boldsymbol{x}} \cdot (\nabla \times \boldsymbol{v}') = \partial_y w' - \partial_z v' = -(\partial_{yy} + \partial_{zz})\psi$.

Eliminating the zonal velocity and the buoyancy

We can eliminate the perturbation zonal velocity, u', and the perturbation buoyancy, b', from the vorticity equation (59.132) by taking another time derivative. Upon doing so we make use of the zonal velocity equation (59.125a) and the buoyancy equation (59.125d), and make use of the assumptions (59.133a)-(59.133c) for the base state:

$$\begin{aligned} -\partial_{tt}(\partial_{yy} + \partial_{zz})\,\psi &= f\,\partial_{zt}u' + \partial_{yt}b' && \text{(59.134a)}\\ &= f\,\partial_z[v'\,(f + \zeta_{\mathrm{g}}) - w'\,\partial_z u_{\mathrm{g}}] - \partial_y(v'\,\partial_y b_{\mathrm{g}} + w'\,\partial_z b_{\mathrm{g}}) && \text{(59.134b)}\\ &= f\,\partial_{zz}\psi\,(f + \zeta_{\mathrm{g}}) - 2\,\partial_{yz}\psi\,\partial_y b_{\mathrm{g}} + \partial_{yy}\psi\,\partial_z b_{\mathrm{g}} && \text{(59.134c)}\\ &= [f\,(f + \zeta_{\mathrm{g}})\,\partial_{zz} + 2\,f\,\partial_z u_{\mathrm{g}}\,\partial_{yz} + N^2\,\partial_{yy}]\psi. && \text{(59.134d)} \end{aligned}$$

Rearrangement leads to the equation for the ageostrophic overturning circulation streamfunction

$$[\partial_{tt}(\partial_{yy} + \partial_{zz}) + f\,(f + \zeta_{\mathrm{g}})\,\partial_{zz} + 2\,f\,\partial_z u_{\mathrm{g}}\,\partial_{yz} + N^2\,\partial_{yy}]\,\psi = 0. \tag{59.135}$$

59.8.4 Dispersion relation for meridional-vertical plane waves

Equation (59.135) is a constant coefficient partial differential equation for the overturning streamfunction. We examine its properties by considering a plane wave ansatz just as for our study of linear waves in Part X of this book. Since the flow is non-divergent, the plane waves are transverse. Furthermore, we continue to assume zonal symmetry with the perturbations, so that the waves have no x dependence. We thus consider waves propagating in the meridional-vertical plane, in which case we take the plane wave ansatz

$$\psi(y, z, t) = \tilde{\psi}\,\mathrm{e}^{\mathrm{i}\,(k_y\,y + k_z\,z - \omega\,t)}, \tag{59.136}$$

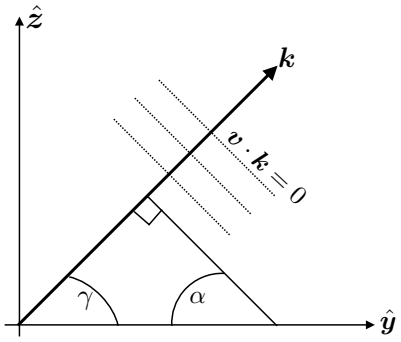
with Figure 59.9 depicting the wave geometry. Plugging this ansatz into the streamfunction equation (59.135) leads to the dispersion relation

$$\begin{aligned} \omega^2 &= \frac{f\,(f + \zeta_{\mathrm{g}})\,k_z^2 + 2\,f\,\partial_z u_{\mathrm{g}}\,k_y\,k_z + N^2\,k_y^2}{k_y^2 + k_z^2} && \text{(59.137a)}\\ &= f\,(f + \zeta_{\mathrm{g}})\cos^2\alpha + 2\,f\,\partial_z u_{\mathrm{g}}\sin\alpha\cos\alpha + N^2\sin^2\alpha && \text{(59.137b)}\\ &= \cos^2\alpha\,[f\,(f + \zeta_{\mathrm{g}}) + 2\,f\,\partial_z u_{\mathrm{g}}\tan\alpha + N^2\tan^2\alpha]. && \text{(59.137c)} \end{aligned}$$

Note that the convention for symmetric instability is to use the angle, α, that the particle trajectories make with the vertical, whereas for our study of internal gravity waves (Section 57.5) and inertia-gravity waves (Section 57.9), we used the angle $\gamma = \pi/2 - \alpha$ that the phase velocity makes with the horizontal. Either way, we see that the dispersion relation (59.137c) depends only on the wave direction along with the prescribed rotation and properties of the background flow. This "orientation-only" character of the dispersion relation is also shared by the dispersion relation for internal gravity waves (equation (57.65)) and inertia-gravity waves (equation (57.147)). Indeed, for the case with zero baroclinicity, in which $u_{\mathrm{g}} = 0$, then the dispersion relation (59.137c) reduces to that for inertia-gravity waves.

59.8.5 Stability conditions

The dispersion relation (59.137c) determines the squared angular frequency, ω^2, for a plane wave ansatz. If $\omega^2 > 0$ then there are propagating waves. However, if $\omega^2 < 0$ then the waves can be exponentially growing, in which case we say the flow is unstable. To determine the condition for



$$\begin{aligned}
&\boldsymbol{k} = \hat{\boldsymbol{y}}\, k_y + \hat{\boldsymbol{z}}\, k_z \\
&\cos\gamma = \sin\alpha = k_y/|\boldsymbol{k}| \\
&\sin\gamma = \cos\alpha = k_z/|\boldsymbol{k}| \\
&\tan\alpha = k_y/k_z \\
&\tan\gamma = k_z/k_y \\
&\alpha = \pi/2 - \gamma
\end{aligned}$$

FIGURE 59.9: Transverse plane wave used to probe the stability of a baroclinic front. The phase vector, $\boldsymbol{k}$, makes an angle γ with the horizontal and α with the vertical.

stability, write the dispersion relation in the form

$$\omega^2 = F(\tan\alpha)\cos^2\alpha, \tag{59.138}$$

where we introduced the quadratic stability function

$$F(\tau) = f\,(f + \zeta_{\mathrm{g}}) + (2\,f\,\partial_z u_{\mathrm{g}})\,\tau + N^2\,\tau^2. \tag{59.139}$$

The question of stability has been reduced to the question of whether there are wave perturbations that realize $F(\tan\alpha) < 0$, in which case $\omega^2 < 0$. To answer this question we write

$$F(\tau) = (\tau - R_+)\,(\tau - R_-), \tag{59.140}$$

with the two roots given by the quadratic formula

$$N^2\,R_\pm = -f\,\partial_z u_{\mathrm{g}} \pm \sqrt{(f\,\partial_z u_{\mathrm{g}})^2 - N^2\,f\,(f + \zeta_{\mathrm{g}})} = -f\,\partial_z u_{\mathrm{g}} \pm \sqrt{-f\,Q_{\mathrm{g}}}, \tag{59.141}$$

where the final equality introduced the base state potential vorticity, Q_{g}, from equation (59.122). Remarkably, local stability has boiled down to the sign of $f\,Q_{\mathrm{g}}$ at any point within the fluid.

Stable case

If $f\,Q_{\mathrm{b}} > 0$, then the two roots, $R_\pm$, are complex conjugates. Yet $\tan\alpha$ is real for all waves with real wavevectors. Hence, if $f\,Q_{\mathrm{g}} > 0$ then there are no waves for which $F(\tan\alpha)$ vanishes, meaning that the stability function has one sign for all waves. To establish the sign, note that for very weak fronts in stably stratified fluids,

$$F(\tau) \approx f^2 + N^2\,\tau^2 > 0, \tag{59.142}$$

which is the case for linear, and stable, inertia-gravity waves. Ramping up the strength of the geostrophic front, while maintaining $f\,Q_{\mathrm{g}} > 0$, ensures that such geostrophic fronts are locally stable.

For the typical case in stratified geophysical fluids, we have $N^2 > f^2$, so that the maximum angular frequency (59.137c) occurs with horizontally propagating waves where $\alpha = \pi/2$ so that

$$\omega^2_{\mathrm{max}} = N^2, \tag{59.143}$$

in which case fluid particles exhibit buoyancy oscillations in the vertical. At the other end of the spectrum, the minimum angular frequency occurs when $\alpha = 0$ so that the wavevector is vertical

and

$$\omega^2_{\text{min}} = f\,(f + \zeta_{\text{g}}), \tag{59.144}$$

which are inertial oscillations in the presence of a nonzero relative vorticity.

Unstable case

If $f\,Q_{\text{g}} < 0$ then the two roots, $R_\pm$, are real

$$R_\pm = \frac{-f\,\partial_z u_{\text{g}} \pm \sqrt{|f\,Q_{\text{g}}|}}{N^2}, \tag{59.145}$$

thus ensuring that there are waves that render $F(\tan\alpha) = 0$. Hence, the stability function changes sign so that waves are unstable if $\omega^2 < 0$. In the unstable case, ω is not an angular frequency but instead it measures the exponential *growth rate* for the unstable wave.

59.8.6 Ertel potential vorticity and local stability

In developing the stability conditions in Section 59.8.5, appearance of the Ertel potential vorticity might not have seemed so remarkable. Namely, it seemingly just provided a useful shorthand for the discriminant of the square root appearing the quadratic formula. In fact, potential vorticity is central to the power of the stability analysis since it provides a direct connection to physical processes required to initiate symmetric instability. Namely, potential vorticity is materially invariant in a perfect fluid (Chapters 41 and 42). Hence, if a fluid starts in a stable state with $f\,Q > 0$, say it starts with zero baroclinicity and with stable stratification so that $f\,Q = f^2\,N^2 > 0$, then it has very restrictive means to evolve into an unstable state with $f\,Q < 0$. One means for inducing $f\,Q < 0$ is to introduce friction, diffusion, boundary processes, and/or other irreversible processes that materially alter Q in such a manner that brings $f\,Q < 0$. Another means is for a perfect fluid parcel to cross the equator so that f changes sign. If the parcel starts from a side of the equator with $f\,Q > 0$, then on the other side it has $f\,Q < 0$ and so it is symmetrically unstable.

As noted by *Thomas et al.* (2013), the instability criteria, $f\,Q < 0$, embodies three instabilities. Namely, for a barotropic fluid, whereby $\nabla_{\text{h}} b = 0$, then the potential vorticity is given by

$$f\,Q = f\,(f + \zeta)\,N^2. \tag{59.146}$$

The $f\,Q > 0$ stability criteria is satisfied with $N^2 > 0$ (gravitational stability; Section 30.6) and $f\,(f + \zeta) > 0$ (horizontal inertial stability; Section 59.5). In the presence of baroclinicity with a symmetric front, the $f\,Q > 0$ stability criteria then reflects symmetric stability of the present section. *Buckingham et al.* (2021) offer a generalization of the stability criteria by allowing for curvature of the front, thus providing a criteria to determine stability with regard to gravitational, centrifugal, horizontal inertial, and symmetric instabilities.

59.8.7 Comments and further study

The bulk of this section is an elaboration of *Hoskins* (1974), which exposed the connection between symmetric instability and Ertel potential vorticity. The study from *Thomas et al.* (2013) provides an example of these ideas for the ocean, offering practical details to map out stability regimes across the spectrum of gravitational, inertial, and symmetric instabilities. *Buckingham et al.* (2021) generalized *Hoskins* (1974) to the allow for a curved front.

59.9 Semi-geostrophy and ageostrophic overturning

We here study the overturning circulation that arises in a symmetric front on an f-plane. This overturning circulation is ageostrophic, and it is sometimes referred to as the *ageostrophic secondary circulation*. *Hoskins* (1975) advanced the study of frontal secondary circulations by rationalizing the equations of *semi-geostrophy*, making use of the *geostrophic momentum approximation*. Semi-geostrophy is a balanced theory (i.e., gravity waves are filtered), just like in the quasi-geostrophic theory of Chapter 45. However, the semi-geostrophic equations allow us to study flows associated with fronts and where the cross-front flows can have relatively small length scales sufficient to reach order unity Rossby numbers. Hence, semi-geostrophic equations are quite useful for studying submesoscale flows surrounding geostrophic fronts and eddies (e.g., see the book chapter by *Thomas et al.* (2008)), as well as the study of atmospheric fronts associated with synoptic scale weather patterns (which motivated *Hoskins* (1975); see also Chapter 9 of *Holton and Hakim* (2013)). In this section we provide just a taste of semi-geostrophy sufficient to derive a diagnostic equation for the ageostrophic secondary overturning circulation.

59.9.1 Hydrostatic and Boussinesq ocean on an f-plane

We develop the semi-geostrophic equations within the perfect fluid hydrostatic Boussinesq ocean equations (see Section 43.7) on an f-plane

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_{\mathrm{h}}\varphi \tag{59.147a}$$

$$\partial_z \varphi = b \tag{59.147b}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = 0 \tag{59.147c}$$

$$\nabla \cdot \boldsymbol{v} = \nabla_{\mathrm{h}} \cdot \boldsymbol{u} + \partial_z w = 0. \tag{59.147d}$$

The geostrophic velocity is written in terms of the pressure field

$$\boldsymbol{u}_{\mathrm{g}} = f^{-1}\,\hat{\boldsymbol{z}} \times \nabla_{\mathrm{h}}\varphi \Longrightarrow u_{\mathrm{g}} = -f^{-1}\,\partial_y \varphi \quad \text{and} \quad v_{\mathrm{g}} = f^{-1}\,\partial_x \varphi, \tag{59.148}$$

which is horizontally non-divergent on the f-plane. It is notable that this geostrophic velocity is written in terms of the pressure field, φ, just like in the planetary geostrophic theory of Chapter 44. It also accords with the gauge choice discussed in Section 45.3.9 for quasi-geostrophy.

Inserting the geostrophic velocity (59.148) into the horizontal momentum equation (59.147a) yields the identity

$$\boldsymbol{u} - \boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \mathcal{D}\boldsymbol{u} \Longrightarrow u - u_{\mathrm{g}} = -\mathcal{D}v \quad \text{and} \quad v - v_{\mathrm{g}} = \mathcal{D}u, \tag{59.149}$$

where we introduced the dimensionless material time derivative operator

$$\mathcal{D} = \frac{1}{f}\frac{\mathrm{D}}{\mathrm{D}t}. \tag{59.150}$$

The horizontal ageostrophic flow can thus be written

$$\boldsymbol{u}_{\mathrm{ag}} = \boldsymbol{u} - \boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \mathcal{D}\boldsymbol{u}, \tag{59.151}$$

with one iteration of this equation leading to

$$\boldsymbol{u}_{\mathrm{ag}} = \hat{\boldsymbol{z}} \times \mathcal{D}\boldsymbol{u}_{\mathrm{g}} - \mathcal{D}^2\boldsymbol{u} \Longrightarrow u_{\mathrm{ag}} = -\mathcal{D}(v_{\mathrm{g}} + \mathcal{D}u) \quad \text{and} \quad v_{\mathrm{ag}} = \mathcal{D}(u_{\mathrm{g}} - \mathcal{D}v). \tag{59.152}$$

This identity motivates the *geostrophic momentum approximation* in Section 59.9.3 that ignores the $\mathcal{D}^2\boldsymbol{u}$ term.

59.9.2 Scaling for frontal flows

For f-plane flow, we lose no generality by orienting the front parallel to the $\hat{\boldsymbol{x}}$ direction, so that the across-front flow is in the $\hat{\boldsymbol{y}}$ direction. We write U for the velocity scale of the along-front flow and L_x for the corresponding length scale.[13] Likewise, write V and L_y for the across-front scales, with our interest in flows satisfying the inequalities

$$L_x \gg L_y \quad \text{and} \quad U \gg V \quad \text{with} \quad L_x/L_y = U/V. \tag{59.153}$$

Inserting these scales into horizontal momentum equation (59.147a) yields

$$\frac{U}{T} + \frac{U\,U}{L_x} + \frac{U\,V}{L_y} - f\,V = -\Phi/L_x \tag{59.154a}$$

$$\frac{V}{T} + \frac{V\,U}{L_x} + \frac{V\,V}{L_y} + f\,U = -\Phi/L_y, \tag{59.154b}$$

where Φ is the pressure scale. Now introduce two Rossby numbers according to

$$\mathrm{Ro}_x = \frac{U}{f\,L_x} \quad \text{and} \quad \mathrm{Ro}_y = \frac{V}{f\,L_y}, \tag{59.155}$$

and then divide equation (59.154a) by $f\,V$ and equation (59.154b) by $f\,U$, thus yielding

$$\mathrm{Ro}_x\,\frac{L_x}{T\,V} + \mathrm{Ro}_x\,\frac{U}{V} + \mathrm{Ro}_x\,\frac{L_x}{L_y} - 1 = -\frac{\Phi}{L_x\,f\,V} \tag{59.156a}$$

$$\mathrm{Ro}_y\,\frac{L_y}{T\,U} + \mathrm{Ro}_y\,\frac{V}{U} + \mathrm{Ro}_y\,\frac{L_y}{L_x} + 1 = -\frac{\Phi}{L_y\,f\,U}. \tag{59.156b}$$

Now assume the time scale is advective so that

$$T = L_x/U = L_y/V, \tag{59.157}$$

in which case equations (59.156a) and (59.156b) become

$$\mathrm{Ro}_x\,L_x/L_y + \mathrm{Ro}_x\,U/V + \mathrm{Ro}_x\,L_x/L_y - 1 = -\Phi/(L_x\,f\,V) \tag{59.158a}$$

$$\mathrm{Ro}_y\,L_y/L_x + \mathrm{Ro}_y\,V/U + \mathrm{Ro}_y\,L_y/L_x + 1 = -\Phi/(L_y\,f\,U). \tag{59.158b}$$

Consider the across-front momentum equation (59.158b). Since $L_y/L_x = V/U \ll 1$, and assuming Ro_y is at most order unity, terms in the across-front momentum equation (59.158b) balance only if the along-front flow is geostrophic

$$f\,U = -\Phi/L_y. \tag{59.159}$$

In turn, the along-front flow has a small Rossby number, $\mathrm{Ro}_x \ll 1$. We emphasize that the along-front flow is geostrophic even if $\mathrm{Ro}_y \sim 1$. In contrast, even with $\mathrm{Ro}_x \ll 1$, each term in equation (59.158a) can be order unity since $U/V = L_x/L_y \gg 1$, so that the across-front flow is not geostrophic. That is, $\mathrm{Ro}_y \sim 1$, so that the across-front flow is ageostrophic.

[13] The radius of curvature for the front provides a suitable along-front length scale. Recall we introduced the radius of curvature in decomposing horizontal flows in Chapter 32. Also, the mathematics of the radius of curvature was introduced in Chapter 5.

Semi-geostrophy is designed to study flow along and across geostrophic fronts, with the along front flow geostrophic and across-front flow ageostrophic. Equivalently, semi-geostrophy is designed to study flows with relatively large cross-front shear induced relative vorticity (and small curvature induced relative vorticity), with correspondingly large vertical velocity magnitudes, both of which are signatures of $\mathrm{Ro}_y \sim 1$ flow (see Section 3 of *Hoskins* (1975)).[14]

59.9.3 Geostrophic momentum approximation

The *geostrophic momentum approximation* assumes the horizontal ageostrophic velocity is given by

$$\boldsymbol{u}_{\text{ag}} \approx \hat{\boldsymbol{z}} \times \mathcal{D}\boldsymbol{u}_{\text{g}}, \tag{59.160}$$

which results from truncating equation (59.152) at the leading order. From equation (59.152) we see that the geostrophic momentum approximation holds so long as the horizontal velocity components satisfy the following respective inequalities

$$|u| \gg |\mathcal{D}^2 u| \implies f^2 \gg \left| \frac{1}{u} \frac{\mathrm{D}^2 u}{\mathrm{D}t^2} \right| \tag{59.161a}$$

$$|v| \gg |\mathcal{D}^2 v| \implies f^2 \gg \left| \frac{1}{v} \frac{\mathrm{D}^2 v}{\mathrm{D}t^2} \right|. \tag{59.161b}$$

These inequalities are satisfied if the Lagrangian timescale of variability for the flow (both its magnitude and direction; see Section 3 of *Hoskins* (1975)) is much longer than an inertial period. Rearranging the geostrophic momentum approximation (59.160) leads to

$$\mathcal{D}\boldsymbol{u}_{\text{g}} + \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{ag}} = 0, \tag{59.162}$$

which is equivalent to

$$\frac{\mathrm{D}\boldsymbol{u}_{\text{g}}}{\mathrm{D}t} + f\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\text{ag}} = 0, \tag{59.163}$$

Hence, for the geostrophic momentum approximation, the material time evolution of the geostrophic velocity is forced by the Coriolis acceleration arising from the horizontal ageostrophic velocity. Furthermore, the material time derivative for the semi-geostrophic system is given by

$$\frac{\mathrm{D}}{\mathrm{D}t} = \partial_t + \boldsymbol{v} \cdot \nabla = \partial_t + (\boldsymbol{u}_{\text{g}} + \boldsymbol{u}_{\text{ag}}) \cdot \nabla_{\text{h}} + w_{\text{ag}}\, \partial_z, \tag{59.164}$$

with

$$\boldsymbol{v} = (\boldsymbol{u}_{\text{g}} + \boldsymbol{u}_{\text{ag}}) + \hat{\boldsymbol{z}}\, w_{\text{ag}}. \tag{59.165}$$

Note that any vertical flow is ageostrophic, so that it is not really necessary to place the "ag" subscript on w_{ag}. Even so, we do so to remind us that it lives at the same order as the horizontal ageostrophic flow, $\boldsymbol{u}_{\text{ag}}$. Furthermore, note that the key distinction between semi-geostrophy and quasi-geostrophy is the presence of w_{ag} in the material time derivative operator for semi-geostrophy, whereas quasi-geostrophy only makes use of advection by the geostrophic flow (see Section 45.3.9).

The geostrophic momentum approximation is consistent with the frontal scaling given in Section 59.9.2, and so it offers a suitable starting point for the study of frontal dynamics. Even so, to make use of the geostrophic momentum approximation to evolve the geostrophic flow requires further work since the ageostrophic velocity appears as part of the material time derivative operator. This situation is analogous to quasi-geostrophy, whereby evolution of the geostrophic flow arises from ageostrophic processes. To derive a closed equation set, *Hoskins* (1975) developed

[14] In Section 38.5 we decomposed relative vorticity into from cross-flow shear and along-flow curvature.

the semi-geostrophic momentum equations via a coordinate transformation to *geostrophic coordinates*, making use also of material constancy of the buoyancy and potential vorticity.[15] We do not present that formulation here. Instead, we focus on deriving a diagnostic equation for the secondary ageostrophic overturning circulation, with the manipulations reminiscent of those used in Section 59.8 for symmetric instability of a baroclinic front.

59.9.4 Geostrophic evolution of the buoyancy gradient

As a preface to the diagnostic equations for the ageostrophic flow, consider the evolution of the horizontal buoyancy gradient, considering just that evolution arising from geostrophic flow. Recall that for the Boussinesq ocean, the horizontal gradient of buoyancy provides a measure of baroclinicity (Section 40.7.2). Flow processes that increase the magnitude of the buoyancy gradient lead to growth of the thermal wind flow and thus the frontal strength.

Start by considering the buoyancy equation for adiabatic and geostrophic flow

$$(\partial_t + \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}})\, b = 0. \tag{59.166}$$

Separately taking the zonal and meridional derivatives and rearranging leads to

$$(\partial_t + \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}})(\partial_x b) = -\partial_x \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}} b \quad \text{and} \quad (\partial_t + \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}})(\partial_y b) = -\partial_y \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}} b, \tag{59.167}$$

which can be combined to

$$(\partial_t + \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}})(\nabla_{\mathsf{h}} b) = \mathbf{Q}, \tag{59.168}$$

where we introduced the horizontal vector

$$\mathbf{Q} = -(\partial_x \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}} b)\, \hat{\boldsymbol{x}} - (\partial_y \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}} b)\, \hat{\boldsymbol{y}}. \tag{59.169}$$

Correspondingly, geostrophic evolution of the squared buoyancy gradient is

$$(\partial_t + \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}})|\nabla_{\mathsf{h}} b|^2 = 2\, \mathbf{Q} \cdot \nabla_{\mathsf{h}} b. \tag{59.170}$$

Evidently, the buoyancy gradient grows in magnitude if $\mathbf{Q}$ has a positive projection onto the horizontal buoyancy gradient.

59.9.5 Secondary ageostrophic circulation

In Sections 59.5 and 59.6 we focused on the stability of a geostrophically balanced equilibrium with flow along a symmetric front. In addition to the geostrophic flow along the front, there is generally an ageostrophic circulation that circulates in the plane orthogonal to the front. We here derive an equation describing this overturning circulation, and then specialize that equation in Section 59.9.6 to a zonally symmetric front. For this purpose, start from the zonal momentum equation, buoyancy equation, and continuity equation within the semi-geostrophic system

$$\partial_t u_{\mathsf{g}} + (\boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}}) u_{\mathsf{g}} + (\boldsymbol{u}_{\mathsf{ag}} \cdot \nabla_{\mathsf{h}}) u_{\mathsf{g}} + w_{\mathsf{ag}}\, \partial_z u_{\mathsf{g}} - f v_{\mathsf{ag}} = 0 \tag{59.171a}$$

$$\partial_t b + \boldsymbol{u}_{\mathsf{g}} \cdot \nabla_{\mathsf{h}} b + \boldsymbol{u}_{\mathsf{ag}} \cdot \nabla_{\mathsf{h}} b + w_{\mathsf{ag}} N^2(z) = 0 \tag{59.171b}$$

$$\partial_x u_{\mathsf{ag}} + \partial_y v_{\mathsf{ag}} + \partial_z w_{\mathsf{ag}} = 0. \tag{59.171c}$$

[15] Some authors reserve the name *semi-geostrophy* for the transformed equations derived by *Hoskins* (1975).

The vertical derivative of the zonal momentum equation (59.171a) leads to

$$\partial_t\partial_z u_{\mathrm{g}} + (\partial_z \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} + (\boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})\partial_z u_{\mathrm{g}} + (\partial_z \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} + (\boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})\partial_z u_{\mathrm{g}} + \partial_z(w_{\mathrm{ag}}\,\partial_z u_{\mathrm{g}}) - f\,\partial_z v_{\mathrm{ag}} = 0, \quad (59.172)$$

and the meridional derivative of the buoyancy equation (59.171b) yields

$$\partial_t\partial_y b + (\partial_y \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})b + (\boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})\partial_y b + (\partial_y \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})b + (\boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})\partial_y b + \partial_y w_{\mathrm{ag}}\,N^2 = 0. \quad (59.173)$$

The thermal wind relation,

$$f\,\partial_z \boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}}\times\nabla_{\mathrm{h}} b \Longrightarrow \partial_z u_{\mathrm{g}} = -f^{-1}\,\partial_y b \quad \text{and} \quad \partial_z v_{\mathrm{g}} = f^{-1}\,\partial_x b, \quad (59.174)$$

brings equation (59.172) to the form

$$\partial_t(\partial_y b) - f\,(\partial_z \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} + (\boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})\partial_y b - f\,(\partial_z \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} + (\boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})\partial_y b + \partial_z(w_{\mathrm{ag}}\,\partial_y b) + f^2\partial_z v_{\mathrm{ag}} = 0, \quad (59.175)$$

and equation (59.173) becomes

$$\partial_t(\partial_y b) + (\partial_y \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})b + (\boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})\partial_y b + (\partial_y \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})b + (\boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})\partial_y b + \partial_y w_{\mathrm{ag}}\,N^2 = 0. \quad (59.176)$$

Subtracting equation (59.176) from equation (59.175) eliminates the time derivative thus revealing the diagnostic relation

$$-f\,(\partial_z \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} - f\,(\partial_z \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} + \partial_z\,(w_{\mathrm{ag}}\,\partial_y b) + f^2\,\partial_z v_{\mathrm{ag}} - (\partial_y \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})b - (\partial_y \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})b - \partial_y w_{\mathrm{ag}}\,N^2 = 0. \quad (59.177)$$

Making use of thermal wind and horizontal non-divergence for the geostrophic velocity allows us to write

$$f(\partial_z \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} = (\partial_y \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}})b = -\mathrm{Q}^y, \quad (59.178)$$

where Q^y is the meridional component of the geostrophic $\mathbf{Q}$-vector introduced in Section 45.4.1 (see equation (45.67)).[16]

$$\mathbf{Q} \equiv -(\partial_x \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}} b)\,\hat{\boldsymbol{x}} - (\partial_y \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_{\mathrm{h}} b)\,\hat{\boldsymbol{y}}. \quad (59.179)$$

Introduction of Q^y into equation (59.177) yields

$$-f\,(\partial_z \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} + \partial_z w_{\mathrm{ag}}\,\partial_y b + w_{\mathrm{ag}}\,\partial_{yz} b + f^2\,\partial_z v_{\mathrm{ag}} - (\partial_y \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})b - \partial_y w_{\mathrm{ag}} N^2 = -2\,\mathrm{Q}^y. \quad (59.180)$$

Again making use of thermal wind and $\nabla_{\mathrm{h}}\cdot\boldsymbol{u}_{\mathrm{g}} = 0$ renders

$$-f\,(\partial_z \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})u_{\mathrm{g}} - (\partial_y \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_{\mathrm{h}})b = f\partial_z u_{\mathrm{ag}}\,\partial_y v_{\mathrm{g}} - f\partial_z v_{\mathrm{ag}}\,\partial_y u_{\mathrm{g}} + f\partial_y u_{\mathrm{ag}}\,\partial_z v_{\mathrm{g}} + f\partial_y v_{\mathrm{ag}}\,\partial_z u_{\mathrm{g}}. \quad (59.181)$$

The mixed partial derivative of the buoyancy vanishes

$$\frac{\partial^2 b}{\partial z\partial y} = \frac{\partial}{\partial y}\frac{\partial b}{\partial z} = \frac{\partial N^2(z)}{\partial y} = 0, \quad (59.182)$$

[16] Be careful to distinguish the geostrophic $\mathbf{Q}$-vector from the potential vorticity, Q. In particular, note the upright $\mathbf{Q}$ versus the slanted Q.

which follows since the background vertical stratification is assumed to be independent of the horizontal direction. Bringing these results together into equation (59.180) leads to

$$f\partial_z u_{\text{ag}}\,\partial_y v_{\text{g}} + f\partial_y u_{\text{ag}}\,\partial_z v_{\text{g}} + f\partial_y v_{\text{ag}}\,\partial_z u_{\text{g}} + \partial_z w_{\text{ag}}\,\partial_y b + f\partial_z v_{\text{ag}}\,(f - \partial_y u_{\text{g}}) - \partial_y w_{\text{ag}} N^2 = -2\mathrm{Q}^y, \quad (59.183)$$

with another use of thermal wind yielding

$$f\partial_z u_{\text{ag}}\,\partial_y v_{\text{g}} + f\partial_y u_{\text{ag}}\,\partial_z v_{\text{g}} + f\partial_z u_{\text{g}}\,(\partial_y v_{\text{ag}} - \partial_z w_{\text{ag}}) + f\partial_z v_{\text{ag}}\,(f - \partial_y u_{\text{g}}) - \partial_y w_{\text{ag}} N^2 = -2\mathrm{Q}^y. \quad (59.184)$$

This equation provides a relation for the ageostrophic cross-flow and vertical circulation, $(v_{\text{ag}}, w_{\text{ag}})$, written in terms of the buoyancy field and the geostrophic flow. We next next consider flow surrounding a symmetric front, in which case equation (59.184) becomes a diagnostic equation for the ageostrophic overturning streamfunction.

59.9.6 Ageostrophic overturning circulation for a symmetric front

Equation ((59.184) is now specialized by assuming the zonal velocity is purely geostrophic (as in a zonal geostrophic front) so that

$$u_{\text{ag}} = 0. \quad (59.185)$$

For this flow, the ageostrophic flow in the cross-flow/depth plane is non-divergent

$$\partial_y v_{\text{ag}} + \partial_z w_{\text{ag}} = 0. \quad (59.186)$$

The diagnostic equation (59.184) now takes on the specialized form for a symmetric front

$$-2\,f\,\partial_z u_{\text{g}}\,\partial_z w_{\text{ag}} + f\,(f + \zeta_{\text{g}})\,\partial_z v_{\text{ag}} - \partial_y w_{\text{ag}}\,N^2 = -2\mathrm{Q}^y, \quad (59.187)$$

where

$$\zeta_{\text{g}} = -\partial_y u_{\text{g}} \quad (59.188)$$

is the vertical component of the geostrophic relative vorticity. Introducing an overturning streamfunction for the cross-flow/vertical ageostrophic circulation

$$\boldsymbol{u}_{\text{ag}} = -\hat{\boldsymbol{x}} \times \nabla\psi \Longrightarrow v_{\text{ag}} = \partial_z\psi \quad \text{and} \quad w_{\text{ag}} = -\partial_y\psi, \quad (59.189)$$

and using thermal wind brings equation (59.187) into the form

$$[N^2\,\partial_{yy} - 2\,\partial_y b\,\partial_{yz} + f\,(f + \zeta_{\text{g}})\,\partial_{zz}]\psi = -2\mathrm{Q}^y. \quad (59.190)$$

Equation (59.190) is useful for the study of ageostrophic (Ro $\sim$ 1) dynamics along a front in which there is an ageostrophic overturning circulation in response to geostrophic forcing from Q^y.

59.9.7 Connection to potential vorticity and symmetric instability

The partial differential equation (59.190) can be written

$$\mathcal{K}\psi = -2\,\mathrm{Q}^y, \quad (59.191)$$

where

$$\mathcal{K} = N^2\,\partial_{yy} - 2\,\partial_y b\,\partial_{zy} + f\,(f + \zeta_{\text{g}})\,\partial_{zz} \quad (59.192)$$

is a linear partial differential operator that is a function of the geostrophic flow and the buoyancy. Following the considerations in Section 6.5, we know that this operator is elliptic if the following inequality holds

$$(\partial_y b)^2 - N^2 f (f + \zeta_g) < 0. \tag{59.193}$$

We can relate the ellipticity condition (59.193) to the Ertel potential vorticity for the Boussinesq geostrophic flow. For this purpose, write the geostrophic vorticity as

$$\begin{aligned} \boldsymbol{\omega}_g &= \nabla \times \boldsymbol{u}_g && \text{(59.194a)} \\ &= -\hat{\boldsymbol{x}}\, \partial_z v_g + \hat{\boldsymbol{y}}\, \partial_z u_g + \hat{\boldsymbol{z}}\, \partial_x v_g - \partial_y u_g) && \text{(59.194b)} \\ &= -f^{-1} (\hat{\boldsymbol{x}}\, \partial_x b + \hat{\boldsymbol{y}}\, \partial_y b) + \hat{\boldsymbol{z}}\, (\partial_x v_g - \partial_y u_g). && \text{(59.194c)} \end{aligned}$$

If we assume the front is zonally symmetric, then the relative vorticity in the geostrophic flow takes the form

$$\boldsymbol{\omega}_g^{2d} = -f^{-1}\, \partial_y b\, \hat{\boldsymbol{y}} - \hat{\boldsymbol{z}}\, \partial_y u_g, \tag{59.195}$$

in which case the Ertel potential vorticity (for the Boussinesq geostrophic flow) takes the form

$$\begin{aligned} Q_g^{2d} &= \nabla b \cdot (\boldsymbol{\omega}_g + f\, \hat{\boldsymbol{z}}) && \text{(59.196a)} \\ &= -f^{-1} (\partial_y b)^2 + N^2 (f - \partial_y u_g). && \text{(59.196b)} \\ &= -f^{-1} (\partial_y b)^2 + N^2 (f + \zeta_g). && \text{(59.196c)} \end{aligned}$$

Ellipticity of the PDE (59.190) is thus assured so long as

$$f\, Q_g^{2d} = -(\partial_y b)^2 + N^2 f (f + \zeta_g) > 0. \tag{59.197}$$

The PDE (59.6) transitions to a hyperbolic system when $f\, Q_g^{2d} < 0$, which is the condition for symmetric instability detailed in Section 59.6. Hence, when $f\, Q_g^{2d} > 0$ the front is stable to symmetric instability, with the ageostrophic circulation acting to relax the front. In contrast, when $f\, Q_g^{2d} > 0$ the front is symmetrically unstable.

59.9.8 Further study

Chapter 9 of *Holton and Hakim* (2013) provides a pedagogical discussion of semi-geostrophy and the study of atmospheric fronts.

59.10 Exercises

EXERCISE 59.1: INERTIAL INSTABILITY IN A SHALLOW WATER LAYER
In Section 59.5 we developed the physics of horizontal inertial instability within the continuous Boussinesq equations. Consider the analysis instead within the context of a single layer of shallow water fluid. What are the conditions for inertial instability within the shallow water layer? Are they the same as for the continuous Boussinesq equations? Why?

EXERCISE 59.2: SYMMETRIC INSTABILITY CRITERIA IN TERMS OF BALANCED RICHARDSON NUMBER
Consider the balanced Richardson number, defined for the geostrophic and hydrostatic balanced

flow, along with a corresponding angle

$$\mathrm{Ri}_{\mathrm{b}} = \frac{N^2}{(\partial_z u_{\mathrm{g}})^2} \quad \text{and} \quad \phi_{\mathrm{Ri}_{\mathrm{b}}} \equiv \tan^{-1}(-1/\mathrm{Ri}_{\mathrm{b}}). \tag{59.198}$$

Show that the instability criteria, $f\,Q < 0$, from Section 59.8 can be written in the equivalent form

$$\phi_{\mathrm{Ri}_{\mathrm{b}}} < \phi_{\mathrm{c}} \equiv \tan^{-1}(-(f + \zeta_{\mathrm{g}})/f). \tag{59.199}$$

As shown by *Thomas et al.* (2013), this alternative form of the instability criteria allows for a very effective means to characterize flow regimes conducive to the suite of local instabilities: gravitational, inertial, and symmetric.

EXERCISE 59.3: GROUP VELOCITY FOR SYMMETRIC MERIDIONAL-VERTICAL WAVES
In this exercise we derive some properties for the group velocity of the stable meridional-vertical plane waves discussed in Section 59.8.4.

(a) Derive the group velocity, $\boldsymbol{c}_{\mathrm{g}}$, for the stable meridional-vertical waves whose dispersion relation is given by equation (59.137c).

(b) Compute $\boldsymbol{c}_{\mathrm{g}} \cdot \boldsymbol{k}$, where the wavevector is $\boldsymbol{k} = k_y\,\hat{\boldsymbol{y}} + k_z\,\hat{\boldsymbol{z}}$.

Chapter 60

STABILITY OF FLUID INTERFACES

In this chapter we study the *Rayleigh-Taylor* and *Kelvin-Helmholtz* instabilities as realized along an infinitesimal material fluid interface that separates two homogeneous (constant density) fluid layers of differing densities, and with the two fluids immiscible and inviscid. The gravitational body force is active throughout the fluid layers, and the surface tension is active at the interface between the layers. We do not consider Coriolis or centrifugal acceleration in this chapter (non-rotating reference frame), and the relative vorticity vanishes in both layers. The *normal mode method*, based on Fourier modal analysis, is suited to developing necessary and sufficient conditions for instability.

The physical system is highly idealized in its assumption that the interface between the fluid layers is infinitesimal, and furthermore that the fluids are inviscid and immiscible. Both assumptions accord with our treatment of surface gravity and capillary waves in Chapter 52. Even though quite idealized, the methods and concepts encountered in studying the instabilities are useful in more realistic cases. Furthermore, experimental results support the relevance of the instability conditions found in this chapter.

READER'S GUIDE FOR THIS CHAPTER

This chapter is an extension of the material in Chapter 52, which is concerned with stable linear surface waves on an interface arising from gravity and/or surface tension. The methods of modal instability analysis used in this chapter are also used for a variety of other instabilities elsewhere in this book.

60.1 Governing equations

Formulation of the stability problem in this chapter closely follows that pursued in Chapter 52 for surface gravity waves and capillary waves. In that study we assumed the waves occur on the interface between two regions of constant density, yet with the upper region having zero density, as motivated by waves on the free surface of the ocean underneath the much less massive atmosphere. Here, we allow for the upper region to have a nonzero density. Under certain circumstances, fluctuations on the interface lead to stable linear waves, and we develop the associated dispersion relations. However, a Rayleigh-Taylor instability occurs when the smaller density layer sits below a heavier layer, and with a base state that is at rest. More precisely, an instability occurs when the destabilizing effects from gravity overcome the stabilizing effects from surface tension. In the absence of surface tension, there is always a Rayleigh-Taylor instability when heavy fluid sits above light fluid.

For the Kelvin-Helmholtz instability, we consider the heavy fluid below the light fluid, yet with a base state velocity that differs between the two layers so that there is a velocity shear (more precisely, a velocity jump) at the interface and an associated vorticity singularity. An instability occurs when the destabilizing effects from the velocity shear are sufficiently strong so as to overcome the stabilizing effects from gravity and surface tension. In the absence of both gravity and surface tension, any velocity shear renders an instability of the interface which, as noted on page 485 of *Chandrasekhar* (1961), leads one to conclude that *the Kelvin-Helmholtz instability arises by the crinkling of the interface by the shear that is present; and this crinkling occurs even for the smallest differences in the velocities of the two fluids.* We find in Chapter 61 a modification to this result when considering a finite shear layer rather than the infinitesimal interface considered in the current chapter.

In this section we develop the equations describing motion of an interface separating two homogeneous, inviscid, and immiscible fluids in a non-rotating reference frame and with densities, ρ_1 and ρ_2, and constant zonal velocities, $\hat{\boldsymbol{x}}\, U_1$ and $\hat{\boldsymbol{x}}\, U_2$. (Figure 60.1). We ignore side boundaries by assuming the domain to be horizontally infinite. This is the idealized physical system that is used to study the Rayleigh-Taylor instability and the Kelvin-Hemholtz instability.

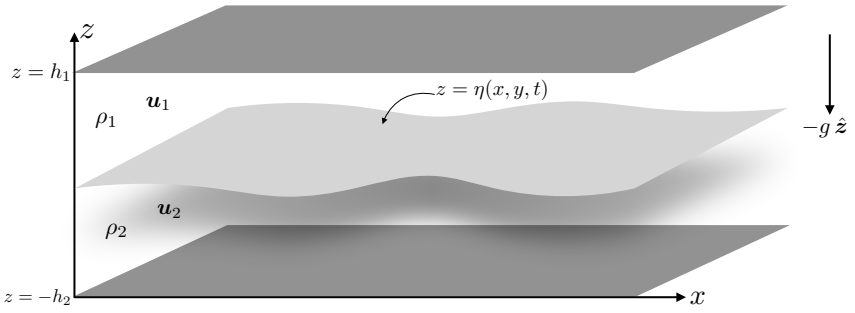


FIGURE 60.1: An infinite box filled with two homogeneous and immiscible fluids with densities, ρ_1 and ρ_2, and horizontal velocities, $\boldsymbol{u}_1$ and $\boldsymbol{u}_2$. The material interface between the layers is located at $z = \eta(x, y, t)$, with $\eta = 0$ when the interface is flat. The fluid region is denoted $\mathcal{R}$, which is infinite in the horizontal directions. For study of the Rayleigh-Taylor instability we assume rigid and flat plates located at $z = -h_2$ and $z = h_1$, whereas for Kelvin-Helmholtz instability we let h_1 and h_2 go to infinity. The interface generally experiences a surface tension due to the density jump.

60.1.1 Equations from potential theory

The fluid in each layer has a constant density and so is incompressible, so that the velocity in each layer is non-divergent, $\nabla \cdot \boldsymbol{v} = 0$. Furthermore, we assume the flow is irrotational ($\nabla \times \boldsymbol{v} = 0$) and so can make use of the potential theory detailed in Section 52.2. In particular, the velocity potential has a time tendency given by Bernoulli's equation of motion (52.16)

$$\partial_t \Psi = \Phi + \mathcal{K} + p/\rho = \mathcal{K} + p_{\mathrm{d}}/\rho, \tag{60.1}$$

where

$$\begin{aligned}
\boldsymbol{v} &= -\nabla\Psi && \text{velocity and velocity potential} && (60.2a)\\
\Phi &= g\,z && \text{geopotential} && (60.2b)\\
\mathcal{K} &= \boldsymbol{v}\cdot\boldsymbol{v}/2 && \text{kinetic energy per mass} && (60.2c)\\
p &= -\rho\,\Phi + p_{\mathrm{d}} && p = \text{pressure and } p_{\mathrm{d}} = \text{dynamic pressure.} && (60.2d)
\end{aligned}$$

The velocity potential, Ψ, satisfies Laplace's equation in the fluid interior and the no-normal flow kinematic boundary condition (Neumann boundary condition) at the rigid top and rigid bottom

$$\begin{aligned}
\nabla^2\Psi &= 0 \quad \boldsymbol{x} \in \mathcal{R} && (60.3a)\\
\hat{\boldsymbol{n}}\cdot\nabla\Psi &= 0 \quad \boldsymbol{x} \in \partial\mathcal{R}. && (60.3b)
\end{aligned}$$

When considering a background zonal velocity, we extract the velocity potential for the static background potential, $\Psi_n^\circ = -U_n\,x$, with $n = 1, 2$ the layer index and with the remaining portion of the velocity potential capturing the perturbation relative to the background. The background velocity potential trivially satisfies Laplace's equation and the no-normal flow boundary condition at the flat and rigid top and bottom boundaries.

60.1.2 Kinematic boundary condition at the interface

Motion of the interface, $z = \eta(x, y, t)$, is determined by boundary conditions evaluated at the interface. The interface is material since the fluid layers are assumed to be immiscible. Focusing first on the lower side, in region 2, the kinematic boundary condition from Section 19.6.2 states that

$$(\boldsymbol{v}_2 - \boldsymbol{v}_\eta)\cdot\hat{\boldsymbol{n}}_2 = 0 \quad \text{at } z = \eta, \tag{60.4}$$

where $\boldsymbol{v}_2$ is the fluid velocity in the lower region, and

$$\hat{\boldsymbol{n}}_2 = \hat{\boldsymbol{n}} = \frac{\nabla(z-\eta)}{|\nabla(z-\eta)|} \quad \text{at } z = \eta, \tag{60.5}$$

is the outward normal direction pointing into the upper layer. The analysis for layer-2 holds equivalantly for layer-1, only with the normal direction pointing from layer-1 down to layer-2. We thus have

$$(\boldsymbol{v}_2 - \boldsymbol{v}_\eta)\cdot\hat{\boldsymbol{n}} = 0 \quad \text{and} \quad (\boldsymbol{v}_\eta - \boldsymbol{v}_1)\cdot\hat{\boldsymbol{n}} = 0 \Longrightarrow (\boldsymbol{v}_2 - \boldsymbol{v}_1)\cdot\hat{\boldsymbol{n}} = 0. \tag{60.6}$$

That is, the normal components to the layer velocities match at the interface. Consequently, the normal derivative of the velocity potential also matches at the interface

$$\hat{\boldsymbol{n}}\cdot(\nabla\Psi_2 - \nabla\Psi_1) = 0 \quad \text{at } z = \eta. \tag{60.7}$$

The velocity of the interface, $\boldsymbol{v}_\eta$, has a normal component given by

$$|\nabla(z-\eta)|\,\boldsymbol{v}_\eta \cdot \hat{\boldsymbol{n}} = \partial_t \eta \quad \text{at } z = \eta, \tag{60.8}$$

so that the kinematic boundary condition (60.4) can be written in the equivalent form

$$(\partial_t + \boldsymbol{u}_1 \cdot \nabla)\,\eta = w_1 \quad \text{and} \quad (\partial_t + \boldsymbol{u}_2 \cdot \nabla)\,\eta = w_2 \quad \text{at } z = \eta. \tag{60.9}$$

Inserting the background velocity and the velocity potential leads to the kinematic boundary conditions at the fluid interface

$$(\partial_t + U_1\,\partial_x - \nabla\Psi_1 \cdot \nabla)\,\eta = -\partial_z \Psi_1 \quad \text{and} \quad (\partial_t + U_2\,\partial_x - \nabla\Psi_2 \cdot \nabla)\,\eta = -\partial_z \Psi_2 \quad \text{at } z = \eta. \tag{60.10}$$

60.1.3 Dynamic boundary condition at the interface

The dynamic boundary condition from Section 25.10 says that the pressure is continuous across the interface so long as we ignore surface tension. For the case with surface tension, the discussion in Section 25.11 reveals a pressure jump across the interface, which here takes the form given by the Young-Laplace formula (25.149),[1]

$$p_2 - p_1 = -\gamma\,\nabla_{\!\mathsf{h}}^2 \eta \quad \text{at } z = \eta. \tag{60.11}$$

In this equation, $\gamma > 0$ is the surface tension (dimensions of force per length = $\mathrm{M\,T^{-2}}$). Evidently, pressure on the concave side of the interface is higher than on the convex side. For example, if the interface extends upward then $p_2 - p_1 > 0$ since the layer-2 fluid is on the concave side and so it has the higher interface pressure. This result also follows since $\nabla_{\!\mathsf{h}}^2 \eta < 0$ for an upward extension of the interface, which leads to a local free surface maximum. The treatment here follows our approach for surface capillary-gravity waves in Section 52.10.1.

60.1.4 Pressures within the two layers

We find it convenient to isolate the hydrostatic pressure within the two layers. For the upper layer we have

$$p_1^{\mathsf{h}} = g\,\rho_1\,(h_1 - z) \quad \text{for } \eta \le z \le h_1, \tag{60.12}$$

where we assumed pressure at $z = h_1$ is zero. Similarly, the hydrostatic pressure in layer two is

$$p_2^{\mathsf{h}} = p_1^{\mathsf{h}}(\eta) + g\,\rho_2\,(\eta - z) = g\,\rho_1\,(h_1 - \eta) + g\,\rho_2\,(\eta - z) \quad \text{for } -h_2 \le z \le 0. \tag{60.13}$$

Note that these hydrostatic pressures match at the interface

$$p_2^{\mathsf{h}}(x, y, z = \eta, t) = p_1^{\mathsf{h}}(x, y, z = \eta, t). \tag{60.14}$$

If there is fluid motion within the layers, then the layer interface is not flat and the pressure is not equal to its resting pressure. In this case we write the pressure as

$$p_1(x, y, z, t) = p_1^{\mathsf{h}}(x, y, z, t) + \delta p_1(x, y, z, t) \tag{60.15a}$$

$$p_2(x, y, z, t) = p_2^{\mathsf{h}}(x, y, z, t) + \delta p_2(x, y, z, t) - \gamma\,\nabla_{\!\mathsf{h}}^2 \eta(x, y, t), \tag{60.15b}$$

[1] We write $\nabla_{\!\mathsf{h}}^2 \eta$ to emphasize that the Laplacian is only acting in the horizontal directions. This notation is not needed when the Laplacian acts on the interface, η, since this field is just a spatial function of the horizontal positions, x, y. However, in equation (60.24) we replace $\partial_t \eta(x, y, t)$ with $-\partial_z \Psi(x, y, z = 0, t)$ as per the linearized kinematic boundary condition (60.20c) with $u_1 = u_2 = 0$. It is this replacement that makes it important to note that the Laplacian is acting just in the horizontal.

where δp_1 and δp_2 are pressures associated with the fluid motion and that vanish when the fluid is at rest. Furthermore, these pressures are continuous at the interface just like the hydrostatic pressures

$$\delta p_1 = \delta p_2 \quad \text{at } z = \eta, \tag{60.16}$$

so that there remains a pressure jump (60.11) in the presence of surface tension

$$p_2 - p_1 = -\gamma \nabla_{\mathrm{h}}^2 \eta \quad \text{at } z = \eta. \tag{60.17}$$

60.1.5 Linearized equations

As for the study of surface gravity waves and capillary waves in Chapter 52, linearization of this system is based on an assumed small slope for the interfaces. Hence, we follow the study of surface waves in Section 52.3 to linearize the Bernoulli equation of motion (60.1). Correspondingly, we linearize the kinematic boundary condition (60.9) and dynamic boundary condition (60.17). In particular, the linearized boundary conditions are evaluated at $z = 0$ rather than at $z = \eta$, in which case the linearized version of p_2^{h} is a function just of z alone.

A new feature here beyond the case of surface waves concerns the presence of a background flow, in which case the kinetic energy contributes at linear order. In particular, the layer-1 Bernoulli equation yields

$$\rho_1 \, \partial_t \Psi_1 = g \, z \, \rho_1 + p_1 + \rho_1 \, [U_1 \, u_1 + (U_1)^2/2]. \tag{60.18}$$

The constant, $\rho_1 \, (U_1)^2/2$, can be eliminated by taking a gauge transformation, as detailed in Section 52.2.3 when studying surface waves. Hence, we drop this term in the following. Writing $u_1 = -\partial_x \Psi_1$ then brings the linearized Bernoulli equation to the form

$$\rho_1 \, (\partial_t + U_1 \, \partial_x) \Psi_1 = g \, z \, \rho_1 + p_1, \tag{60.19}$$

so that the background zonal flow provides a constant advection of the velocity potential. We are thus led to the following linearized layer equations

$$\rho_1 \, (\partial_t + U_1 \, \partial_x) \Psi_1 = g \, z \, \rho_1 + p_1 \quad \text{linearized Bernoulli equation for layer 1} \tag{60.20a}$$
$$\rho_2 \, (\partial_t + U_2 \, \partial_x) \Psi_2 = g \, z \, \rho_2 + p_2 \quad \text{linearized Bernoulli equation for layer 2} \tag{60.20b}$$
$$(\partial_t + U_1 \, \partial_x) \eta = -\partial_z \Psi_1 \quad \text{linearized kinematic b.c. at } z = 0 \tag{60.20c}$$
$$(\partial_t + U_2 \, \partial_x) \eta = -\partial_z \Psi_2 \quad \text{linearized kinematic b.c. at } z = 0 \tag{60.20d}$$
$$\delta p_2 - \delta p_1 = 0 \quad \text{dynamic b.c. at } z = 0 \tag{60.20e}$$
$$p_2 - p_1 = -\gamma \nabla_{\mathrm{h}}^2 \eta \quad \text{dynamic jump b.c. at } z = 0. \tag{60.20f}$$

Taking the difference between the Bernoulli equations in the two layers gives

$$\rho_2 \, (\partial_t + U_2 \, \partial_x) \Psi_2 - \rho_1 \, (\partial_t + U_1 \, \partial_x) \Psi_1 = g \, (\rho_2 \, z_2 - \rho_1 \, z_1) + p_2 - p_1, \tag{60.21}$$

and then evaluating this difference on the interface ($z_1 = z_2 = \eta$) leads to

$$\rho_2 \, (\partial_t + U_2 \, \partial_x) \Psi_2 - \rho_1 \, (\partial_t + U_1 \, \partial_x) \Psi_1 = (g \, \delta\rho - \gamma \nabla_{\mathrm{h}}^2) \, \eta \tag{60.22}$$

where the density difference is written

$$\delta\rho = \rho_2 - \rho_1. \tag{60.23}$$

Note that when multiplied by gravity, we evaluate the interface position at $z = \eta$, whereas other

terms in the linear theory are evaluated at $z = 0$.[2]

60.2 Rayleigh-Taylor instability

For the Rayleigh-Taylor instability analysis, we assume the background flow is at rest so that $U_1 = U_2 = 0$. Hence, we are here examining stability of the rest state to small perturbations of the layer interface.

60.2.1 Boundary value problem and dispersion relation

With zero background flow it is a simple matter to eliminate the free surface from the interface condition (60.22). We do so by taking a time derivative and using the linearized kinematic boundary condition (60.20c) (or equivalently equation (60.20d))

$$\partial_{tt}(\rho_2 \Psi_2 - \rho_1 \Psi_1) = -[g\,\delta\rho - \gamma\,\nabla_h^2]\,\partial_z \Psi \quad \text{at } z = 0, \tag{60.24}$$

where $w_1 = w_2 = -\partial_z \Psi$ at $z = 0$. We are thus led to the boundary value problem

$$\partial_z \Psi_1 = 0 \qquad z = h_1 \tag{60.25a}$$
$$\nabla^2 \Psi_1 = 0 \qquad 0 < z < h_1 \tag{60.25b}$$
$$\partial_{tt}(\rho_2 \Psi_2 - \rho_1 \Psi_1) = -[g\,\delta\rho - \gamma\,\nabla_h^2]\,\partial_z \Psi \qquad z = 0 \tag{60.25c}$$
$$\nabla^2 \Psi_2 = 0 \qquad -h_2 < z < 0 \tag{60.25d}$$
$$\partial_z \Psi_2 = 0 \qquad z = -h_2. \tag{60.25e}$$

Following the approach for surface waves in Section 52.5, we seek a traveling plane wave solution with horizontal wavevector,

$$\boldsymbol{k} = k_x\,\hat{\boldsymbol{x}} + k_y\,\hat{\boldsymbol{y}} \quad \text{and} \quad \hat{\boldsymbol{k}} = \boldsymbol{k}/|\boldsymbol{k}|, \tag{60.26}$$

and a wave ansatz in the form of a cosine modulated by a vertical structure function

$$\Psi(x, y, z, t) = A\,\Gamma(z)\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t), \tag{60.27}$$

where A is a real amplitude. The solution to Laplace's equation with Neumann boundary conditions in the two half-domains is given by[3]

$$\Psi_1 = A\,\frac{\cosh[|\boldsymbol{k}|\,(z - h_1)]}{\sinh[-|\boldsymbol{k}|h_1]}\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t) \qquad 0 \le z \le h_1 \tag{60.28a}$$
$$\Psi_2 = A\,\frac{\cosh[|\boldsymbol{k}|\,(z + h_2)]}{\sinh[|\boldsymbol{k}|h_2]}\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t), \qquad -h_2 \le z \le 0. \tag{60.28b}$$

The dispersion relation is obtained by plugging equations (60.28a)-(60.28b) into the interface

[2] We detailed this treatment of the boundary position when deriving the linear equations for surface waves in Section 52.3.4. The same considerations hold here.

[3] As noted in Section 52.2.2, solutions to Laplace's equation do not support spatial oscillations in all three directions since the sum of the curvature in each direction (i.e., second partial derivatives) must vanish. Correspondingly, the velocity potential supports traveling waves in the horizontal and exponential behavior in the vertical.

condition (60.25e), with the following pieces needed (recall each term is evaluated at $z = 0$)

$$\partial_{tt}(\rho_2 \Psi_2 - \rho_1 \Psi_1) = -\omega^2 A [\rho_2 \coth(|\boldsymbol{k}| h_2) - \rho_1 \coth(-|\boldsymbol{k}| h_1)] \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega t) \tag{60.29a}$$

$$\partial_z \Psi_1 = \partial_z \Psi_2 = A |\boldsymbol{k}| \cos(\boldsymbol{k} \cdot \boldsymbol{x} - \omega t) \tag{60.29b}$$

$$(\partial_{xx} + \partial_{yy})\Psi = -|\boldsymbol{k}|^2 \Psi, \tag{60.29c}$$

thus leading to the dispersion relation

$$\omega^2 = \frac{|\boldsymbol{k}| (g \delta\rho + \gamma |\boldsymbol{k}|^2)}{\rho_1 \coth(|\boldsymbol{k}| h_1) + \rho_2 \coth(|\boldsymbol{k}| h_2)}. \tag{60.30}$$

As for the surface waves in Chapter 52, the horizontal wavenumber, $|\boldsymbol{k}|$, determines the vertical scale of the wave. We now examine various cases for stable and unstable waves.

60.2.2 Stable traveling plane waves

When the squared angular frequency (60.30) is positive, $\omega^2 > 0$, then the waves are interface waves related to those studied in Chapter 52.[4] For example, when the waves are so short that they do not feel the rigid boundaries at $z = h_1$ and $z = -h_2$, then we can set $\coth(|\boldsymbol{k}| h_2) \approx 1$ and $\coth(|\boldsymbol{k}| h_1) \approx 1$, in which case the dispersion relation takes on the approximate form

$$\omega^2 \approx \frac{|\boldsymbol{k}| (g \delta\rho + \gamma |\boldsymbol{k}|^2)}{\rho_1 + \rho_2} \quad \text{shortwave limit with } |\boldsymbol{k}| h_1 \gg 1 \text{ and } |\boldsymbol{k}| h_2 \gg 1. \tag{60.31}$$

This limit (when surface tension is set to zero) corresponds to the deep water waves from Section 52.5.5. For the longwave limit, in which case the waves feel the top and bottom boundaries, we set $\coth(|\boldsymbol{k}| h_1) \approx 1/(|\boldsymbol{k}| h_1)$ and $\coth(|\boldsymbol{k}| h_2) \approx 1/(|\boldsymbol{k}| h_2)$ so that

$$\omega^2 \approx \frac{|\boldsymbol{k}|^2 g \delta\rho}{\rho_1/h_1 + \rho_2/h_2} \quad \text{longwave limit with } |\boldsymbol{k}| h_1 \ll 1 \text{ and } |\boldsymbol{k}| h_2 \ll 1. \tag{60.32}$$

Note that we dropped the surface tension term since $|\boldsymbol{k}|$ is very small in the longwave limit. Evidently, since $\omega^2/|\boldsymbol{k}|^2$ is independent of $\boldsymbol{k}$, the longwaves are non-dispersive gravity waves and are thus the analog of non-dispersive shallow water gravity waves studied in Section 55.5. The waves here are affected by a modified value for the gravitational acceleration, which we write as[5]

$$g^r H \equiv \frac{g \delta\rho}{\rho_1/h_1 + \rho_2/h_2} \quad \text{with} \quad H = h_1 + h_2. \tag{60.33}$$

By introducing this *reduced gravity*, g^r, the two-layer shallow water dispersion relation (60.32) takes the form

$$\omega^2 = (g^r H) |\boldsymbol{k}|^2. \tag{60.34}$$

Recall that the dispersion relation for a single shallow water layer (Section 55.5) is given by $\omega^2 = (g H) |\boldsymbol{k}|^2$. We thus see that long gravity waves on an interface between two fluid layers feels a reduced version of the gravitational acceleration, with $g^r \ll g$ when there is a small density difference. In fact, even the case of a single shallow water can be formulated as a two-layer system, with the upper layer having zero density so that the reduced gravity equals to g.

[4] More precisely, if we set $\rho_1 = 0$ as for a vacuum, then the waves are identical to the surface waves from Chapter 52.

[5] The reduced gravity in a shallow water model is defined (e.g., see equation (35.54)) without the layer thicknesses introduced in equation (60.33). A key difference is that in the present section we start with the non-hydrostatic equations and then take the longwave limit, whereas in Section 35.3.2 we only work with the hydrostatic shallow water equations.

60.2.3 Unstable exponentially growing plane waves

The case with $\omega^2 < 0$ leads to unstable wave growth. This case is rendered by $\delta\rho = \rho_2 - \rho_1 < 0$. That is, if there is heavy fluid above light fluid then the system can be unstable, depending on whether the gravitationally unstable stratification can overcome the stabilizing effects from surface tension. We now examine various cases to explore this unstable case, known as the *Rayleigh-Taylor instability.*

The growth rate

To express the temporal structure of the unstable wave, introduce the growth rate

$$\omega^2 = -\sigma^2 \Longrightarrow \omega = \pm \mathrm{i}\,\sigma, \tag{60.35}$$

where $\sigma > 0$ is given by

$$\sigma = \left[\frac{|\boldsymbol{k}| \left(g\,|\delta\rho| - \gamma\,|\boldsymbol{k}|^2 \right)}{\rho_2 \coth(|\boldsymbol{k}|\,h_2) + \rho_1 \coth(|\boldsymbol{k}|\,h_1)} \right]^{1/2} > 0. \tag{60.36}$$

We furthermore express the velocity potential (60.28a) and (60.28b) as the real part of complex exponentials. In particular, write for the top layer

$$\Psi_1 = A\,\Gamma(z)\ \mathrm{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)}] = A\,\Gamma(z)\,\mathrm{e}^{\pm\sigma\,t}\,\mathrm{Re}[\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}] = A\,\Gamma(z)\,\mathrm{e}^{\pm\sigma\,t}\cos(\boldsymbol{k}\cdot\boldsymbol{x}). \tag{60.37}$$

The solution with the time behavior, $\mathrm{e}^{\sigma\,t}$, is exponentially growing and this is the unstable wave.

All waves are unstable in the absence of surface tension

In the absence of surface tension, the growth rate is given by

$$\sigma = \left[\frac{g\,|\boldsymbol{k}|\,|\delta\rho|}{\rho_2 \coth(|\boldsymbol{k}|\,h_2) + \rho_1 \coth(|\boldsymbol{k}|\,h_1)} \right]^{1/2} \quad \text{if } \gamma = 0. \tag{60.38}$$

Evidently, all waves are unstable, with the smallest waves having the largest growth rate given approximately by

$$\sigma \approx \sqrt{g\,|\boldsymbol{k}|\,|\delta\rho|/(\rho_1 + \rho_2)} \quad \text{with } |\boldsymbol{k}|\,h_2 \gg 1 \text{ and } |\boldsymbol{k}|\,h_1 \gg 1. \tag{60.39}$$

We thus expect to find the smallest scales rapidly going unstable, with the instability halted only after all of the denser fluid occupies the lower layer.

The stabilizing role of surface tension

The growth rate (60.36) vanishes at the critical wavenumber

$$|\boldsymbol{k}|_{\mathrm{c}}^2 = g\,|\delta\rho|/\gamma. \tag{60.40}$$

All waves with wavenumbers larger than $|\boldsymbol{k}|_{\mathrm{c}}$ are stablized by surface tension, in which case the stable linear waves are capillary-gravity waves. We studied the physics of surface tension in Section 25.11, where we noted that it can counteract the effects from gravity when the radius of curvature is sufficiently small. To get a sense for the size of these stable waves, recall our discussion of capillary-gravity waves in Section 52.10. For an air-water interface the surface tension is approximately $\gamma = 0.072$ N m^{-1} $= 0.072$ kg s^{-2}, along with the air density $\rho_1 = 1$ kg m^{-3}, water density of $\rho_2 = 1020$ kg m^{-3}. With these physical constants the critical

wavenumber is given by

$$|\boldsymbol{k}|_{\mathrm{c}} \approx 372 \text{ m}^{-1} \Longrightarrow \Lambda_{\mathrm{c}} = 2\pi/|\boldsymbol{k}|_{\mathrm{c}} \approx 1.7 \text{ cm}. \tag{60.41}$$

Again, waves of wavelength smaller than Λ_{c} are stable.

Maximum growth rate with both surface tension and gravity

We saw above that all waves are unstable without surface tension, with the growth rate increasing as $|\boldsymbol{k}|^{1/2}$ as per equation (60.39). However, surface tension introduces a high wavenumber cutoff so that all waves with $|\boldsymbol{k}| > |\boldsymbol{k}|_{\mathrm{c}}^2$ are stable. Again, such waves are stablized since surface tension dominates over gravity when the radius of curvature is small enough. What is the most unstable wave when there is both surface tension and gravity? One might expect that in the presence of random forcing, this wavenumber will be the one most visibly growing in any particular situation.

To simplify the algebra for computing the most unstable wave, we consider the growth rate (60.36) in the limit that the two rigid boundaries separate to infinity. This limit is not overly constraining since the waves exponentially decay away from the interface, and we expect that the most unstable wavenumber is within an order of magnitude of $|\boldsymbol{k}|_{\mathrm{c}}$. With h_1, h_2 set to infinity the dispersion relation is given by

$$\sigma^2 = \frac{g\,|\delta\rho|\,|\boldsymbol{k}| - \gamma\,|\boldsymbol{k}|^3}{\rho_2 + \rho_1}. \tag{60.42}$$

The wavenumber leading to the maximum growth rate is found by setting $\partial\sigma^2/\partial|\boldsymbol{k}| = 0$, in which case

$$|\boldsymbol{k}|_{\mathrm{max}}^2 = g\,|\delta\rho|/(3\,\gamma) = |\boldsymbol{k}|_{\mathrm{c}}^2/3. \tag{60.43}$$

Using the numbers above for an air-water interface, we see that the wavelength for the most unstable wave is roughly $1.7 \text{ cm} * \sqrt{3} \approx 3$ cm.

60.2.4 Further study

The current section follows the approach from section 2 from *Fetter and Walecka* (2003), whereas chapter X of *Chandrasekhar* (1961) and chapter 2 of *Sutherland* (2010) provide more detailed presentations. The 18 minute mark of this video from Prof. Mollo-Christensen provides a laboratory example of Rayleigh-Taylor instability.

60.3 Kelvin-Helmholtz instability

Kelvin-Helmholtz instability arises when the two fluid layers in Figure 60.1 are moving horizontally relative to each other. In the following we assume the velocities are zonal and written $\hat{\boldsymbol{x}}\,U_1$ and $\hat{\boldsymbol{x}}\,U_2$. Furthermore, we assume the fluids are stably stratified so that $\delta\rho > 0$. Finally, to simplify the analysis, assume the rigid boundaries are moved to infinity so that the only boundary of concern is at the fluid interface.

60.3.1 Velocity potential

The velocity potential satisfying Laplace's equation in the two half spaces is given by

$$\Psi_1 = -U_1\,x + A_1\,\mathrm{e}^{-|\boldsymbol{k}|z}\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)} \qquad 0 \leq z < \infty \tag{60.44a}$$

$$\Psi_2 = -U_2\,x + A_2\,\mathrm{e}^{|\boldsymbol{k}|z}\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)} \qquad -\infty < z \leq 0. \tag{60.44b}$$

In contrast to the Rayleigh-Taylor instability, as given by equations (60.28a) and (60.28b), we here use complex exponentials, with the real part of each expression assumed. We also introduced two real amplitudes, A_1 and A_2. Both of these features proves of use in the following analysis. Furthermore, the nonzero background flow makes it less convenient to eliminate the interface height, so that we explicitly consider its wave ansatz in the form

$$\eta = \eta_\circ \, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}. \tag{60.45}$$

To develop a dispersion relation, we make use of the difference in the Bernoulli equation of motion when evaluated at the interface (equation (60.22)), as well as the kinematic and dynamic boundary conditions (60.20c)-(60.20f).

60.3.2 Dispersion relation from the interface conditions

Evaluating equation (60.22) at $z = 0$ for the waves (60.44a), (60.44b), and (60.45), leads to the following relation between the wave amplitudes

$$\mathrm{i}\,[\rho_2\,(-\omega + k_x\,U_2)\,A_2 - \rho_1\,(-\omega + k_x\,U_1)\,A_1] = (g\,\delta\rho + \gamma|\boldsymbol{k}|^2)\,\eta_\circ \tag{60.46}$$

Likewise, the linearized kinematic boundary conditions (60.20c) and (60.20d) render the relations

$$\mathrm{i}\,(-\omega + k_x\,U_1)\,\eta_\circ = |\boldsymbol{k}|\,A_1 \tag{60.47a}$$

$$\mathrm{i}\,(-\omega + k_x\,U_2)\,\eta_\circ = -|\boldsymbol{k}|\,A_2. \tag{60.47b}$$

Use of equations (60.47a) and (60.47b) in equation (60.46) leads to the dispersion relation

$$\rho_1\,(\omega - k_x\,U_1)^2 + \rho_2\,(\omega - k_x\,U_2)^2 = |\boldsymbol{k}|\,(g\,\delta\rho + \gamma|\boldsymbol{k}|^2). \tag{60.48}$$

We can readily check that this result agrees with that found for the Rayleigh-Taylor instability in equation (60.30). Expanding equation (60.48) and solving the quadratic expression leads to the more conventional form of the dispersion relation

$$\omega = \frac{k_x\,(U_1\,\rho_1 + U_2\,\rho_2)}{\rho_1 + \rho_2} \pm \sqrt{\frac{|\boldsymbol{k}|\,(g\,\delta\rho + \gamma\,|\boldsymbol{k}|^2)}{\rho_1 + \rho_2} - \frac{k_x^2\,\rho_1\,\rho_2\,(U_1 - U_2)^2}{(\rho_1 + \rho_2)^2}}. \tag{60.49}$$

We consider facets of this dispersion relation in the following.

60.3.3 Analysis of the stability condition

The angular frequency is a real number, and the flow is stable, so long as the discriminant in equation (60.49) is positive,

$$\frac{\rho_1\,\rho_2\,(U_1 - U_2)^2}{(\rho_1 + \rho_2)} < \frac{|\boldsymbol{k}|\,(g\,\delta\rho + \gamma\,|\boldsymbol{k}|^2)}{k_x^2} \quad \Longrightarrow \text{stable state}, \tag{60.50}$$

with the perturbations organizing into stable linear capillary-gravity waves modified by the background velocity. To help understand this stability condition, we find it useful to consider a few special cases. To reduce algebra, assume the wavevector is aligned in the $\hat{\boldsymbol{x}}$ direction so that $|\boldsymbol{k}|^2 = k_x^2$. Now write the stability condition (60.50) as a condition on the squared velocity difference, in which case

$$(U_1 - U_2)^2 < \frac{(\rho_1 + \rho_2)}{\rho_1\,\rho_2}\,(g\,\delta\rho/|\boldsymbol{k}| + \gamma\,|\boldsymbol{k}|) \quad \Longrightarrow \text{stable state}. \tag{60.51}$$

This equation says that the waves are stable so long as the squared velocity difference is insufficient to counteract the stabilizing effects from surface tension and gravity. Notice that the gravitational effects are weighted by the density difference, $\delta\rho = \rho_2 - \rho_1$, so that gravity plays no role when the densities are the same. In general, as the wave number increases (wavelength decreases), the effects from gravity acting to stabilize the waves become less important than those from surface tension, whereas the converse situation holds for low wavenumber waves (long wavelength). We illustrate these properties in Figure 60.2.

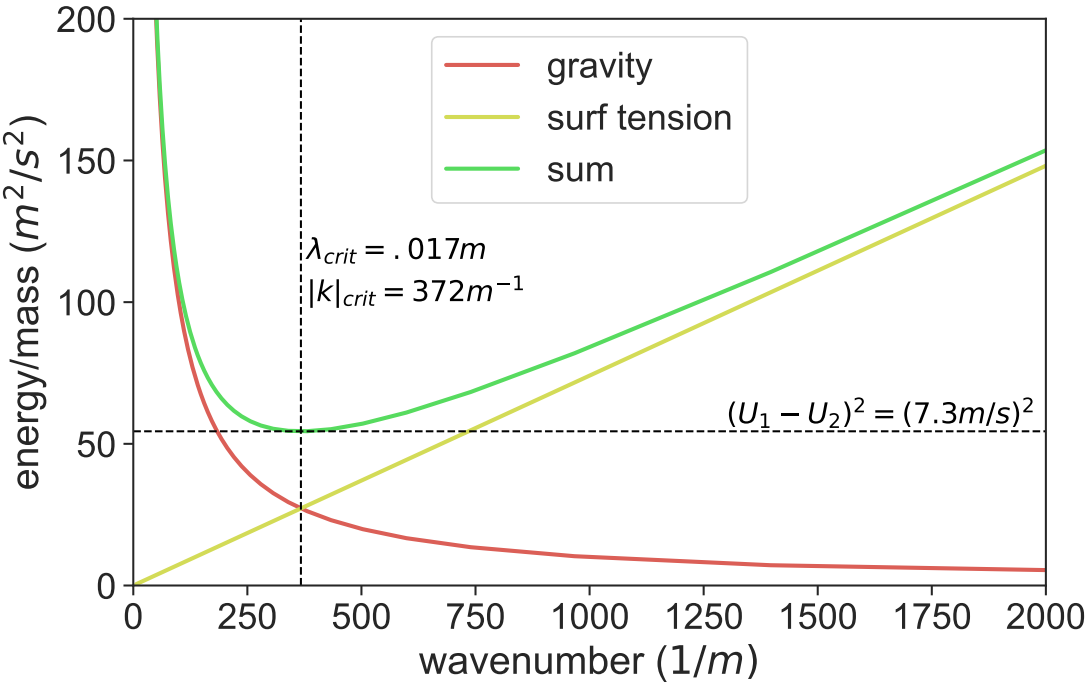

FIGURE 60.2: Stability diagram for Kelvin-Helmholtz instability of the interface between two constant density layers in a gravity field and with surface tension at the interface. The red curve arises from the gravity contribution to equation (60.51); the yellow curve is for the surface tension; and the green curve is the sum. If the squared velocity difference, $(U_1 - U_2)^2$, is above the green line then there are unstable waves whose wavenumbers are between the low and high wavenumber bounds defined by the green line. This figure is generated using the following numbers appropriate for the interface between the atmosphere (region 1) and ocean (region 2): $\rho_1 = 1$ kg m^{-3}, $\rho_2 = 1020$ kg m^{-3}, $g = 9.8$ m s^{-2}, $\gamma = 0.072$ kg s^{-2}. The critical wavenumber from equation (60.52) equals to $|\boldsymbol{k}|_c = \sqrt{g\,\delta\rho/\gamma} = 372$ m^{-1}, which corresponds to a critical wavelength $\lambda_{\text{crit}} = 2\pi/|\boldsymbol{k}|_c = 0.017$ m. As the velocity difference increases from zero, this is the first wave that goes unstable when the velocity difference reaches $U_1 - U_2 = 7.3$ m s^{-1} $= 26$ km hr^{-1}.

Most easily growing wave

The stability condition (60.51) indicates that that waves that are either small enough or large enough are stable, whereas waves of intermediate length are unstable in the presence of sufficient velocity difference (shear) across the interface. To find the wavenumber of the unstable wave that appears with the least amount of shear (e.g., minimum of the green curve in Figure 60.2), we find where the derivative, $\partial/\partial|\boldsymbol{k}|$, of the right hand of equation (60.51) vanishes, which leads to the critical squared wavenumber

$$|\boldsymbol{k}|_c^2 = g\,\delta\rho/\gamma, \tag{60.52}$$

which is the same as found for the Rayleigh-Taylor instability in Section 60.2.3. Evidently, when the wavenumber equals to $|\boldsymbol{k}|_c$, then the stability condition is most easily violated by the smallest squared shear, thus leading to exponential growth for this wave. Plugging in $|\boldsymbol{k}|_c$ to the stability

condition (60.51) leads to

$$(U_1 - U_2)^4_{\text{crit}} < \frac{4\,\gamma\,g\,(\rho_1+\rho_2)^2\,(\rho_2-\rho_1)}{\rho_1^2\,\rho_2^2} \quad \Longrightarrow \text{stable state.} \tag{60.53}$$

This expression shows how surface tension and gravity act together to help maintain stability in the face of a velocity difference. Yet if the velocity difference grows, eventually the inequality swaps sign so that the flow becomes unstable. Furthermore, the wavenumber $|\boldsymbol{k}|_{\text{c}}$ is the first wave to exponentially grow.

The case of vanishing surface tension

If the surface tension vanishes then equation (60.53) says that there are always unstable high wavenumber waves for an arbitrarily small velocity difference. More precisely, we return to the general condition (60.51) with $\gamma = 0$ to find

$$(U_1 - U_2)^2 < \frac{g\,(\rho_1+\rho_2)\,\delta\rho}{|\boldsymbol{k}|\,\rho_1\,\rho_2} \quad \Longrightarrow \text{stable state.} \tag{60.54}$$

Evidently, no matter how small the velocity difference, there are waves with high enough wavenumber that violate this inequality and thus lead to an instability. In Figure 60.2, the case with zero surface tension means that the green and red curves are identical, so that without the effects from surface tension, there is no high wavenumber cutoff for the instability.

The case of vanishing gravity

If we align the layers horizontally rather than vertically, then gravity is no longer able to enhance stability in the face of the velocity difference. Just like in the case with zero surface tension, there are always waves that go unstable in this case. However, the unstable waves here have arbitrarily low wavenumber, so that in the absence of gravity there is no low wavenumber cutoff.

Stability is enhanced when $\rho_1/\rho_2 \ll 1$

If the upper layer has a vanishingly small density relative to the lower layer, then the right hand side of the stability condition (60.51) becomes large. We say that this case is strongly stable since it takes a large velocity difference to produce an instability. A geophysically relevant example is air blowing over water with $\gamma = 0.072$ N m^{-1} $= 0.072$ kg s^{-2}, $\rho_2 = 1020$ kg m^{-3} and air density $\rho_1 = 1$ kg m^{-3}. Equation (60.53) says that the most unstable wave is stimulated with an air-sea velocity difference

$$U_1 - U_2 = 7.3 \text{ m s}^{-1} = 26 \text{ km hr}^{-1}. \tag{60.55}$$

These numbers are used to generate Figure 60.2.

60.3.4 Insights from vorticity

The vorticity vanishes everywhere in the fluid, except at the interface. At the interface the velocity jump leads to a Dirac delta *vortex sheet*. We compute the vorticity of the base state by writing the velocity in terms of Heaviside step functions (equation (7.19))

$$\boldsymbol{v} = \hat{\boldsymbol{x}}\,[U_1\,\mathcal{H}(z) + U_2\,\mathcal{H}(-z)] \tag{60.56}$$

so that the vorticity is given by

$$\hat{\boldsymbol{y}} \cdot \nabla \times \boldsymbol{v} = \partial_z [U_1 \, \mathcal{H}(z) + U_2 \, \mathcal{H}(-z)] = (U_1 - U_2) \, \delta(z), \tag{60.57}$$

with Figure 60.3 providing an illustration. The vortex sheet is a stationary equilibrium state since the flow felt by adjacent vortices exactly cancels. However, as shown in Figure 60.4, the vortex sheet is unstable to small perturbations. Indeed, in the absence of gravity or surface tension then any perturbation is unstable, which is the Kelvin-Helmholtz instability.

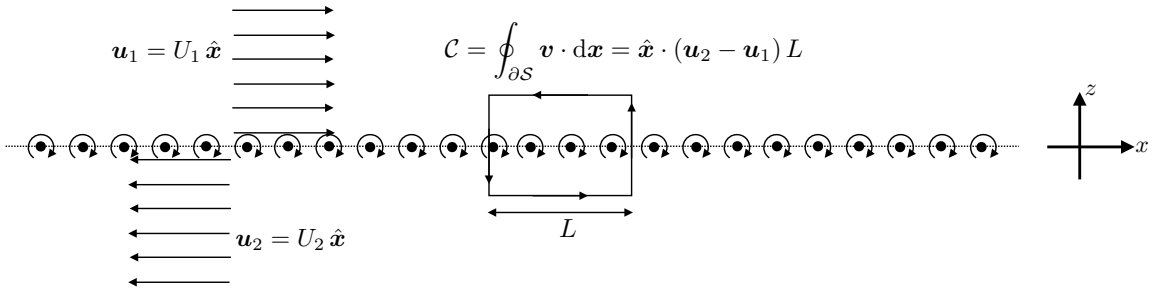

FIGURE 60.3: A vorticity perspective on the Kelvin-Helmholtz instability, whereby the velocity jump leads to a Dirac delta vorticity at the interface and a corresponding circulation for loops that enclose a portion of the sheet. Each circular arrow surrounding a black dot represents a point vortex induced by the velocity jump, with the $z = 0$ plane filled with a continuum of such point vortices. The circulation around the sheet is $\mathcal{C} = \hat{\boldsymbol{x}} \cdot (\boldsymbol{u}_2 - \boldsymbol{u}_1) \, L$, where L is the length of the side parallel to the sheet. This configuration is a stationary equilibrium since the flow felt by adjacent vortices exactly cancels so that they remain fixed. However, it is generally unstable, as shown in Figure 60.4.

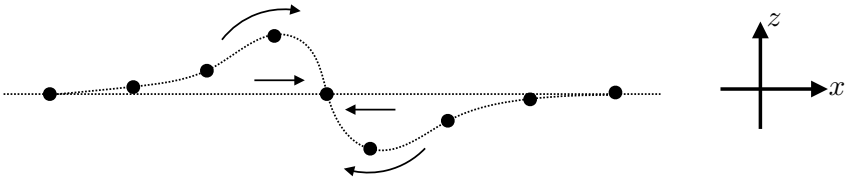

FIGURE 60.4: The equilibrium configuration from Figure 60.3 is unstable to small perturbations, and in the case of zero surface tension and zero gravity any perturbation is unstable. We understand the cause of the instability by observing that if a vortex is displaced away from the sheet, the flow from adjacent vortices and the background flow causes the sheet to roll-up on itself, which is the Kelvin-Helmholtz instability. This figure is a variant of Figure 7.1.3 of *Batchelor* (1967) (who provides full details of the vorticity interpretation of the Kelvin-Helmholtz instability), Figure 1.3 of *Drazin and Reid* (1981), and Figure 3.9 of *McWilliams* (2006).

60.3.5 Insights from Bernoulli's theorem

Figure 60.5 provides a schematic of the pressure forces active next to the interface in the presence of a wavelike perturbation. A wavelike perturbation along the interface gives rise, through Bernoulli's theorem, to pressure anomalies of opposite sign in the regions near to the interface.[6] In particular, consider the case of an interface that enters one of the two regions and so reduces the cross-sectional area for the fluid flow. The flow is incompressible, and so the flow speed increases in this region, with increased speed associated with an anomalously low pressure. The opposite occurs in the other region, where there is an anomalously high pressure. Evidently, the pressure dipoles increase the amplitude of the wavelike perturbation. If the pressure perturbation

[6] At the interface, the pressure has a jump given by the Young-Laplace equation (60.11). We are here interested in the region local to the boundary.

is sufficiently strong to overcome the stabilizing effects from gravity and surface tension, then the perturbation grows and becomes nonlinear, which is the Kelvin-Helmholtz instability.

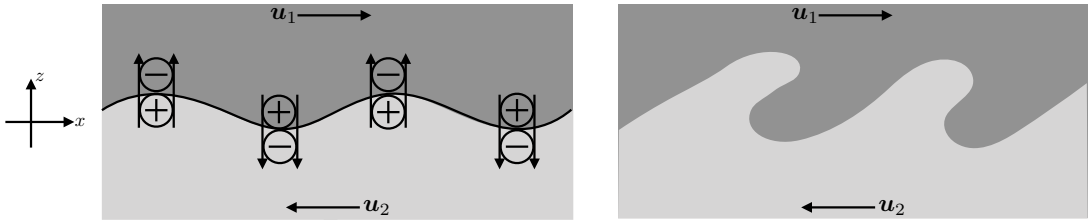

FIGURE 60.5: Schematic of a region near the interface between two uniform density and immiscible fluid regions with nonzero relative motion between the regions. The left panel shows a small wavelike perturbation along the interface that gives rise, through Bernoulli's theorem, to pressure anomalies of opposite signs in the regions on either side of the interface. Evidently, the pressure dipoles increase the amplitude of the wavelike perturbation, thus leading to a positive feedback. If the feedback is sufficiently strong to overcome the stabilizing effects from gravity and surface tension, then it will lead to the Kelvin-Helmholtz instability. The right panel shows the nonlinear stage in which the waves are growing and eventually break.

60.3.6 An energetic perspective on Kelvin-Helmholtz induced mixing

Kinetic energy of the background flow provides the energy source for the Kelvin-Helmholtz instability. Once the instability fully acts, it produces a well mixed state whereby the density and velocity are mixed within a region local to the initial interface. The kinetic energy of the final mixed state is less than the initial state, which we can infer since mixing removes the velocity jump across the interface; i.e., mixing smooths the velocity profile. Conversely, the gravitational potential energy is increased since some of the light fluid from the upper region is mixed with the heavy fluid from the lower region, and vice versa, thus raising the center of mass of the fluid column.[7]

A deductive analysis of the energetics of mixing is outside our scope. Indeed, without information about the pressure forces causing the base flow, we do not have sufficient information to perform an energy budget. However, we can study the energetic effects from mixing by making reasonable assumptions about the final flow profile, and in so doing we can quantitatively support the above inferences about the effects of mixing on kinetic energy and gravitational potential energy. For analytical tractability we assume the mixing region extends over the symmetric range, $-H \leq z \leq H$, with negligible signature of mixing outside of this range. Furthermore, we make use of the Boussinesq ocean from Chapter 29 with density a linear function of temperature and with a reference density ρ_o.

To estimate the thickness, H, of the mixing region, recall the expression (60.54) allows us to compute the low wavenumber cutoff for the case of Kelvin-Helmholtz instability in the absence of surface tension

$$|\boldsymbol{k}|_{\text{low}} = \frac{g\,(\rho_1 + \rho_2)\,\delta\rho}{\rho_1\,\rho_2\,(U_1 - U_2)^2}. \tag{60.58}$$

The unstable waves riding on the interface are exponentially decaying in the direction away from the interface, with their decay scale given by $|\boldsymbol{k}|$. Evidently, unstable Kelvin-Helmholtz waves extend a distance $\sim 1/|\boldsymbol{k}|_{\text{low}}$ away from the interface, thus suggesting that a scale for the associated mixing is given by

$$H \sim \frac{\rho_1\,\rho_2\,(U_1 - U_2)^2}{g\,(\rho_1 + \rho_2)\,\delta\rho} \approx \frac{\rho_o\,(U_1 - U_2)^2}{2\,g\,\delta\rho}, \tag{60.59}$$

[7] We studied this effect of mixing on gravitational potential energy in Section 26.2.6.

where the approximate expression made use of the oceanic Boussinesq approximation.

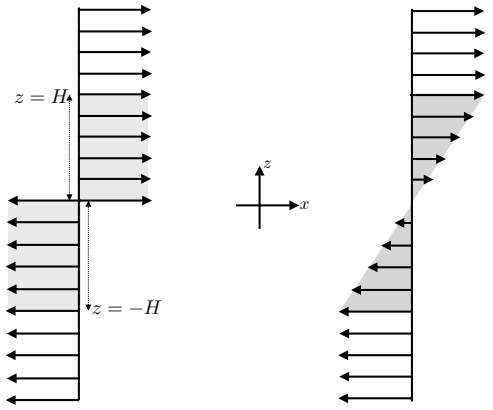

FIGURE 60.6: The initial velocity profile (left panel) for the study of Kelvin-Helmholtz instability, with $U_1 = U_2$. This profile is assumed to evolve to the linear profile (right panel) after mixing. The kinetic energy in the mixed profile is less than the kinetic energy in the initial profile. In turn, mixing raises the center of mass of the fluid so that it increases the gravitational potential energy. It is notable that the final state velocity profile shown here could be unstable to shear instability, as discussed in Chapter 61, in which case the shear instability will further act to homogenize the velocity and density.

The initial density and velocity profiles are given by the jump across the interface at $z = 0$, with the initial velocity and density having a depth integral of

$$\int_{-H}^{H} u \, \mathrm{d}z = H \, (U_1 + U_2) \quad \text{and} \quad \int_{-H}^{H} \rho \, \mathrm{d}z = H \, (\rho_1 + \rho_2). \tag{60.60}$$

We assume the final density and velocity profiles have a depth integral equal to those in the initial state, thus ensuring that zonal momentum and heat are conserved by the mixing. For simplicity, assume the final state profiles are linear, in which case (see Figure 60.6)

$$\overline{\rho}(z) = \rho_2 - (\rho_2 - \rho_1) \, (1 + z/H)/2 = (\rho_1 + \rho_2)/2 - z \, \delta\rho/(2\,H) \qquad \text{for } -H \le z \le H \tag{60.61a}$$

$$\overline{u}(z) = U_2 - (U_2 - U_1) \, (1 + z/H)/2 = (U_1 + U_2)/2 - z \, \delta U/(2\,H) \quad \text{for } -H \le z \le H. \tag{60.61b}$$

The depth integrated kinetic energy and gravitational potential energy per horizontal area

$$K = \frac{\rho_\circ}{2} \int_{-H}^{H} u^2 \, \mathrm{d}z \quad \text{and} \quad P = g \int_{-H}^{H} z \, \rho \, \mathrm{d}z, \tag{60.62}$$

take on the following initial values

$$K_{\text{init}} = \frac{\rho_\circ}{2} \int_{-H}^{H} u^2 \, \mathrm{d}z = H \, \rho_\circ \, (U_1^2 + U_2^2)/2 \tag{60.63a}$$

$$P_{\text{init}} = g \, \rho_2 \int_{-H}^{0} z \, \mathrm{d}z + g \, \rho_1 \int_{0}^{H} z \, \mathrm{d}z = -g \, H^2 \, \delta\rho/2. \tag{60.63b}$$

Use of the linear profiles (60.61a) and (60.61b) render the final mixed state energies

$$K_{\text{final}} = \frac{\rho_\circ}{2} \int_{-H}^{H} u^2 \, \mathrm{d}z = H \, \rho_\circ \left[U_1^2 + U_2^2 + U_1 \, U_2 \right] /3 \tag{60.64a}$$

$$P_{\text{final}} = g \int_{-H}^{H} \overline{\rho} \, z \, \mathrm{d}z = -g \, H^2 \, \delta\rho/6. \tag{60.64b}$$

As anticipated, we find that the kinetic energy is reduced upon mixing whereas the gravitational potential energy increases

$$K_{\text{final}} - K_{\text{init}} = -H\,\rho_\circ\,(U_1 - U_2)^2/6 < 0 \quad \text{and} \quad P_{\text{final}} - P_{\text{init}} = g\,H^2\,\delta\rho/3 > 0. \tag{60.65}$$

The ratio of the change in potential energy to the change in kinetic energy is

$$\frac{P_{\text{final}} - P_{\text{init}}}{K_{\text{final}} - K_{\text{init}}} = -\frac{2\,g}{\rho_\circ}\,\frac{\delta\rho/H}{[(U_1 - U_2)/H]^2}, \tag{60.66}$$

which is the ratio of the density stratification to the squared vertical shear. This ratio is a discrete version of the *gradient Richardson number* as discussed in Section 61.7.5. Indeed, in Section 61.7.5 we consider an energetic argument similar to that given here as applied to the final state linear sheared profile in Figure 60.6, which can be unstable to strataified shear instability if the Richardson number is less than 1/4.

60.3.7 Further study

Chapter XI of *Chandrasekhar* (1961) provides a detailed study of Kelvin-Helmholtz instability, with particular comments in Section 101b on the geophysical relevance of the critical shear. Section 2 of *Fetter and Walecka* (2003) also provides a presentation consistent with that gien here. The first half of this video from Prof. Mollo-Christensen provides laboratory examples of Kelvin-Helmholtz instabilities. This video from Prof. Worster's fluids lab provides a vivid illustration of Kelvin-Helmholtz instability in a two-layer fluid.

Chapter 61

SHEAR INSTABILITY

In this chapter we study *shear instability* as realized in two canonical cases. The first concerns a meridionally sheared zonal flow in a horizontally non-divergent barotropic fluid, with this instability sometimes called *barotropic instability*. We derive integral stability conditions for arbitrary zonal flow profiles, and then study a special flow profile that admits an analytic solution. The analytic study exposes the underlying *wave resonance* mechanism active in shear instability, with this mechanism involving the interaction of *edge waves* that live on the background vorticity field (Section 54.5). We thus interpret shear instability as the constructive interference of two vorticity (edge) waves, where interference supports the mutual exponential growth of both waves that is characteristic of a modal instability.

The second kind of shear instability concerns vertically sheared flows in a gravitationally stratified fluid ($N^2 > 0$) in the absence of planetary rotation ($f = 0$). The stable vertical stratification creates a potential energy barrier that stabilizes the vertically sheared flow relative to the horizontally sheared case without gravity. If the kinetic energy of the vertically sheared flow is large enough, then the potential energy barrier can be overcome to produce a shear instability. Our study of *stratified shear instability* makes use of normal mode stability analysis just like for the barotropic shear flow. The *gradient Richardson number* provides a non-dimensional measure of the potential energy relative to the kinetic energy, with a normal mode instability occuring if the Richardson number is below a critical value. We offer a derivation following *Miles* (1961) revealing that the critical Richardson number is 1/4.

READER'S GUIDE FOR THIS CHAPTER

Surface tension is ignored throughout this chapter, so that we focus on sheared flows of scales larger than the $\approx 10^{-3}$ m characteristic of capillary waves. To study horizontal shear instability, we assume familiarity with the horizontally non-divergent barotropic model from Chapter 38 and the associated wave mechanics in Sections 54.2 and 54.3. We make particular use of edge waves studied in Section 54.5 as part of our wave resonance interpretatation of shear instability. For our study of stratified shear instability, we make use of the perfect Boussinesq fluid from Chapter 29. In linearizing the equations we follow many of the same steps used for the study of internal gravity waves in Chapter 57. The linear partial differential equation appearing in the stability analysis is known as the *Taylor-Goldstein* equation, which is very similar to the *Rayleigh* equation encountered in the barotropic shear instability. Methods and concepts from this chapter are very useful in the study of baroclinic instability in Chapter 62.

Kelvin and Helmholtz studied the interfacial instability described in Chapter 60. Even so, the continuous shear layer instability of the present chapter is also, sometimes, referred to as Kelvin-Helmholtz instability.

61.1 Loose threads

- Discuss Couette flow stability in Section 61.5.1 even though it satisfies the Rayleigh inflection point theorem.

- Look at the pressure field in the waves to offer a force balance interpretation of the instabilties. Also, to help understand why unstable waves tilt into the shear.

61.2 Global versus local instabilities

The wave/modal interpretation of shear instability that we pursue in this chapter contrasts to the variety of symmetric instabilities studied in Chapter 59. In particular, symmetric stablility of a given flow can be deduced by the local necessary and sufficient condition, $f\,Q < 0$, with Q the Ertel potential vorticity. A corresponding mechanistic interpretation follows from parcel arguments. As emphasized by *Cushman-Roisin and Beckers* (2011) (see their Chapter 17), wave instabilities, such as shear instability of this chapter, are not characterized by a local flow property. The reason is that a wave instability arises from the constructive interaction between coherent wave motion, with that interaction a function of boundary conditions and phase relations. Hence, a quantitative understanding of shear instability requires the solution of an eigenvalue problem to determine properties of the interacting waves.

Squire's theorem (*Squire*, 1933) states that for every three-dimensional perturbation to a plane shear flow, there exists a more unstable two-dimensional perturbation.[1] Hence, to characterize the most unstable perturbations, it is sufficient to study shear instability in a two-dimensional flow. Even so, as presented in Chapter 3 of *Smyth and Carpenter* (2019), it can be pedagogically useful to start from the more general three-dimensional case and then show the validity of Squire's theorem.

61.3 Governing barotropic equations

As in the study of edge waves in Section 54.5, we here consider flow of a horizontally non-divergent barotropic fluid in the presence of a prescribed background zonal flow that is a function of latitude

$$\boldsymbol{u}_{\mathrm{b}} = u_{\mathrm{b}}(y)\,\hat{\boldsymbol{x}}. \tag{61.1}$$

This background velocity has zero material acceleration

$$(\partial_t + \boldsymbol{u}_{\mathrm{b}} \cdot \nabla)\boldsymbol{u}_{\mathrm{b}} = 0, \tag{61.2}$$

so that it is in exact geostrophic balance with a background pressure gradient

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{b}} = -\nabla\varphi_{\mathrm{b}} \implies f\,u_{\mathrm{b}} = -\partial_y\varphi_{\mathrm{b}}. \tag{61.3}$$

Much of this chapter (e.g., the linearized equations with a modulated wave ansatz in Section 61.4 and the interacting edge waves in Section 61.6) considers the case of a non-rotating reference frame ($f = 0$), in which case the background flow is generated by an unspecified pressure gradient. In other sections we retain planetary rotation in the form of the β plane, such as for the integral stability conditions of Section 61.5. In the remainder of this section we develop the equations describing the velocity and the kinetic energy of fluid flow in the presence of the prescribed zonal background flow, and with details for generation of the background flow left unspecified.

61.3.1 Velocity equation

Writing the velocity and pressure as the sum of a background plus a fluctuation

$$\boldsymbol{u} = \boldsymbol{u}_{\mathrm{b}} + \boldsymbol{u}' \quad \text{and} \quad \varphi = \varphi_{\mathrm{b}} + \varphi', \tag{61.4}$$

[1] See *Drazin and Reid* (2004) or Section 11.8 of *Kundu et al.* (2016) for more details of Squire's theorem. We illustrate Squre's theorem in Section 62.7.3 when studying the growth rate of unstable Eady edge waves.

leads to the material acceleration

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = (\partial_t + \boldsymbol{u}\cdot\nabla)\boldsymbol{u} = (\partial_t + \boldsymbol{u}'\cdot\nabla)\boldsymbol{u}' + (\boldsymbol{u}'\cdot\nabla)\boldsymbol{u}_\mathrm{b} + (\boldsymbol{u}_\mathrm{b}\cdot\nabla)\boldsymbol{u}', \tag{61.5}$$

and the corresponding equation of motion

$$(\partial_t + \boldsymbol{u}'\cdot\nabla)\boldsymbol{u}' + (\boldsymbol{u}'\cdot\nabla)\boldsymbol{u}_\mathrm{b} + (\boldsymbol{u}_\mathrm{b}\cdot\nabla)\boldsymbol{u}' + f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}' = -\nabla\varphi', \tag{61.6}$$

which takes on the linearized form with the given background flow (61.1)

$$(\partial_t + u_\mathrm{b}\,\partial_x)\boldsymbol{u}' + \hat{\boldsymbol{x}}\,v'\,\partial_y u_\mathrm{b} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}' = -\nabla\varphi'. \tag{61.7}$$

61.3.2 Eddy kinetic energy

As detailed in Section 38.1.2, energetic transfers in the horizontally non-divergent barotropic fluid only involve the kinetic energy since the gravitational potential energy is a constant. Working with the linearized equation of motion (61.7), we find that the kinetic energy per mass contained in the fluctuating flow, $\boldsymbol{u}'\cdot\boldsymbol{u}'/2$, satisfies

$$[\partial_t + u_\mathrm{b}\,\partial_x](\boldsymbol{u}'\cdot\boldsymbol{u}')/2 = -u'\,v'\,\partial_y u_\mathrm{b} - \nabla\cdot(\boldsymbol{u}'\,\varphi). \tag{61.8}$$

We commonly refer to $\boldsymbol{u}'\cdot\boldsymbol{u}'/2$ as the *eddy kinetic energy*. The first term on the right hand side of equation (61.8) arises from fluctuations of the zonal and meridional velocity weighted by the meridional derivative of the background zonal flow. This term is associated with the transfer of kinetic energy from the background flow to the fluctuating flow.[2] The second term is the convergence of the pressure flux that is determined by the fluctuating flow. Taking a zonal average over the domain, and assuming all zonal boundary contributions vanish, leads to

$$\partial_t\overline{\mathcal{K}} = -\overline{u'\,v'}\,\partial_y u_\mathrm{b} - \partial_y(\overline{v'\,\varphi'}), \tag{61.9}$$

where we defined the zonal averaged eddy kinetic energy in the fluctuating fields

$$\overline{\mathcal{K}} = \overline{\boldsymbol{u}'\cdot\boldsymbol{u}'}/2. \tag{61.10}$$

Evidently, equation (61.9) says that the zonal averaged kinetic energy of the fluctuating fields has an Eulerian time derivative determined by the following two terms:

$$-\partial_y(\overline{v'\,\varphi'}) = \text{meridional convergence of pressure flux} \tag{61.11a}$$

$$-\overline{u'\,v'}\,\partial_y u_\mathrm{b} = \text{shear production}. \tag{61.11b}$$

We assume that the pressure convergence term vanishes when integrated over the meridional extent of the domain (e.g., $v' = 0$ along the meridional boundaries), in which case it represents a redistribution or transport that moves eddy kinetic energy around but does not alter its domain integrated value. In contrast, the shear production term is a source/sink that measures the rate that eddy kinetic energy is modified via the zonal correlations between u' and v' and as modulated by the meridional gradient of the background flow. As noted above, this term provides a transfer of kinetic energy between the mean flow and the fluctuating flow. It is expected that this term provides the source of the growing kinetic energy of an unstable wave. Note that its name arises since it is a nonzero production of kinetic energy in the presence of a background shear.

[2] Note that we do not have access to the energy equation for the background flow since it is prescribed and remains static.

We can interpret the shear production term as the meridional flux of zonal momentum contained in the fluctuating field. Evidently, kinetic energy in the fluctuating fields increases if this flux is down the gradient of the background meridional shear

$$\overline{v'\,u'}\,\partial_y u_\mathsf{b} < 0 \quad \text{growing kinetic energy of fluctuations.} \tag{61.12}$$

Such downgradient transport by the growing fluctuations acts in a direction that smooths the meridional shear of the backgound zonal flow.

61.3.3 Pressure equation

Taking the divergence of the linearized velocity equation (61.7), and noting that $\nabla \cdot \boldsymbol{u}' = 0$, leads to the Poisson equation for pressure

$$-\nabla^2 \varphi' = 2\,(\partial_y u_\mathsf{b})\,(\partial_x v') + \beta\,u' - f\,\zeta', \tag{61.13}$$

where we introduced the relative vorticity contained in the fluctuating field (i.e., the eddy vorticity)

$$\zeta' = \partial_x v' - \partial_y u'. \tag{61.14}$$

The analysis of interacting edge waves in Section 61.6 is formulated in a non-rotating reference frame, in which the pressure equation simplifies to

$$-\nabla^2 \varphi' = 2\,(\partial_y u_\mathsf{b})\,(\partial_x v'). \tag{61.15}$$

61.3.4 Meridional velocity equation

The meridional component of the linearized velocity equation (61.7) is given by

$$\partial_t v' + u_\mathsf{b}\,\partial_x v' + f\,u' = -\partial_y \varphi'. \tag{61.16}$$

Setting $f = 0$ and taking the Laplacian leads to

$$\partial_t(\nabla^2 v') + \nabla^2(u_\mathsf{b}\,\partial_x v') = -\partial_y(\nabla^2 \varphi'). \tag{61.17}$$

Use of the pressure equation (61.15) then provides an equation for the meridional velocity

$$(\partial_t + u_\mathsf{b}\,\partial_x)(\nabla^2 v') = (\partial_x v')\,\partial_{yy} u_\mathsf{b}. \tag{61.18}$$

Evidently, the background zonal flow provides an advection of $\nabla^2 v'$ as well as an interaction term on the right hand side.

61.4 Barotropic flow with a modulated wave ansatz

We here study a modulated wave ansatz for a non-rotating reference frame using the linearized flow in the presence of a background state with a meridionally sheared zonal flow. Following the development in Section 54.5, we expect plane traveling waves in the zonal direction, with a meridionally dependent modulation function. This expectation leads to the ansatz for the streamfunction

$$\psi(x, y, t) = \widetilde{\psi}(y)\,\mathrm{e}^{\mathrm{i}\,(k\,x - \omega\,t)}. \tag{61.19}$$

61.4.1 Accounting for the edge wave direction

An edge wave can move in either the positive or negative $\hat{\boldsymbol{x}}$ direction, so that the wavevector is

$$\boldsymbol{k} = |\boldsymbol{k}|\,\hat{\boldsymbol{k}} = |k|\,\hat{\boldsymbol{k}} = \pm|k|\,\hat{\boldsymbol{x}}. \tag{61.20}$$

A convenient means to incorporate the two directions of motion is to write the phase as

$$k\,x - \omega\,t = k\,[x - (\omega/k)\,t] = k\,(x - c\,t), \tag{61.21}$$

where the phase velocity is[3]

$$\boldsymbol{c}_{\mathsf{p}} = (\omega/|k|)\,\hat{\boldsymbol{k}} = (\omega/k)\,\hat{\boldsymbol{x}} = c\,\hat{\boldsymbol{x}}. \tag{61.22}$$

For the geometry of this problem, an edge wave only moves along one-dimension, in which case it is sufficient to refer to $c = \omega/k$ as the phase velocity and $|c| = \omega/|k|$ the phase speed.[4] A real and positive wave velocity, $c > 0$, has $\boldsymbol{k} = k\,\hat{\boldsymbol{x}}$ with $k > 0$, thus indicating a stable edge wave with phase moving in the $+\hat{\boldsymbol{x}}$ direction. Conversely, $c < 0$ has $\boldsymbol{k} = k\,\hat{\boldsymbol{x}} = -|k|\,\hat{\boldsymbol{x}}$ with $k < 0$, thus indicating a stable edge wave with phase moving in the $-\hat{\boldsymbol{x}}$ direction.

61.4.2 Polarization relations

The horizontal velocity components are computed from the streamfunction via

$$\psi = \widetilde{\psi}\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)} \tag{61.23a}$$

$$\boldsymbol{u}' = \hat{\boldsymbol{z}} \times \nabla\psi = \mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)}\,(-\hat{\boldsymbol{x}}\,\partial_y + \hat{\boldsymbol{y}}\,\mathrm{i}\,k)\widetilde{\psi} \tag{61.23b}$$

$$u' = (\mathrm{i}/k)\,\partial_y v' = -\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)}\,\partial_y\widetilde{\psi} \tag{61.23c}$$

$$v' = \mathrm{i}\,k\,\psi = \mathrm{i}\,k\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)}\,\widetilde{\psi}. \tag{61.23d}$$

As a check we confirm that the horizontal velocity is non-divergent

$$\partial_x u' + \partial_y v' = \mathrm{i}\,k\,\partial_y\widetilde{\psi}\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)}\,(-1+1) = 0. \tag{61.24}$$

To get the pressure perturbation, return to the zonal component of the velocity equation (61.7) (with $f = 0$)

$$(\partial_t + u_{\mathsf{b}}\,\partial_x)u' + v'\,\partial_y u_{\mathsf{b}} = -\partial_x\varphi', \tag{61.25}$$

and make the ansatz

$$\varphi' = \widetilde{\varphi}(y)\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)}. \tag{61.26}$$

Use of this pressure ansatz along with the horizontal velocity equations (61.23c) and (61.23d), yields the pressure amplitude in terms of the streamfunction amplitude

$$\widetilde{\varphi} = [(u_{\mathsf{b}} - c)\,\partial_y - \partial_y u_{\mathsf{b}}]\widetilde{\psi}. \tag{61.27}$$

In summary, the amplitude equations (polarization relations) for the horizontal velocity components and the pressure are given, in terms of the streamfunction, by

$$\psi = \widetilde{\psi}(y)\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)} \tag{61.28a}$$

$$u' = \widetilde{u}(y)\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)} \quad \text{and} \quad v' = \widetilde{v}(y)\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)} \quad \text{and} \quad \varphi' = \widetilde{\varphi}(y)\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)} \tag{61.28b}$$

[3] Remember that for a stable wave, $\omega \geq 0$ in this book (see Section 49.2.3).

[4] Many books refer to c as the phase speed, even though c can be positive or negative. However, as emphasized in Section 49.5.2, the phase speed is the non-negative magnitude of the phase velocity.

$$\widetilde{u} = -\partial_y \widetilde{\psi} \qquad \text{and} \quad \widetilde{v} = \mathrm{i}\, k\, \widetilde{\psi} \qquad \text{and} \quad \widetilde{\varphi} = [(u_\mathrm{b} - c)\, \partial_y - \partial_y u_\mathrm{b}]\widetilde{\psi}. \tag{61.28c}$$

61.4.3 Complex phase velocity

To investigate shear instability, we are interested in flow properties that lead to the phase velocity, c, having an imaginary part, in which case

$$c = c_\mathrm{r} + \mathrm{i}\, c_\mathrm{i} = c_\mathrm{r} + \mathrm{i}\, \sigma/k. \tag{61.29}$$

In this case, it is the real part, c_r, that is the phase velocity whereas c_i measures the decay rate or growth rate for the wave amplitude

$$\psi(x, y, t) = \widetilde{\psi}(y)\, \mathrm{e}^{\mathrm{i}\, k\, (x - c_\mathrm{r}\, t)}\, \mathrm{e}^{k\, c_\mathrm{i}\, t} = \widetilde{\psi}(y)\, \mathrm{e}^{\mathrm{i}\, k\, (x - c_\mathrm{r}\, t)}\, \mathrm{e}^{\sigma\, t}. \tag{61.30}$$

If $c_\mathrm{i} > 0$ then the wave is exponentially unstable with *growth rate*,

$$\sigma = k\, c_\mathrm{i}, \tag{61.31}$$

whereas if $\sigma < 0$ then the wave exponentially decays.

As we see in Section 61.4.4, if c is complex then it appears along with its complex conjugate, so that the exponentially growing mode and the decaying mode appear as a pair. Furthermore, note that the complex conjugate of the streamfunction (61.30) is given by

$$\psi^* = \widetilde{\psi}^*(y)\, \mathrm{e}^{-\mathrm{i}\, k\, (x - c_\mathrm{r}\, t)}\, \mathrm{e}^{\sigma\, t}, \tag{61.32}$$

so that

$$|\psi|^2 = \psi^*\, \psi = |\widetilde{\psi}|^2\, \mathrm{e}^{2\, \sigma\, t}, \tag{61.33}$$

along with the analogs for the horizontal velocity components

$$|u'|^2 = u'\, (u')^* = |\partial_y \widetilde{\psi}|^2\, \mathrm{e}^{2\, \sigma\, t} \quad \text{and} \quad |v'|^2 = v'\, (v')^* = k^2\, |\widetilde{\psi}|^2\, \mathrm{e}^{2\, \sigma\, t}. \tag{61.34}$$

These identities are used when developing the phase averaged kinetic energy budget in Section 61.4.6.

61.4.4 Rayleigh-Kuo equation for the streamfunction

Inserting the modulated wave ansatz (61.19) into the linearized vorticity equation (54.82) leads to the *Rayleigh equation*

$$(u_\mathrm{b} - c)\, (\partial_{yy} - k^2)\, \widetilde{\psi} + \partial_y \zeta_\mathrm{b}\, \widetilde{\psi} = 0. \tag{61.35}$$

Or, in the presence of $\beta \neq 0$ we find the Rayleigh-Kuo equation (54.84)

$$(u_\mathrm{b} - c)\, (\partial_{yy} - k^2)\, \widetilde{\psi} + (\beta + \partial_y \zeta_\mathrm{b})\, \widetilde{\psi} = 0. \tag{61.36}$$

For a study of instabilities, the phase velocity, $c = \omega/k$, and the streamfunction, $\widetilde{\psi}$, are generally complex, whereas all other terms are real. Hence, the complex conjugate of the Rayleigh-Kuo equation (61.36) is given by

$$(u_\mathrm{b} - c^*)\, (\partial_{yy} - k^2)\, \widetilde{\psi}^* + (\beta + \partial_y \zeta_\mathrm{b})\, \widetilde{\psi}^* = 0. \tag{61.37}$$

Evidently, if c satisfies the Rayleigh-Kuo equation (61.36) with streamfunction $\widetilde{\psi}$, then c^* satisfies the complex conjugate equation (61.37) with streamfunction $\widetilde{\psi}^*$. Hence, the phase velocities come in complex conjugate pairs.

61.4.5 Rayleigh-Kuo equation for the meridional displacement

Let $\xi(x,y,t)$ be the meridional component of the fluid particle displacement from its equilibrium position. This particle displacement satisfies the evolution equation

$$v' = (\partial_t + u\,\partial_x)\xi = [\partial_t + (u' + u_\text{b})\,\partial_x]\xi. \tag{61.38}$$

Linearizing for small amplitude displacements leads to

$$v' = (\partial_t + u_\text{b}\,\partial_x)\xi, \tag{61.39}$$

with the usual ansatz,

$$\xi = \widetilde{\xi}(y)\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)}, \tag{61.40}$$

yielding

$$\widetilde{\psi} = (u_\text{b} - c)\,\widetilde{\xi}. \tag{61.41}$$

Evidently, for small amplitude motion, the streamfunction amplitude, $\widetilde{\psi}$, equals to the meridional particle excursion amplitude, $\widetilde{\xi}$, multiplied by the difference between the phase velocity and the background flow, $u_\text{b} - c$.

With the relation (61.41), we can convert the Rayleigh equation (61.35) for the streamfunction into an equation for the meridional particle excursion. For this purpose make use of the derivative

$$\partial_{yy}\widetilde{\psi} = \widetilde{\xi}\,\partial_{yy}u_\text{b} + 2\,\partial_y\widetilde{\xi}\,\partial_y u_\text{b} + (u_\text{b} - c)\,\partial_{yy}\widetilde{\xi}, \tag{61.42}$$

along with a few lines of algebra to derive the Rayleigh-Kuo equation in terms of the meridional excursion

$$\partial_y[(u_\text{b} - c)^2\,\partial_y\widetilde{\xi}] = (u_\text{b} - c)\,[-\beta + k^2\,(u_\text{b} - c)]\,\widetilde{\xi}. \tag{61.43}$$

We make use of equation (61.43) in Section 61.5.3 to derive a condition required for a modal perturbation to initiate an instability.

61.4.6 Phase and zonal averaged eddy kinetic energy equation

In Section 61.3.2 we developed the equation for the kinetic energy of the fluctuating field and took its zonal average to find

$$\partial_t(\overline{u'\,u' + v'\,v'})/2 = -\overline{u'\,v'}\,\partial_y u_\text{b} - \partial_y(\overline{v'\,\varphi'}). \tag{61.44}$$

Following the methods of complex variables and phase averaging as detailed in Section 8.1, use of the polarization relations from Section 61.4.2, and recognition that the phase velocity is generally complex according to equations (61.33) and (61.34), lead to[5]

$$2\,\langle\overline{u'\,u'}\rangle = |\partial_y\widetilde{\psi}|^2\,\mathrm{e}^{2\,\sigma\,t} \tag{61.45a}$$

$$2\,\langle\overline{v'\,v'}\rangle = k^2\,|\widetilde{\psi}|^2\,\mathrm{e}^{2\,\sigma\,t} \tag{61.45b}$$

$$2\,\langle\overline{u'\,v'}\rangle = k\,\mathrm{Re}[\mathrm{i}\,\widetilde{\psi}^*\,\partial_y\widetilde{\psi}]\,\mathrm{e}^{2\,\sigma\,t} = -k\,\mathrm{Im}[\widetilde{\psi}^*\,\partial_y\widetilde{\psi}]\,\mathrm{e}^{2\,\sigma\,t} = k\,\mathrm{Im}[\widetilde{\psi}\,\partial_y\widetilde{\psi}^*]\,\mathrm{e}^{2\,\sigma\,t}, \tag{61.45c}$$

along with the phase average of the meridional velocity and pressure

$$2\,\mathrm{e}^{-2\,\sigma\,t}\,\langle\overline{v'\,\varphi'}\rangle = k\,\mathrm{Re}[\mathrm{i}\,\widetilde{\psi}\,\widetilde{\varphi}^*] \tag{61.46a}$$

$$= -k\,\mathrm{Im}[\widetilde{\psi}\,\widetilde{\varphi}^*] \tag{61.46b}$$

$$= -k\,\mathrm{Im}[(u_\text{b} - c)\,\widetilde{\psi}\,\partial_y\widetilde{\psi}^* - \partial_y u_\text{b}\,|\widetilde{\psi}|^2] \tag{61.46c}$$

[5]Exercise 61.1 derives the identity $\mathrm{Im}\left[\widetilde{\psi}^*\,\partial_y\widetilde{\psi}\right] = -\,\mathrm{Im}\left[\widetilde{\psi}\,\partial_y\widetilde{\psi}^*\right]$ used in equation (61.45c).

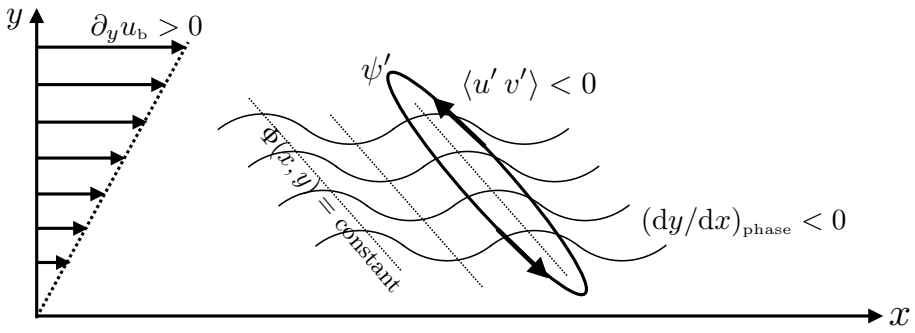

FIGURE 61.1: The lines of constant phase, $\Phi(x, y) = k\, x - \alpha(y)$, for the streamfunction (or the meridional velocity) in an unstable barotropic wave. The wave depicted here has an increasing kinetic energy since the phase lines are tilted into the shear. That is, this orientation of the wave ensures that the barotropic shear production increases the kinetic energy of the wave as per equation (61.56). Namely, since the waves are transverse, fluid particles move on constant phase lines, with the tilt shown here ensuring that $\langle u'\, v' \rangle < 0$. That is, a meridionally positive particle motion corresponds to a zonally negative motion, and vice versa. This behavior is characteristic of unstable waves whose kinetic energy grows by feeding off the unstable background shear state. Observe that if one placed a passive tracer in the flow, or an array of fluid particles, then they would be stretched to align with the shear rather than against the shear. The growing wave, however, is an active flow feature, with the present analysis indicating that energy growth for this feature requires phase lines to tilt into the shear as depicted here.

$$= -k\, \mathrm{Im}[(u_\flat - c)\, \widetilde{\psi}\, \partial_y \widetilde{\psi}^*], \tag{61.46d}$$

where we used $\mathrm{Im}[\partial_y u_\flat\, |\widetilde{\psi}|^2] = 0$ for the final equality. Bringing terms together leads to the phase and zonal averaged eddy kinetic energy budget

$$2\,\sigma \left[|\partial_y \widetilde{\psi}|^2 + k^2\, |\widetilde{\psi}|^2 \right] /2 = \underbrace{-k\, \partial_y u_\flat\, \mathrm{Im}\left[\widetilde{\psi}\, \partial_y \widetilde{\psi}^* \right] /2}_{\text{shear production}} + \underbrace{k\, \partial_y\, \mathrm{Im}\left[(u_\flat - c)\, \widetilde{\psi}\, \partial_y \widetilde{\psi}^* \right] /2}_{\text{KE flux convergence}}, \tag{61.47}$$

where we recognize $\sigma/k = c_\mathrm{i}$ according to equation (61.29).

61.4.7 Phase lines of unstable waves tilt into the shear

As noted in Section 61.3.2, the only way for the globally integrated kinetic energy to grow is through the shear production term, since the globally integrated pressure flux convergence vanishes. A sufficient, though not necessary, condition for global kinetic energy growth is that the shear production is positive at each point within the fluid domain. From equation (61.47) we thus have

$$k\, \partial_y u_\flat\, \mathrm{Im}\left[\widetilde{\psi}^*\, \partial_y \widetilde{\psi} \right] > 0 \Longrightarrow \text{sufficient condition for kinetic energy growth.} \tag{61.48}$$

If the kinetic energy growth arises from shear instability, then equation (61.48) offers a sufficient condition for shear instability.

To develop a geometric view for the energy growth condition (61.48), introduce the phase, $\alpha(y)$, of the streamfunction via

$$\widetilde{\psi}(y) = |\widetilde{\psi}(y)|\, \mathrm{e}^{\mathrm{i}\,\alpha(y)}, \tag{61.49}$$

so that

$$\mathrm{Im}\left[\widetilde{\psi}^*\, \partial_y \widetilde{\psi} \right] = \mathrm{Im}\left[|\widetilde{\psi}|\, \mathrm{e}^{-\mathrm{i}\,\alpha(y)}\, (\partial_y |\widetilde{\psi}| + \mathrm{i}\, |\widetilde{\psi}|\, \partial_y \alpha)\, \mathrm{e}^{\mathrm{i}\,\alpha(y)} \right] = |\widetilde{\psi}|^2\, \partial_y \alpha, \tag{61.50}$$

thus bringing the sufficient condition (61.48) to the form

$$k\, \partial_y u_\flat |\widetilde{\psi}|^2\, \partial_y \alpha > 0 \Longrightarrow \text{sufficient condition for energy growth.} \tag{61.51}$$

Now write the full streamfunction as

$$\psi = \widetilde{\psi}(y)\, \mathrm{e}^{\mathrm{i}\, k\, (x - c\, t)} = |\widetilde{\psi}(y)|\, \mathrm{e}^{\mathrm{i}\, \alpha(y)}\, \mathrm{e}^{\mathrm{i}\, (k\, x - c\, t)} = |\widetilde{\psi}(y)|\, \mathrm{e}^{\mathrm{i}\, (\Phi(x,y) - c\, t)}, \tag{61.52}$$

where we defined the spatial phase function

$$\Phi(x, y) \equiv k\, x + \alpha(y). \tag{61.53}$$

Lines of constant phase are defined by

$$\mathrm{d}\Phi = 0 = k\, \mathrm{d}x + (\partial_y \alpha)\, \mathrm{d}y \implies (\mathrm{d}y/\mathrm{d}x)_{\text{phase}} = -k/\partial_y \alpha, \tag{61.54}$$

so that the instability condition (61.48) can be written

$$k\, \partial_y u_{\mathsf{b}}\, |\widetilde{\psi}|^2\, \partial_y \alpha = -k^2\, |\widetilde{\psi}|^2 \frac{\partial_y u_{\mathsf{b}}}{(\mathrm{d}y/\mathrm{d}x)_{\text{phase}}} > 0 \implies \text{sufficient condition for energy growth.} \tag{61.55}$$

Simplifying this equation leads to the condition for the ratio of the shear and the phase slope

$$\frac{\partial_y u_{\mathsf{b}}}{(\mathrm{d}y/\mathrm{d}x)_{\text{phase}}} < 0 \implies \text{sufficient condition for energy growth.} \tag{61.56}$$

This inequality says that kinetic energy of the wave grows when the wave's phase lines tilt into the background flow shear, such as depicted in Figure 61.1. The tilted phase lines reflect the ability of the wave to extract kinetic energy from the background state. This geometric property offers a visual indicator that the wave is acting on an unstable shear state, thus providing a valuable diagnostic tool for identifying shear instabilities as they are happening.

61.5 Integral conditions necessary for shear instability

In this section we develop integral conditions for stability of an inviscid horizontally sheared fluid on a β plane, with the conditions arrived at by forming spatial integrals of the Rayleigh equation (61.35) and the Rayleigh-Kuo equation (61.36). These integral conditions allow us to determine stability properties even without explicitly solving the detailed instability problem for a particular flow (see Section 61.6 for a solution example). We do so by deriving geometric conditions that are necessary for the flow to be unstable, or conversely that are sufficient to ensure the flow is stable. We also consider conditions needed for a particular perturbation to initiate an instability. Generally, the conditions we derive are necessary though not sufficient to ensure instability. Evidently, even if a flow satisfies the necessary conditions for instability, the flow can still be stable. This situation for the modal instabilities of sheared flows contrasts to the parcel instabilities from Chapter 59, where the instability conditions are both necessary and sufficient.

61.5.1 Rayleigh-Kuo inflection point theorem

Here we establish the *Rayleigh instability criteria*, also known as the *Rayleigh inflection-point criteria*. In the presence of β, it is known as the *Rayleigh-Kuo condition*. To proceed, start from the Rayleigh-Kuo equation (61.36) written as

$$(\partial_{yy} - k^2)\, \widetilde{\psi} + \frac{(\beta - \partial_{yy} u_{\mathsf{b}})\, \widetilde{\psi}}{u_{\mathsf{b}} - c} = 0. \tag{61.57}$$

Multiplying by $\widetilde{\psi}^*$ (complex conjugate of $\widetilde{\psi}$) and integrating over the meridional extent of the domain, $\mathcal{R}$, leads to

$$\int_{\mathcal{R}} [\partial_y(\widetilde{\psi}^* \, \partial_y \widetilde{\psi}) - |\partial_y \widetilde{\psi}|^2 - k^2 \, |\widetilde{\psi}|^2] \, \mathrm{d}y = - \int_{\mathcal{R}} \frac{(\beta - \partial_{yy} u_\mathrm{b}) \, |\widetilde{\psi}|^2}{u_\mathrm{b} - c} \, \mathrm{d}y. \tag{61.58}$$

If the streamfunction or its derivatives vanish on the meridional boundaries (or vanish when bounded away from the region of interest), then the left hand side is a negative real number. Now all terms on the right hand side are real except, possibly, the phase velocity, c. Hence, this equation is self-consistent only if the imaginary part of the right hand side vanishes

$$c_\mathrm{i} \int_{\mathcal{R}} \frac{(\beta - \partial_{yy} u_\mathrm{b}) \, |\widetilde{\psi}|^2}{|u_\mathrm{b} - c|^2} \, \mathrm{d}y = 0. \tag{61.59}$$

This condition can be satisfied in two ways. The first way is if the phase velocity is real, so that $c_\mathrm{i} = 0$ and hence all waves are stable.[6] The second way is if the integral vanishes. For the integral to vanish requires $\beta - \partial_{yy} u_\mathrm{b}$ to change sign somewhere in the domain, since all the other terms in the integral are positive. That is, somewhere in the domain there must be an extrema of the base state's absolute vorticity,

$$\beta - \partial_{yy} u_\mathrm{b} = \partial_y (f + \zeta_\mathrm{b}). \tag{61.60}$$

There are many qualifiers to this result. In particular, for $\beta - \partial_{yy} u_\mathrm{b}$ to change sign in the domain represents a necessary condition for a shear instability, and yet it is not a sufficient condition for instability. Indeed, there are flow profiles that satisfy the inflection point criteria and yet there are still no growing wave modes. Turning the condition around we find that a sufficient condition for stability is that there are no sign changes for $\beta - \partial_{yy} u_\mathrm{b}$. We summarize the result by stating the following theorem.

> RAYLEIGH-KUO INFLECTION POINT THEOREM: Consider an inviscid and homogeneous (constant density) fluid, with flow in an inertial reference frame (no Coriolis) and with a base state of zonal flow with meridional shear. A necessary condition for shear instability is that there exists an inflection point in the base state zonal flow somewhere in the domain; i.e., where $\partial_{yy} u_\mathrm{b} = 0$ and so where the relative vorticity has an extrema, $\partial_y \zeta_\mathrm{b} = -\partial_{yy} u_\mathrm{b} = 0$. For flow on the β-plane, this criteria is generalized to $\partial_y (f + \zeta_\mathrm{b}) = \beta - \partial_{yy} u_\mathrm{b} = 0$, in which case the absolute vorticity must have an extrema in the domain in order to admit an instability. If there is no inflection point, then its absence is sufficient to conclude that the flow is stable to shear instability.

It is notable that $\beta > 0$ always acts to stabilize the flow since its contribution requires a stronger background flow curvature to realize an inflection point. So if β is large enough then it can eliminate the inflection point, $\partial_y (f + \zeta_\mathrm{b}) = \beta - \partial_{yy} u_\mathrm{b} = 0$, from the domain, and in so doing it can stabilize the flow according to the Rayleigh-Kuo theorem. We can understand this stabilizing effect by noting that β supports planetary Rossby waves (Section 54.3), with such waves offering an alternative means to discharge the kinetic energy carried by shear in the base state flow.

61.5.2 Fjørtoft's theorem

Roughly 70 years after *Rayleigh* (1880) introduced the inflection point theorem, and a year after *Kuo* (1949) extended the inflection point theorem to the β-plane, *Fjørtoft* (1950) established

[6] Recall from Section 61.6.1 that if c solves the Rayleigh equation with streamfunction $\widetilde{\psi}$, then c^* also satisfies the equation with streamfunction $\widetilde{\psi}^*$. Hence, for each decaying mode there is a growing mode. So a sufficient condition for instability is to find a wave in which $c_\mathrm{i} \neq 0$.

another necessary condition for instability that is somewhat more constraining than the Rayleigh-Kuo theorem from Section 61.5.1.

To derive Fjørtoft's theorem, return to equation (61.58). Rather than focus on the imaginary part as done for the Rayleigh criteria, consider the real part

$$\int_{\mathcal{R}} \frac{(u_b - c_r)\,(\beta - \partial_{yy} u_b)\,|\widetilde{\psi}|^2}{|u_b - c|^2}\,dy = \int_{\mathcal{R}} [|\partial_y \widetilde{\psi}|^2 + k^2\,|\widetilde{\psi}|^2]\,dy > 0. \tag{61.61}$$

We are interested in profiles that satisfy the Rayleigh criteria for instability, so that the integral (61.59) vanishes, in which case we have

$$\int_{\mathcal{R}} \frac{c_r\,(\beta - \partial_{yy} u_b)\,|\widetilde{\psi}|^2}{|u_b - c|^2}\,dy = 0, \tag{61.62}$$

since c_r is a constant. Hence, equation (61.61) is trivially satisfied with any constant, U_s, inserted into the integral

$$\int_{\mathcal{R}} \frac{(u_b - U_s)\,(\beta - \partial_{yy} u_b)\,|\widetilde{\psi}|^2}{|u_b - c|^2}\,dy > 0. \tag{61.63}$$

A particularly useful constant is the value of the zonal velocity at the inflection point, $y = y_s$, where the absolute vorticity has an extrema $\partial_y(f + \zeta_b) = \beta - \partial_{yy} u_b = 0$. We are thus led to the following theorem.

> FJØRTOFT'S THEOREM: Under the same assumptions as the Rayleigh-Kuo theorem (Section 61.5.1), a necessary condition for shear instability is that $(u_b - U_s)\,(\beta - \partial_{yy} u_b) > 0$ occurs somewhere in the domain in order to satisfy the condition (61.63). Here, the inflection point is determined by $\partial_y(f + \zeta_b) = \beta - \partial_{yy} u_b(y_s) = 0$, with $U_s = u_b(y_s)$ the velocity at the inflection point.

Fjørtoft's theorem is rather subtle in its meaning, in particular it implies that an instability can occur only if the absolute vorticity has its maximum magnitude within the domain interior rather than at the domain boundary. One means to support this conclusion is by considering example zonal velocity profiles in Section 61.5.4.

61.5.3 Critical latitude theorem

The Rayleigh-Kuo condition and Fjørtoft's condition are statements about the geometry of the base flow state. Here we derive a condition necessary for a wave perturbation to support an instability. To do so, consider the Rayleigh-Kuo equation (61.43) written in terms of the meridional displacement

$$\partial_y[(u_b - c)^2\,\partial_y \widetilde{\xi}] = (u_b - c)\,[-\beta + k^2\,(u_b - c)]\,\widetilde{\xi}. \tag{61.64}$$

Following the approach taken for the Rayleigh-Kuo theorem in Section 61.5.1, multiply by $\widetilde{\xi}^*$, integrate over the domain, and assume boundary contributions are zero so that

$$\int_{\mathcal{R}} (|\partial_y \xi|^2 + k^2\,|\xi|^2)\,(u_b - c)^2\,dy = \beta \int_{\mathcal{R}} (u_b - c)\,|\xi|^2\,dy. \tag{61.65}$$

Writing

$$(u_b - c)^2 = (u_b - c_r)^2 - (c_i)^2 - 2\,i\,c_i\,(u_b - c_r), \tag{61.66}$$

leads to the two conditions taken from the real and imaginary parts of equation (61.65)

$$\int_{\mathcal{R}} (|\partial_y \xi|^2 + k^2 |\xi|^2) [(u_{\mathsf{b}} - c_{\mathsf{r}})^2 - (c_{\mathsf{i}})^2] \, \mathrm{d}y = \beta \int_{\mathcal{R}} (u_{\mathsf{b}} - c_{\mathsf{r}}) |\xi|^2 \, \mathrm{d}y \tag{61.67a}$$

$$2 c_{\mathsf{i}} \int_{\mathcal{R}} (|\partial_y \xi|^2 + k^2 |\xi|^2) (u_{\mathsf{b}} - c_{\mathsf{r}}) \, \mathrm{d}y = c_{\mathsf{i}} \beta \int_{\mathcal{R}} |\xi|^2 \, \mathrm{d}y. \tag{61.67b}$$

We are interested in unstable flows, in which case $c_{\mathsf{i}} \neq 0$. So the second condition provides a statement about the value of the real phase velocity relative to the background flow

$$2 \int_{\mathcal{R}} (|\partial_y \xi|^2 + k^2 |\xi|^2) (u_{\mathsf{b}} - c_{\mathsf{r}}) \, \mathrm{d}y = \beta \int_{\mathcal{R}} |\xi|^2 \, \mathrm{d}y \geq 0. \tag{61.68}$$

Since the first portion of the left hand side integral is positive, the integral condition (61.68) can only be met if $u_{\mathsf{b}} - c_{\mathsf{r}}$ is predominantly positive throughout the domain. For the special case of $\beta = 0$, we find the more definitive statement

$$\int_{\mathcal{R}} (|\partial_y \xi|^2 + k^2 |\xi|^2) (u_{\mathsf{b}} - c_{\mathsf{r}}) \, \mathrm{d}y = 0 \quad \text{if } \beta = 0. \tag{61.69}$$

Evidently, when $\beta = 0$ then $u_{\mathsf{b}} - c_{\mathsf{r}}$ must change sign within the domain in order to support an instability. That is, for an instability to exist we must have the real phase velocity of a modal perturbation equal the background velocity at some latitude within the domain. For a wave perturbation to grow requires it to travel with the flow at least at one latitude, where the wave perturbation is stationary relative to the background flow and can thus extract kinetic energy to feed the growing wave. We are thus led to the *critical latitude theorem*.

> Critical latitude theorem: Under the same assumptions as the Rayleigh-Kuo theorem (Section 61.5.1), a modal perturbation to a sheared flow with $\beta = 0$ is able to initiate an instability if its real phase velocity equals to the background flow velocity somewhere in the domain, thus ensuring that the real phase velocity is within the range of the background velocity.

We return to this theorem in Section 61.7.6, where we find that this result also holds for stratified shear instability as represented by Howard's semi-circle theorem.

61.5.4 Stability conditions for sample profiles

We here consider a suite of example velocity profiles and discuss their stability properties as per the Rayleigh inflection point theorem and Fjørtoft's theorem, with consideration given only to the case of $\beta = 0$. We leave the velocity, U, and length L, scales arbitrary, noting that the stability theorems of Rayleigh and Fjørtoft are statements about the flow geometry rather than the scale of the flow.

Parabolic profile is stable

In Figure 61.2 we display a parabolic velocity profile, sometimes referred to as *Poiseuille flow*, which can be considered a highly smoothed version of the point jet studied in Section 54.5. Recall the point jet supports stable edge waves. In the absence of multiple point jets that can interact with one another, we expect the flow to be stable. Hence, extrapolating from the point jet motivates us to guess that the parabolic jet in Figure 61.2 is stable. Indeed, it is stable according to the Rayleigh inflection point theorem simply because there is no inflection point given that the derivative of the vorticity is constant.

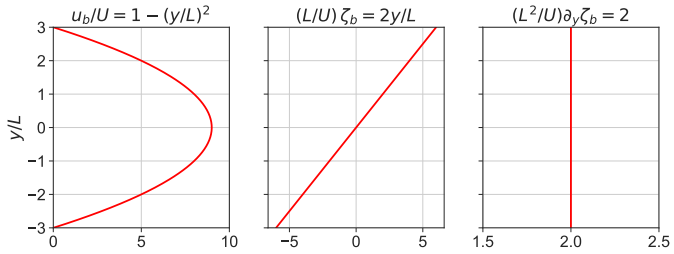

FIGURE 61.2: A parabolic velocity profile (Poiseuille flow) and its derivatives. Left panel: $u_b/U = (y/L)^2$. Middle panel: vorticity, $(L/U)\,\zeta_b = -(L/U)\,\partial_y u_b = -2\,(y/L)$. Right panel: derivative of the vorticity, $(L^2/U)\,\partial_y\zeta_b = -(L^2/U)\,\partial_{yy}u_b = -2$. Rayleigh's inflection point theorem says that this profile is stable since there is no inflection point.

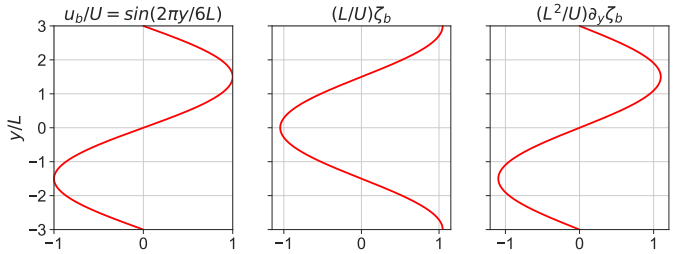

FIGURE 61.3: A sinusoidal velocity profile and its derivatives. Left panel: $u_b/U = \sin(2\pi\, y/6L)$. Middle panel: vorticity, $(L/U)\,\zeta_b = -(L/U)\,\partial_y u_b = -(2\pi/6)\cos(2\pi\, y/6L)$. Right panel: derivative of the vorticity, $(L^2/U)\,\partial_y\zeta_b = -(2\pi/6)^2\,u_b/U$. This velocity profile satisfies both the Rayleigh and Fjørtoft criteria for instability.

Sinusoidal profile is unstable according Rayleigh and Fjørtoft

Figure 61.3 shows a sinusoidal velocity profile. This flow has an inflection point at $y = 0$, and so satisfies the Rayleigh inflection point condition for instability. It also satisfies the Fjørtoft condition for instability, which we see with $U_s = 0$ at the $y = 0$ inflection point so that

$$(u_b - U_s)\,(\beta - \partial_{yy}u_b) = (u_b - 0)\,(0 - \partial_{yy}u_b) = (2\pi\, y/6L)^2\,(u_b)^2 > 0. \tag{61.70}$$

Gaussian jet profile is unstable according to Rayleigh and Fjørtoft

Figure 61.4 shows a Gaussian jet profile. There are two inflections points, $y = \pm L$, so that this profile is unstable according to the Rayleigh inflection point theorem. It is also unstable due to Fjørtoft's theorem since the vorticity extrema are within the domain.

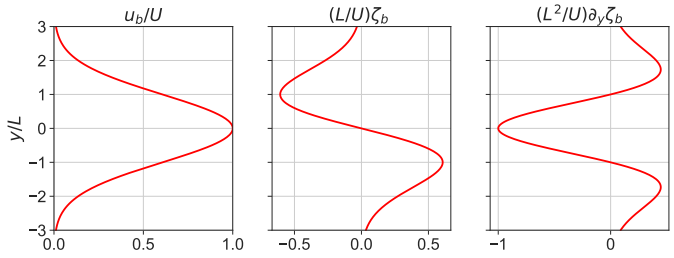

FIGURE 61.4: A Gaussian velocity profile and its derivatives. Left panel: $u_b/U = \mathrm{e}^{-(y/L)^2/2}$. Middle panel: vorticity, $(L/U)\,\zeta_b = -(L/U)\,\partial_y u_b = -(y/L)\,u_b/U$. Right panel: derivative of the vorticity, $(L^2/U)\,\partial_y\zeta_b = -(L^2/U)\,\partial_{yy}u_b = [(y/L)^2 - 1]\,(u_b/U)$. This velocity profile is unstable according to the Rayleigh inflection point theorem, with the two inflection points at $y = \pm L$.

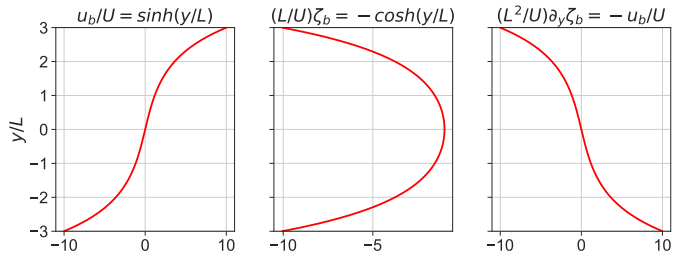

FIGURE 61.5: A sinh velocity profile and its derivatives. Left panel: $u_b/U = \sinh(y/L)$. Middle panel: vorticity, $(L/U)\,\zeta_b = -(L/U)\,\partial_y u_b = -\cosh(y/L)$. Right panel: derivative of the vorticity, $(L^2/U)\,\partial_y\zeta_b = -(L^2/U)\,\partial_{yy}u_b = -\sinh(y/L)$. This velocity profile satisfies the Rayleigh inflection point theorem, suggesting that it is unstable to shear instability. However, Fjørtoft's theorem says that it is stable.

Sinh profile is unstable according to Rayleigh but stable according to Fjørtoft

Consider the sinh velocity profile,

$$u_b = U\sinh(y/L) \tag{61.71a}$$
$$\zeta_b = -\partial_y u_b = -(U/L)\cosh(y/L) \tag{61.71b}$$
$$\partial_y\zeta_b = -\partial_{yy}u_b = -(U/L^2)\sinh(y/L), \tag{61.71c}$$

as shown in Figure 61.5. The velocity vanishes at the $y = 0$ inflection point (where $\partial_y\zeta_b = -\partial_{yy}u_b = 0$), so that $U_s = 0$. Consequently, the velocity profile satisfies Rayleigh's necessary condition for instability. However, for Fjørtoft's theorem we note that

$$(u_b - U_s)\,(\beta - \partial_{yy}u_b) = (u_b - 0)\,(0 - \partial_{yy}u_b) = -(U/L)^2\sinh^2(y/L) < 0. \tag{61.72}$$

Evidently, the flow is stable via the Fjørtoft theorem since $(u_b - U_s)\,(\beta - \partial_{yy}u_b)$ is never positive in the domain. In particular, the vorticity extrema are at the latitudinal bounds of the domain (see middle panel of Figure 61.5), with the extrema increasing in magnitude as the domain is expanded. In Exercise 61.2 we consider $\beta > 0$, where we find that the sinh profile is also stable according to Fjørtoft.

61.6 Interacting edge waves and shear instability

So far in this chapter we developed sufficient conditions for sheared flows to be stable. Conversely, we developed necessary conditions for the sheared flow to be unstable. In this section we study a particular flow configuration and solve the Rayleigh equation to determine the dispersion relation and corresponding instability conditions. This case study exposes the interacting wave mechanism for shear instability. For this purpose, recall from Section 54.5 the theory for edge waves riding on a single jump in the base state vorticity, with salient features given by the following.

- Edge waves propagate along the interface where vorticity experiences a jump, with the waves trapped to this interface due to the exponential decay of the wave in the direction orthogonal to the jump surface.
- The edge wave phase velocity, $\boldsymbol{c}_p$, is built from two contributions: one due to a Doppler shift from the background flow, and the other from the vorticity jump. The vorticity jump contribution is referred to as the intrinsic phase velocity, $\boldsymbol{c}_{\text{phase}}^{\text{intrinsic}}$.
- The intrinsic phase velocity is directed so that the higher relative vorticity is to the right when facing in the direction of the phase velocity. Equivalently, the phase velocity is

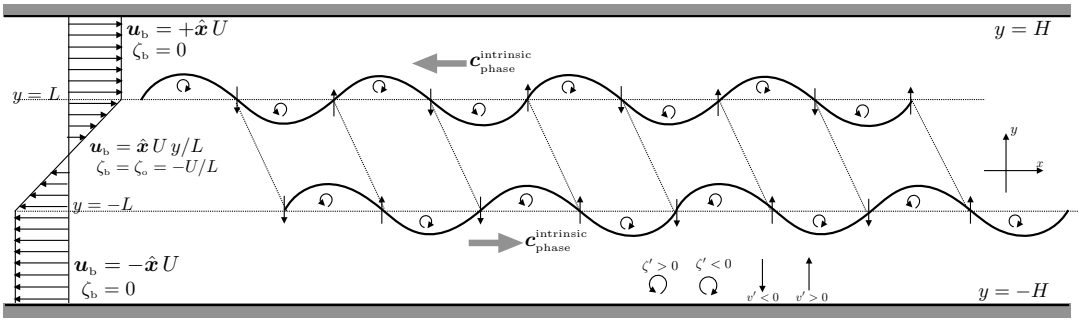

FIGURE 61.6: Depicting the interaction between two edge waves generated by a base flow that is unstable to shear instability. On the left we show the zonal base flow, with velocity kinks at $y = \pm L$. At $y = -L$, the vorticity jumps from zero to the south to a negative value to the north, so that the higher vorticity is to the south. This vorticity jump supports an edge wave with eastward intrinsic phase velocity, $\boldsymbol{c}_{\text{phase}}^{\text{intrinsic}}$. For the $y = L$ kink, the vorticity jumps from negative to zero when moving north. This vorticity configuration has higher vorticity to the north, thus supporting an edge wave with westward intrinsic phase velocity. These phase directions, both of which are contrary to the background flow, allow for Doppler shifting to make each of the edge waves stationary (i.e., zero real phase velocity). The oriented circles denote the anomalous vorticity associated with a particular fluctuation of the respective interfaces. For example, on the southern edge wave, a northward fluctuation brings fluid with higher relative vorticity northward, thus denoted by $\zeta' > 0$ and a counter-clockwise oriented circle. The secondary circulations induced by the anomalous vorticity induce anomalous meridional flows, depicted by the meridional arrows. These meridional flows have maximum amplitude at the wave nodes, pointing upward in front of a wave peak and downward on the back side. Interactions between the waves are mutually constructive with a phase shift whereby the southern wave is shifted to the east of the northern wave (see Figure 61.1); i.e., with the $y = L$ wave shifted ahead of the $y = -L$ wave so that lines of constant phase are slanted into the background shear. With this phase shift, a northward anomalous flow from the southern wave enhances the peak of the northern wave, thus supporting its further growth. A similar enhancement occurs for the opposite wave, thus resulting in mutual amplification of each wave's amplitude. To optimize the growth requires the waves to be *phase locked*, whereby they stay stationary relative to one another, thus allowing the positive feedback to create the exponential wave growth.

directed towards the concave portion of the velocity profile. One can understand this orientation via the conservation of relative vorticity (holding for an inviscid flow in an inertial reference frame), as explained for the point jet in Figure 54.8.

We focus in this section on interactions between two edge waves, with the aim to characterize conditions that support shear instability. For analytical tractability, we focus on the case with zero planetary beta ($\beta = 0$). This assumption serves to clearly expose the underlying *wave resonance* instability mechanism that arises from mutually reinforcing edge wave interactions. Additionally, it is convenient to set $H \to \infty$ so that there are no solid boundaries, thus studying stability of a *free shear layer*.

Figure 61.6 illustrates the wave resonance mechanism, with the figure caption detailing the basic ingredients. In brief, the two edge waves, with oppositvely directed intrinsic phase velocities, are *phase locked* due to Doppler shifting by the background flow. Phase locking means that the interacting waves move with the same phase velocity. Indeed, symmetry of the setup in Figure 61.6 leads to phase locked waves that are stationary, meaning that the real part of the phase velocity vanishes. When the waves are phase locked with a phase shift so that lines of constant phase are slanted into the background shear, then that orientation supports a mutual reinforcement of the opposing wave's amplitude, which is a signature of a modal instability. The goal of this section is to expose mathematical details supporting this figure.

61.6.1 Phase locked streamfunction and Rayleigh equation

Our mathematical task is to derive the streamfunction corresponding to the interacting edge waves supported by the velocity kinks at $y = L$ and $y = -L$ shown in Figure 61.6. Ingredients

for this derivation were developed in Section 54.5 when studying a single edge wave along a single velocity jump. As for that analysis, start with the wave ansatz given by equation (61.30), written here again

$$\psi(x,y,t) = \widetilde{\psi}(y)\, \mathrm{e}^{\mathrm{i}\, k\,(x - c_\mathrm{r}\, t)}\, \mathrm{e}^{k\, c_\mathrm{i}\, t} = \widetilde{\psi}(y)\, \mathrm{e}^{\mathrm{i}\, k\,(x - c_\mathrm{r}\, t)}\, \mathrm{e}^{\sigma\, t}. \tag{61.73}$$

As noted at the start of this section, writing a wave function with a single phase velocity is consistent with a phase locked system of two edge waves. With this wave ansatz we then solve the Rayleigh equation (61.35) (i.e., the vorticity equation) in the fluid region between the kinks, and use kinematic and dynamic boundary conditions to match the streamfunction across the kinks.

With the velocity profile in Figure 61.6, the meridional derivative of the background vorticity, $\partial_y \zeta_\mathrm{b}$, has a Dirac delta at each of the vorticity jumps so that the Rayleigh equation (61.35) is

$$(u_\mathrm{b} - c)\,(\partial_{yy} - k^2)\,\widetilde{\psi} + \zeta_\circ\,[\delta(y+L) - \delta(y-L)]\,\widetilde{\psi} = 0 \quad \text{with} \quad \zeta_\circ = -U/L. \tag{61.74}$$

The solution to this equation outside of the singular vorticity interfaces (at $y = \pm L$) is given by

$$\widetilde{\psi}(y) = \begin{cases} A_1\, \mathrm{e}^{-|k|(y-L)} & y \geq L \\ A_2\, \mathrm{e}^{|k|(y-L)} + A_3\, \mathrm{e}^{-|k|(y+L)} & -L \leq y \leq L \\ A_4\, \mathrm{e}^{+|k|(y+L)} & y \leq -L, \end{cases} \tag{61.75}$$

where $A_{1,2,3,4}$ are constants determined by the kinematic and dynamic boundary conditions applied (in the linear theory) at $y = \pm L$.

61.6.2 Kinematic boundary condition at $y = \pm L$

We derived the kinematic boundary condition in Section 54.5.4, which arises from the material nature of the interface. The velocity is continuous at $y = \pm L$, so that the kinematic boundary condition means that the streamfunction is also continuous at the kinks. Evaluating equation (61.75) at $y = \pm L$ leads to the relations

$$A_1 = A_2 + A_3\, \mathrm{e}^{-2|k|L} \quad \text{and} \quad A_4 = A_3 + A_2\, \mathrm{e}^{-2|k|L}, \tag{61.76}$$

so that

$$\widetilde{\psi}(y) = \begin{cases} A_\mathrm{up}\, \mathrm{e}^{-|k|(y-L)} + A_\mathrm{lo}\, \mathrm{e}^{-|k|(y+L)} & y \geq L \\ A_\mathrm{up}\, \mathrm{e}^{|k|(y-L)} + A_\mathrm{lo}\, \mathrm{e}^{-|k|(y+L)} & -L \leq y \leq L \\ A_\mathrm{up}\, \mathrm{e}^{|k|(y-L)} + A_\mathrm{lo}\, \mathrm{e}^{|k|(y+L)} & y \leq -L, \end{cases} \tag{61.77}$$

which can be written in the more succinct form

$$\widetilde{\psi}(y) = A_\mathrm{up}\, \mathrm{e}^{-|k||y-L|} + A_\mathrm{lo}\, \mathrm{e}^{-|k||y+L|}, \tag{61.78}$$

where we wrote

$$A_\mathrm{up} = A_2 \quad \text{and} \quad A_\mathrm{lo} = A_3. \tag{61.79}$$

The notation (61.79) for the amplitudes correspond to the latitude ($y = L$ or $y = -L$) where their respective exponentials are maximized. Equation (61.78) reveals that the streamfunction is the sum of two functions, each peaked at one of the kinks in the background flow.

The coefficients, A_up and A_lo, are generally complex. However, symmetry of the setup for when the edge waves are phase locked requires their magnitudes to be equal, in which case

$$A_\mathrm{up} = \Gamma\, \mathrm{e}^{\mathrm{i}\,\theta_\mathrm{up}} \quad \text{and} \quad A_\mathrm{lo} = \Gamma\, \mathrm{e}^{\mathrm{i}\,\theta_\mathrm{lo}} \quad \text{with} \quad \Gamma > 0, \tag{61.80}$$

and the corresponding streamfunction

$$\widetilde{\psi}(y) = \Gamma \left[\mathrm{e}^{-|k||y-L|+\mathrm{i}\,\theta_{\mathsf{up}}} + \mathrm{e}^{-|k||y+L|+\mathrm{i}\,\theta_{\mathsf{lo}}} \right]. \tag{61.81}$$

61.6.3 Dynamic boundary condition at $y = L$

As detailed in Section 54.5.5, the dynamic boundary condition is based on continuity of pressure across an interface (ignoring surface tension). Equivalently, it arises from integrating the Rayleigh equation (61.74) across each interface, with the Dirac delta rendering a jump condition. For this purpose, it is convenient to write the Rayleigh equation in the form of equation (54.85)

$$\partial_y[(u_{\mathsf{b}} - c)\,\partial_y\widetilde{\psi} - \widetilde{\psi}\,\partial_y u_{\mathsf{b}}] + [-k^2\,(u_{\mathsf{b}} - c)]\,\widetilde{\psi} = 0. \tag{61.82}$$

Since u_{b} and $\widetilde{\psi}$ are everywhere continuous, integration across $y = L$ yields

$$\lim_{\epsilon\to 0} \int_{L-\epsilon}^{L+\epsilon} \partial_y[(u_{\mathsf{b}} - c)\,\partial_y\widetilde{\psi} - \widetilde{\psi}\,\partial_y u_{\mathsf{b}}]\,\mathrm{d}y = 0, \tag{61.83}$$

which leads to the jump condition

$$\left[(U-c)\,\partial_y\widetilde{\psi} + \widetilde{\psi}\,\zeta_{\mathsf{o}}\right]_{y=L-\epsilon} = \left[(U-c)\,\partial_y\widetilde{\psi}\right]_{y=L+\epsilon}, \tag{61.84}$$

where we noted that there is zero vorticity for $y > L$, and the zonal velocity equals to $+U$ at $y = L$. Note that ϵ is set to zero once evaluating the expressions. Making use of the streamfunction (61.77) and its derivative,

$$\partial_y\widetilde{\psi} = |k| \begin{bmatrix} -A_{\mathsf{up}}\,\mathrm{e}^{-|k|(y-L)} - A_{\mathsf{lo}}\,\mathrm{e}^{-|k|(y+L)} & y \geq L \\ A_{\mathsf{up}}\,\mathrm{e}^{|k|(y-L)} - A_{\mathsf{lo}}\,\mathrm{e}^{-|k|(y+L)} & -L \leq y \leq L \\ A_{\mathsf{up}}\,\mathrm{e}^{|k|(y-L)} + A_{\mathsf{lo}}\,\mathrm{e}^{|k|(y+L)} & y \leq -L, \end{bmatrix} \tag{61.85}$$

brings the $y = L$ jump boundary condition to

$$A_{\mathsf{up}}\,[2\,(U-c)\,|k| + \zeta_{\mathsf{o}}] + A_{\mathsf{lo}}\,\zeta_{\mathsf{o}}\,\mathrm{e}^{-2|k|L} = 0, \tag{61.86}$$

which, with $\zeta_{\mathsf{o}} = -U/L$ (equation (61.74)), can be written as

$$A_{\mathsf{up}}\,[2\,(1-c/U)\,|k|\,L - 1] = A_{\mathsf{lo}}\,\mathrm{e}^{-2|k|L}. \tag{61.87}$$

Solving for the dimensionless phase velocity leads to

$$c/U = 1 - \frac{1}{2\,|k|\,L}\left[1 + \frac{A_{\mathsf{lo}}}{A_{\mathsf{up}}}\,\mathrm{e}^{-2\,|k|\,L}\right] = 1 - \frac{1}{2\,|k|\,L}\left[1 + \mathrm{e}^{-2\,|k|\,L - \mathrm{i}\,\Delta\theta}\right], \tag{61.88}$$

where we introduced the phase for the amplitudes according to equation (61.80) and wrote the phase difference as

$$\Delta\theta = \theta_{\mathsf{up}} - \theta_{\mathsf{lo}}. \tag{61.89}$$

The phase velocity (61.88) is comprised of three terms

$$c = \underbrace{U}_{\text{Doppler}} \underbrace{-\frac{U}{2\,|k|\,L}}_{\text{free wave}} \underbrace{-\frac{U}{2\,|k|\,L}\,\mathrm{e}^{-2\,|k|\,L - \mathrm{i}\,\Delta\theta}}_{\text{interaction}}. \tag{61.90}$$

The first term arises from the Doppler shift via the background flow at the upper interface that

is directed to the east,

$$\boldsymbol{u}_{\mathsf{b}}(y = L) = U\,\hat{\boldsymbol{x}}. \tag{61.91}$$

The second term corresponds to the phase velocity of a free edge wave at the upper interface, with the westward intrinsic phase velocity

$$\boldsymbol{c}_{\text{phase}}^{\text{intrinsic}} = -U/(2\,|k|\,L)\,\hat{\boldsymbol{x}} = \zeta_{\mathsf{o}}/(2\,|k|)\,\hat{\boldsymbol{x}}. \tag{61.92}$$

For high wavenumbers (short wavelengths), the first and second terms dominate, with the phase velocity positive (eastward) as it is dominated by the Doppler term.

The final term in the phase velocity (61.90) arises from interactions between the upper and lower edge waves. The interaction decays both exponentially and algebraically according to $|k|\,L$, meaning that the edge waves have vanishingly small interactions for short wavelength zonal waves. Furthermore, the interaction term is generally a complex number that can be written

$$-\frac{U}{2\,|k|\,L}\,\mathrm{e}^{-2\,|k|\,L - \mathrm{i}\,\Delta\theta} = \frac{U\,\mathrm{e}^{-2\,|k|\,L}}{2\,|k|\,L}\left[-\cos(\Delta\theta) + \mathrm{i}\sin(\Delta\theta)\right] = c_{\mathsf{r}} + \mathrm{i}\,c_{\mathsf{i}}. \tag{61.93}$$

Evidently, the growth rate, $\sigma = c_{\mathsf{i}}\,k$, is positive (meaning the wave grows) if

$$k\sin(\Delta\theta) > 0 \implies \sigma = c_{\mathsf{i}}\,k > 0 \implies \text{growing waves}. \tag{61.94}$$

For $k > 0$ this condition means that the lines of constant phase are slanted into the background shear, just as anticipated by Figures 61.1 and 61.6.

61.6.4 Dynamic boundary condition at $y = -L$

The interface at $y = -L$ has the jump condition

$$\left[(-U - c)\,\partial_y\widetilde{\psi}\right]_{y=-L-\epsilon} = \left[(-U - c)\,\partial_y\widetilde{\psi} + \widetilde{\psi}\,\zeta_{\mathsf{o}}\right]_{y=-L+\epsilon}, \tag{61.95}$$

where the vorticity is zero for $y < -L$ and the zonal velocity is $-U$. Making use of the streamfunction (61.77) and the derivative (61.85) brings the $y = -L$ jump boundary condition to

$$A_{\mathsf{up}}\,\zeta_{\mathsf{o}}\,\mathrm{e}^{-2|k|L} + A_{\mathsf{lo}}\left[2\,(U + c)\,|k| + \zeta_{\mathsf{o}}\right] = 0, \tag{61.96}$$

which can be written as

$$A_{\mathsf{lo}}\left[2\,(1 + c/U)\,|k|\,L - 1\right] = A_{\mathsf{up}}\,\mathrm{e}^{-2|k|L}, \tag{61.97}$$

thus leading to the dimensionless phase velocity

$$c/U = -1 + \frac{1}{2\,|k|\,L}\left[1 + \frac{A_{\mathsf{up}}}{A_{\mathsf{lo}}}\,\mathrm{e}^{-2\,|k|\,L}\right] = -1 + \frac{1}{2\,|k|\,L}\left[1 + \mathrm{e}^{-2\,|k|\,L + \mathrm{i}\,\Delta\theta}\right], \tag{61.98}$$

where we introduced the phase for the amplitudes according to equation (61.80). Just like for the $y = L$ interface, we have the following interpretation for the phase velocity

$$c = \underbrace{-U}_{\text{Doppler}}\ \underbrace{+\frac{U}{2\,|k|\,L}}_{\text{free wave}}\ \underbrace{+\frac{U}{2\,|k|\,L}\,\mathrm{e}^{-2\,|k|\,L + \mathrm{i}\,\Delta\theta}}_{\text{interaction}} = c_{\mathsf{r}} + \mathrm{i}\,c_{\mathsf{i}}. \tag{61.99}$$

At the $y = -L$ interface the background flow is

$$\boldsymbol{u}_{\mathsf{b}}(y = -L) = -U\,\hat{\boldsymbol{x}}, \tag{61.100}$$

so that the Doppler shift is in the opposite direction to that at the upper interface, as is the free edge wave intrinsic phase velocity

$$\boldsymbol{c}_{\text{phase}}^{\text{intrinsic}} = U/(2\,|k|\,L)\,\hat{\boldsymbol{x}} = -\zeta_o/(2\,|k|)\,\hat{\boldsymbol{x}}. \tag{61.101}$$

The interaction term in equation (61.99) shares much with that at the upper interface given by equation (61.90). Namely, both decay exponentially and algebraically according to $|k|\,L$. Furthermore, the interaction term is generally a complex number that can be written

$$\frac{U}{2\,|k|\,L}\,\mathrm{e}^{-2|k|L+\mathrm{i}\,\Delta\theta} = \frac{U\,\mathrm{e}^{-2|k|L}}{2\,|k|\,L}\,\big[\cos(\Delta\theta) + \mathrm{i}\sin(\Delta\theta)\big] = c_r + \mathrm{i}\,c_i. \tag{61.102}$$

Just like for the upper interface, the growth rate, $\sigma = c_i\,k$, is positive (meaning the wave grows) if

$$k\,\Delta\theta > 0 \Longrightarrow \sigma = c_i\,k > 0 \Longrightarrow \text{growing waves}. \tag{61.103}$$

61.6.5 Phase velocity for phase locked edge waves

Application of the dynamical boundary condition at $y = L$ and $y = -L$ resulted in two expressions for the phase velocity as given by equations (61.88) and (61.98). The two phase velocities must be identical for the edge waves to be phase locked, with inspection of the two expressions leading to

$$c_r/U = 0 = \pm\left[-1 + \frac{1}{2\,|k|\,L} + \frac{\mathrm{e}^{-2\,|k|L}\cos\Delta\theta}{2\,|k|\,L}\right] \tag{61.104a}$$

$$c_i/U = \frac{\sin(\Delta\theta)\,\mathrm{e}^{-2|k|L}}{2\,|k|\,L}. \tag{61.104b}$$

That is, the phase velocity for the phase locked edge waves is purely imaginary, so that the edge waves are stationary and have a streamfunction given by

$$\psi(x,y,t) = \widetilde{\psi}(y)\,\mathrm{e}^{\mathrm{i}\,k\,x + k\,c_i\,t} = \widetilde{\psi}(y)\,\mathrm{e}^{\mathrm{i}\,k\,x+\sigma\,t}. \tag{61.105}$$

Growth rate

The phase velocity for the phase locked edge waves has a nonzero imaginary component when there is a nonzero phase shift between the two edge waves. Growth occurs when $k\,c_i = \sigma > 0$, which leads to the sufficient condition for instability

$$k\,\Delta\theta > 0 \Longrightarrow \sigma > 0 \Longrightarrow \text{unstable waves}. \tag{61.106}$$

Vanishing real phase velocity

The vanishing real phase velocity puts a constraint on the zonal wavenumber, in which case

$$2\,|k|\,L = 1 + \mathrm{e}^{-2|k|L}\cos\Delta\theta. \tag{61.107}$$

The maximum wavenumber that can satisfy this constraint is found when there is no phase shift ($\Delta\theta = 0$), in which we define a critical wavenumber

$$(1 - 2\,|k|\,L) = \mathrm{e}^{-2|k|L} \Longrightarrow (|k|\,L)_{\text{crit}} = 0.6329. \tag{61.108}$$

This is a high wavenumber cutoff, meaning that for wavenumbers larger than $(|k|\,L)_{\text{crit}}$ (i.e., relatively short waves), then there is a nonzero real component to the phase velocity. The nonzero real component to the phase velocity means that the two edge waves are in fact not phase locked, and as a result their amplitudes do not grow. Hence, the dimensionless wavenumber (61.108) separates the stable regime (high wavenumbers, $|k|\,L > (|k|\,L)_{\text{crit}}$) from the unstable regime (low wavenumbers, $|k|\,L < (|k|\,L)_{\text{crit}}$).

61.6.6 Dispersion relation and its interpretation

Here we derive the dispersion relation, which captures much of the information already gleaned by studying the phase velocity as well as some complementary perspectives.

Deriving the dispersion relation

Combine the two jump conditions (61.86) and (61.96) into a matrix-vector equation

$$\begin{bmatrix} [2\,(U-c)\,|k| + \zeta_{\text{o}}] & \zeta_{\text{o}}\,\text{e}^{-2|k|L} \\ \zeta_{\text{o}}\,\text{e}^{-2|k|L} & [2\,(U+c)\,|k| + \zeta_{\text{o}}] \end{bmatrix} \begin{bmatrix} A_{\text{up}} \\ A_{\text{lo}} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{61.109}$$

Nontrivial solutions to this equation exist if the determinant of the 2×2 matrix vanishes, which then leads to the dispersion relation

$$(c/U)^2 = \frac{1}{(2\,|k|\,L)^2}\left[(1 - 2\,|k|\,L)^2 - \text{e}^{-4|k|L}\right] = \left[1 - \frac{1}{2\,|k|\,L}\right]^2 - \frac{\text{e}^{-4|k|L}}{(2\,|k|\,L)^2}. \tag{61.110}$$

Interpreting the two roots to the dispersion relation

The dispersion relation (61.110) leads to two roots for the phase velocity, $c = \omega/k$, with roots either both real or both imaginary. We already saw in Section 61.6.5 that the real roots must vanish for phase locked edge waves, with a vanishing real phase velocity present when the horizontal wavenumber satisfies $|k|\,L < (|k|\,L)_{\text{crit}}$ from equation (61.108). We interpret the nonzero real roots that arise with $|k|\,L > (|k|\,L)_{\text{crit}}$ as stable and non-phase locked edge waves moving in opposite directions along the velocity kinks at $y = L$ and $y = -L$. For example, in the high wavenumber limit the roots are real and have the approximate value

$$c \approx \pm U\left[1 - \frac{1}{2\,|k|\,L}\right]. \tag{61.111}$$

In this limit, the two edge waves correspond to the isolated edge waves studied in Section 54.5. Evidently, the wavenumber is so large (small wavelength) that the meridional structure of the edge waves rapidly decays in the direction away from their respective interfaces. As a result the two edge waves are effectively free waves since their interaction is negligible and they are not phase locked. As $|k|\,L$ gets smaller, the wavelength gets longer and the meridional extent of the two edge waves broadens. Interactions between the waves thus occurs, with these interactions possible even when the waves are stable. However, phase locking occurs for $|k|\,L < (|k|\,L)_{\text{crit}}$, with such waves unstable.

Critical wavenumber separating the stable and unstable regimes

As seen in equation (61.108), the real part of the phase velocity vanishes when the dimensionless wavenumber satisfies

$$(1 - 2\,|k|\,L)^2 = \text{e}^{-4|k|L} \implies (|k|\,L)_{\text{crit}} = 0.6329. \tag{61.112}$$

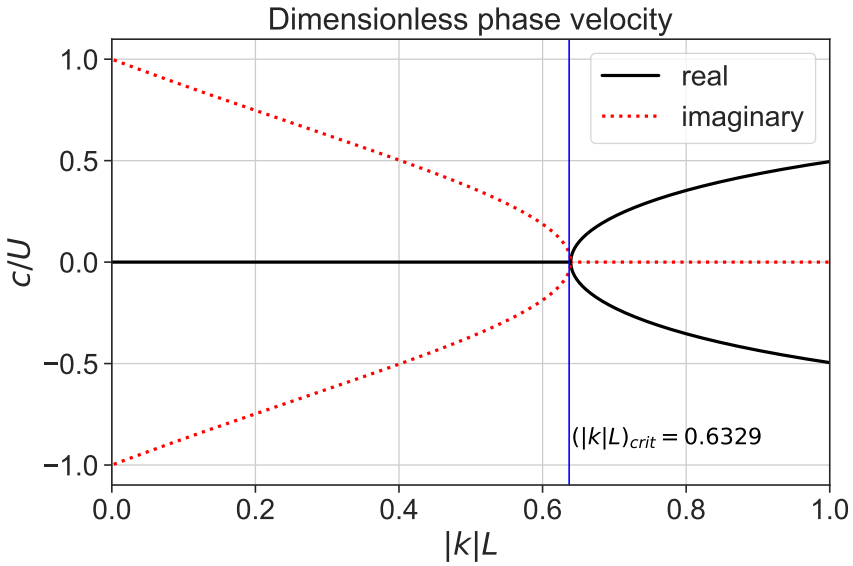

FIGURE 61.7: Dimensionless phase velocity, $c/U = \omega/(k\,U)$, from equation (61.110) derived for the piecewise linear velocity profile shown in Figure 61.6. A nonzero real phase velocity corresponds to stable edge waves that are not phase locked. If there are two edge waves, one on each of the velocity jumps and moving in the opposite directions, then they can interact. If the interaction is weak then it does not support a growing instability. Imaginary phase velocities correspond to phase locked edge waves with zero real phase velocity, so that the waves are stationary and have both an exponentially growing and decaying mode. The dimensionless wavenumber, $|k|_{\rm crit}\,L = 0.6329$, separates the stable (high wavenumber) regime from the unstable (low wavenumber) regime.

That is, for lower dimensionless wavenumbers, the squared phase speed (61.110) becomes negative

$$(c/U)^2 < 0 \Longrightarrow c = \mathrm{i}\,c_{\rm i}, \tag{61.113}$$

in which case the two real roots vanish and, for smaller wavenumbers, become two imaginary roots. One of the imaginary roots is an exponentially decaying mode and the other is the exponentially growing mode. Since the real part of the phase velocity vanishes, the modes are stationary relative to the shear layer, and thus they are either decaying or growing in place.

Fastest growth rate

The growth rate, $\sigma = c_{\rm i}\,k$, is given by

$$(\sigma\,L/U) = \pm\left[\mathrm{e}^{-4|k|L}/4 - (|k|\,L - 1/2)^2\right]^{1/2}, \tag{61.114}$$

which we plot in Figure 61.8. The fastest growth rate is given by

$$\frac{\mathrm{d}(\sigma\,L/U)^2}{\mathrm{d}(|k|L)} = 0 \Longrightarrow (|k|\,L)_{\rm fastest} \approx 0.4 \Longrightarrow \Lambda_{\rm fastest} \approx 2\pi L/0.4 = 5\pi L. \tag{61.115}$$

Evidently, the most unstable mode has a zonal wavelength that is roughly 16 times the meridional width of the shear zone (see Figure 61.6). For this mode the positive dimensionless growth rate is

$$(\sigma\,L/U) \approx 0.2 \Longrightarrow \sigma = 0.2\,U/L. \tag{61.116}$$

The growth rate increases as the horizontal shear, U/L, increases, either by increasing the background flow speed, U, or by decreasing the width of the shear zone.

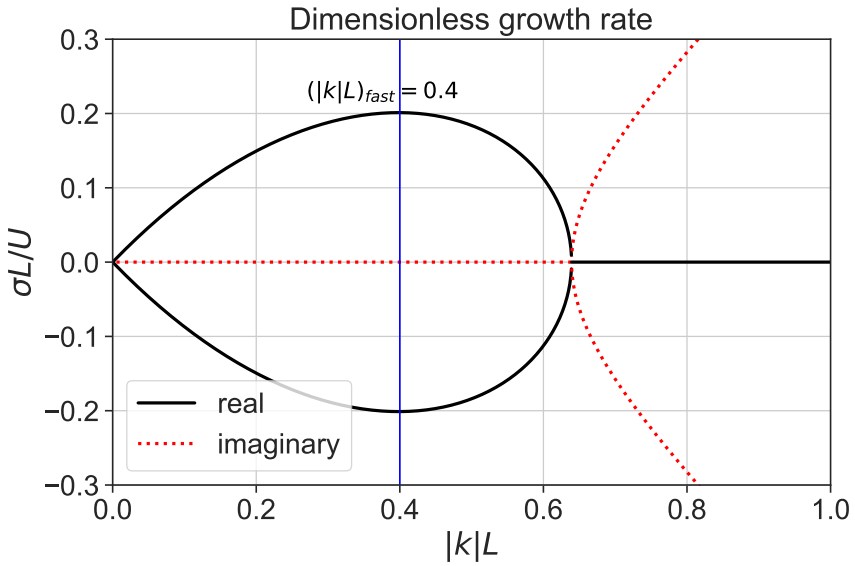

FIGURE 61.8: Dimensionless growth rate, $\sigma\, L/U$, from equation (61.114) derived for the piecewise linear velocity profile shown in Figure 61.6. A real growth rate corresponds to imaginary phase velocity from Figure 61.7, and represents exponentially growing ($\sigma > 0$) and decaying ($\sigma < 0$) modes. The dimensionless wavenumber, $|k|_{\text{crit}}\, L = 0.6329$, separates the stable (higher wavenumber) from unstable (lower wavenumber) regimes.

Phase shift for the fastest growing unstable mode

Making use of equation (61.104b) renders the expression for the phase shift present for phase locked unstable edge waves

$$\sin(\Delta\theta) = \frac{2\,|k|\,L\,\sigma}{k\,U}\,\mathrm{e}^{-2|k|L}. \tag{61.117}$$

Equation (61.116) says that the fastest growing mode has a growth rate of $\sigma\, L/U \approx 0.2$ at the non-dimensional wavenumber $|k|\, L \approx 0.4$ (equation (61.115)), so that

$$\sin(\Delta\theta) = \pm 2\,(\sigma\, L/U)\,\mathrm{e}^{2|k|L} \approx \pm 0.4\,\mathrm{e}^{0.8}. \tag{61.118}$$

For an eastward intrinsic phase velocity, so that $k > 0$, the constraint (61.94) says that the growing wave has $k \sin(\Delta\theta) > 0$, with $\sin(\Delta\theta) = 0.4\,\mathrm{e}^{0.8}$ yielding a phase shift of

$$\Delta\theta \approx 1.3\,\pi/2. \tag{61.119}$$

From Figure 61.6 we infer that the optimal alignment for growth of the two edge waves occurs with a $\pi/2$ phase shift. However, this phase shift requires a larger $|k|\, L$, and a larger $|k|\, L$ reduces the exponential appearing in the interaction between the two edge waves and thus slows the growth rate. Hence, the most unstable wave results from the dual need to optimize the relative phase of the two waves as well as the amplitude of the interaction.

61.6.7 Plotting the $\widetilde{\psi}(y)$ streamfunctions

In Figure 61.9 we plot the streamfunction based on equation (61.78)

$$\widetilde{\psi}(y) = A_{\text{up}}\,\mathrm{e}^{-L|k|\,|y/L-1|} + A_{\text{lo}}\,\mathrm{e}^{-L|k|\,|y/L+1|}, \tag{61.120}$$

for stable waves with $k\, L = 1$ and $k\, L = -1$, and for an unstable wave with $k\, L = 0.4$. There are some subtleties with producing these plots, thus motivating the following presentation of details.

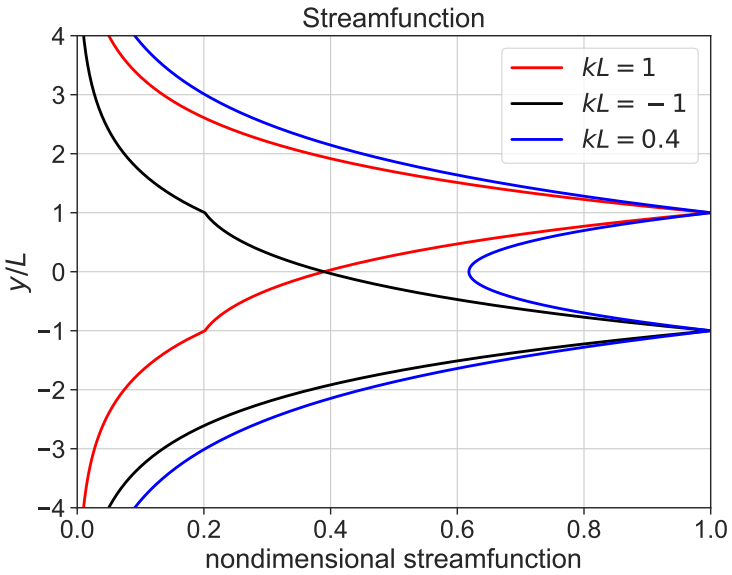

FIGURE 61.9: Streamfunction, $\widetilde{\psi}(y)$, for stable and unstable edge waves on the free shear layer shown in Figure 61.6. Each streamfunction is non-dimensionalized with an amplitude set so that the maximum streamfunction is unity. The black and red streamfunctions are for stable and non-phase locked edge waves maximized at the upper velocity kink (red at $y = L$) and lower kink (black at $y = -L$). The two stable streamfunctions have zero phase shift ($\theta_{\text{lo}} = \theta_{\text{up}} = 0$). The blue streamfunction is for the unstable mode with $|k|L = 0.4$ and with the phase shift $\Delta\theta = 1.3\,\pi/2$, with the streamfunction given by equation (61.127). Details for how to compute these streamfunctions are given in Section 61.6.7.

The stable streamfunction maximized at $y = L$

The stable streamfunctions have zero phase shifts (since they are stable waves) and they have unequal amplitudes, $A_{\text{up}} \neq A_{\text{lo}}$. The $k\,L = -1$ wave is maximized on the $y = L$ velocity kink since this is where the edge wave has a westward intrinsic phase velocity. The dimensionless phase velocity is given by the dispersion relation (61.110) with $k\,L = -1$, which yields (see also equation (61.90))

$$c/U \approx 0.495, \tag{61.121}$$

with the eastward phase velocity arising from dominance of the eastward background flow at $y = L$. That is, the stable edge wave maximized at $y = L$ is swept eastward by the background flow, thus precluding it from being phase locked with the edge wave centered on $y = -L$. The amplitude ratio is computed from equation (61.87)

$$A_{\text{lo}}/A_{\text{up}} = \mathrm{e}^2\,[2\,(1 - c/U) - 1] \approx 0.068, \tag{61.122}$$

with the resulting streamfunction (61.120)

$$\widetilde{\psi}^{(\text{L})}(y) = A_{\text{up}}\left[\mathrm{e}^{-|y/L-1|} + (A_{\text{lo}}/A_{\text{up}})\,\mathrm{e}^{-|y/L+1|}\right]. \tag{61.123}$$

We specify the amplitude, A_{up}, so that the maximum of $\widetilde{\psi}^{(\text{L})}(y)$ is unity as plotted in Figure 61.9.

The stable streamfunction maximized at $y = -L$

The $k\,L = 1$ wave is symmetric with respect to the $k\,L = -1$ wave. Namely, the $k\,L = 1$ wave is maximized on the $y = -L$ velocity kink since this is where the edge wave has a westward intrinsic phase velocity. The dimensionless phase velocity is given by the dispersion relation

(61.110) with $k\,L = 1$, which yields (see also equation (61.99))

$$c/U \approx -0.495, \tag{61.124}$$

with the westward phase velocity due to dominance of the westward background flow at $y = -L$. That is, the stable edge wave maximized at $y = -L$ is swept westward by the background flow, thus precluding it from being phase locked with the edge wave centered on $y = L$. The amplitude ratio is computed from equation (61.97)

$$A_{\text{up}}/A_{\text{lo}} = \mathrm{e}^2\,[2\,(1 + c/U) - 1] \approx 0.068, \tag{61.125}$$

which is numerically equal to the ratio $A_{\text{lo}}/A_{\text{up}}$ in equation (61.122) for the wave maximized at $y = L$. The resulting streamfunction (61.120) is

$$\widetilde{\psi}^{(-\text{L})}(y) = A_{\text{lo}}\left[(A_{\text{up}}/A_{\text{lo}})\,\mathrm{e}^{-|y/L-1|} + \mathrm{e}^{-|y/L+1|}\right]. \tag{61.126}$$

We specify the amplitude, A_{lo}, so that the maximum of $\widetilde{\psi}^{(-\text{L})}(y)$ is unity as plotted in Figure 61.9.

The unstable streamfunction

When the zonal wavenumber gets smaller than $(|k|\,L)_{\text{crit}} = 0.6329$, then the two edge waves become phase locked and stationary (zero real phase velocity), with a phase shift allowing for mutual growth to manifest shear instability. In Figure 61.9 we plot the magnitude of the streamfunction for $|k|\,L = 0.4$ according to equation (61.81)

$$\widetilde{\psi}(y) = \Gamma\,\mathrm{e}^{\mathrm{i}\,\theta_{\text{up}}}\left[\mathrm{e}^{-L|k|\,|y/L-1|} + \mathrm{e}^{-L|k|\,|y/L+1|+\mathrm{i}\,\Delta\theta}\right], \tag{61.127}$$

where the phase shift is given by $\Delta\theta = 1.3\,\pi/2$ as per equation (61.119), and the magnitude is computed by

$$|\widetilde{\psi}| = \sqrt{\widetilde{\psi}\,\widetilde{\psi}^*}. \tag{61.128}$$

61.6.8 Lack of mutual wave growth for stable flows

The wave mechanism for shear instability offers a mechanistic understanding of the integral stability theorems from Section 61.5. For example, the case of Figure 61.6 illustrates how waves can mutually reinforce each other's amplitudes if there is an inflection point in the background flow, thus satisfying the necessary condition for Rayleigh's inflection point theorem. We sketch a profile in Figure 61.10 that has no inflection point, and for which the edge waves have their phase velocities in the same direction. If their relative phases are oriented so that the lower wave enhances the amplitude of the upper wave, as in Figure 61.10, then the upper wave in turn diminishes the amplitude of the lower. This result holds regardless the value for the relative phase. Whereas one wave's amplitude growth is supported by the other wave, that growth comes at the cost of diminishing the amplitude of its partner. We conclude that no matter what the relative phase relations, no mutual wave resonance can occur for the background flow profile of Figure 61.10 so there is no instability.

61.6.9 Further study

The linear sheared velocity profile in an unbounded domain was first analyzed by *Rayleigh* (1894) (volume II, page 393), and it forms the basis for most subsequent treatments, such as *Chandrasekhar* (1961), *Drazin and Reid* (2004), *Vallis* (2017), and *Smyth and Carpenter* (2019).

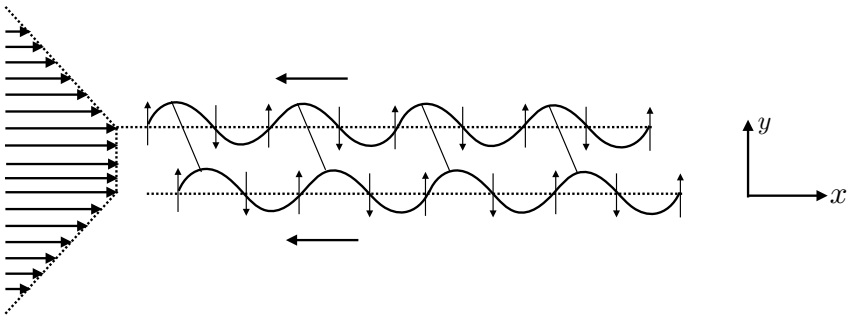

FIGURE 61.10: Two edge waves riding on their respective velocity jumps. There is no inflection point for this velocity profile, so that the velocity profile is stable according to the Rayleigh inflection point theorem from Section 61.5.1. We can mechanistically understand this result by noting the that two edge waves have a phase velocity in the same direction. Consequently, the waves cannot enter into the mutual resonance condition needed to create exponential growth. In this sketch, the secondary circulation from the lower wave enhances the amplitude of the upper wave. However, the upper wave diminishes the amplitude of the lower wave. Any other phase arrangement results in a similar situation whereby the two waves cannot mutually enhance each other's amplitude.

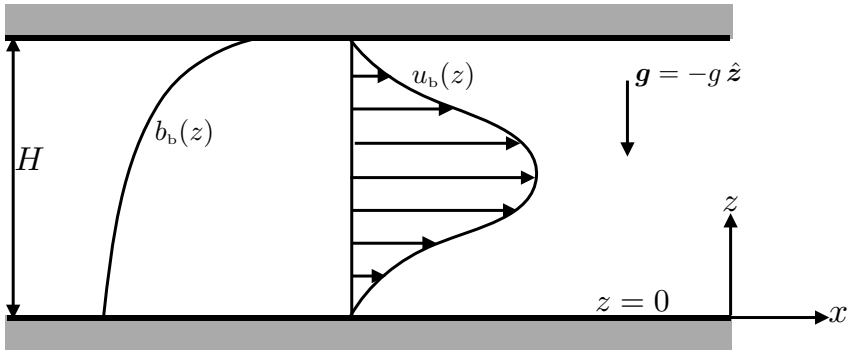

FIGURE 61.11: Schematic of the flow configuration used to examine stratified shear instability. The fluid is contained within a vertically bounded yet horizontally unbounded domain, with no-normal flow at the top and bottom meaning that the vertical flow vanishes at these boundaries, $w(0) = w(H) = 0$. The background flow is zonal with a vertical shear, $u_b(z)\,\hat{\boldsymbol{x}}$. The background buoyancy, $b_b(z)$, is stably stratified with $\mathrm{d}b_b/\mathrm{d}z = N^2(z) > 0$. The analysis in Section 61.7 reveals that the flow is stable if the gradient Richardson number, $\mathrm{Ri} = N^2/(\mathrm{d}u_b/\mathrm{d}z)^2$, is everywhere less than the critical value of 1/4. In contrast, the flow satisfies a necessary (though not sufficient) condition for shear instability if the Richardson number somewhere drops below 1/4.

In particular, the treatment of *Smyth and Carpenter* (2019) offers many insights into the nature of the wave phases and phase speeds, with the presentation in this section emulating much from theirs. This video from Prof. Mollo-Christensen provides a pedagogical introduction to a variety of instabilities.

61.7 Integral conditions for stratified shear stability/instability

In this section we examine the stability of a vertically sheared zonal flow in the presence of gravity and with a gravitationally stable vertical buoyancy stratification. The fluid is contained within a vertically bounded domain yet with no boundaries in the horizontal, with Figure 61.11 providing an illustration of the configuration. Much in this discussion reflects that given for the meridionally sheared zonal flow in Section 61.5, here with the added feature of buoyancy stratification along with a slight increase in algebraic complexity.

61.7.1 Governing equations

We formulate the problem using the inviscid and adiabatic Boussinesq ocean equations in a rotating reference frame as developed in Section 29.1.6, with the governing equations given by

$$\partial_t \boldsymbol{v} + (\boldsymbol{v} \cdot \nabla)\boldsymbol{v} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{v} = -\nabla\varphi + b\,\hat{\boldsymbol{z}} \tag{61.129a}$$

$$(\partial_t + \boldsymbol{v} \cdot \nabla)\, b = 0 \tag{61.129b}$$

$$\nabla \cdot \boldsymbol{v} = 0, \tag{61.129c}$$

where b is the buoyancy, φ is the pressure divided by the Boussinesq reference density, and $\boldsymbol{v}$ is the non-divergent velocity.

The Coriolis acceleration generally plays a minor role in the mechanics of stratified shear instabilities, since the space-time scales are far too small for the Coriolis acceleration to play a noticeable role in the dynamics. We thus set $f = 0$ in this section. In this case,

$$\boldsymbol{v} = u_{\mathrm{b}}(z)\,\hat{\boldsymbol{x}} + v_{\mathrm{b}}(z)\,\hat{\boldsymbol{y}}, \tag{61.130}$$

is an exact solution to the inviscid equations (61.129a)-(61.129c) if the background pressure has a zero horizontal gradient.[7] Evidently, the static and depth dependent horizontal flow (61.130) is an exact solution to the inviscid equations of motion in the absence of a Coriolis acceleration. It represents an unforced (free) mode for inviscid hydrostatic flow with pressure, $\varphi(z)$, and buoyancy $b(z)$, in exact hydrostatic balance.

With zero Coriolis acceleration, it is sufficient to orient the background flow along the $\hat{\boldsymbol{x}}$ axis so that we set $v_{\mathrm{b}} = 0$ in the following. We can further make use of Squire's theorem (Section 61.2) to note that the most unstable perturbation is two-dimensional and in the x-z plane (the plane of the background flow). We thus focus on stability of two-dimensional flows in the form

$$\boldsymbol{v} = [u_{\mathrm{b}}(z) + u'(x,z,t)]\,\hat{\boldsymbol{x}} + w'(x,z,t)\,\hat{\boldsymbol{z}}, \tag{61.131}$$

where $u'\,\hat{\boldsymbol{x}} + w'\,\hat{\boldsymbol{z}}$ is the non-divergent perturbation flow in the x-z plane

$$\partial_x u' + \partial_z w' = 0. \tag{61.132}$$

Given the above flow perturbation, we decompose the buoyancy and pressure fields according to

$$\varphi = \varphi_{\mathrm{b}}(z) + \varphi'(x,z,t) \quad \text{and} \quad b = b_{\mathrm{b}}(z) + b'(x,z,t), \tag{61.133}$$

where

$$\frac{\mathrm{d}\varphi_{\mathrm{b}}}{\mathrm{d}z} = b_{\mathrm{b}} \quad \text{and} \quad \frac{\mathrm{d}b_{\mathrm{b}}}{\mathrm{d}z} = N^2 > 0. \tag{61.134}$$

In this manner, the governing equations (61.129a)-(61.129c) take the form

$$\partial_t u' + (u_{\mathrm{b}} + u')\,\partial_x u' + w'\,\partial_z(u_{\mathrm{b}} + u') = -\partial_x \varphi' \tag{61.135a}$$

$$\partial_t w' + (u_{\mathrm{b}} + u')\,\partial_x w' + w'\,\partial_z w' = -\partial_z \varphi' + b' \tag{61.135b}$$

$$\partial_t b' + (u_{\mathrm{b}} + u')\,\partial_x b' + w'\,\partial_z b' = -w'\,N^2 \tag{61.135c}$$

$$\partial_x u' + \partial_z w' = 0. \tag{61.135d}$$

[7] This point is noted in Section 21 of *Drazin and Reid* (2004).

61.7.2 The linear vorticity equation

To develop an integral condition for stability, linearize the governing equations (61.135a)-(61.135d) (i.e., drop all terms with products of primed fields) to have

$$\partial_t u' + u_{\mathrm{b}}\,\partial_x u' + w'\,\partial_z u_{\mathrm{b}} = -\partial_x \varphi' \tag{61.136a}$$

$$\partial_t w' + u_{\mathrm{b}}\,\partial_x w' = -\partial_z \varphi' + b' \tag{61.136b}$$

$$(\partial_t + u_{\mathrm{b}}\,\partial_x) b' = -w'\,N^2 \tag{61.136c}$$

$$\partial_x u' + \partial_z w' = 0. \tag{61.136d}$$

Taking the z-derivative of the zonal equation (61.136a) and the x-derivative of the vertical equation (61.136b), and then subtracting, eliminates the pressure gradient to render

$$\partial_t(\partial_z u' - \partial_x w') + \partial_z(u_{\mathrm{b}}\,\partial_x u') - u_{\mathrm{b}}\,\partial_{xx} w' + \partial_z(w'\,\partial_z u_{\mathrm{b}}) = -\partial_x b'. \tag{61.137}$$

A bit of rearrangement, and use of the continuity equation (61.136d), yields the linearized vorticity equation

$$(\partial_t + u_{\mathrm{b}}\,\partial_x)(\partial_z u' - \partial_x w') + w'\,\partial_{zz} u_{\mathrm{b}} = -\partial_x b', \tag{61.138}$$

with

$$\partial_z u' - \partial_x w' = \hat{\boldsymbol{y}} \cdot (\nabla \times \boldsymbol{v}') \tag{61.139}$$

the meridional component to the vorticity of the fluctuating flow.

Since the x-z flow is non-divergent (equation (61.136d)), it is convenient to introduce a zonal-depth streamfunction

$$u'\,\hat{\boldsymbol{x}} + w'\,\hat{\boldsymbol{z}} = \hat{\boldsymbol{y}} \times \nabla\psi = \partial_z\psi\,\hat{\boldsymbol{x}} - \partial_x\psi\,\hat{\boldsymbol{z}}, \tag{61.140}$$

in which case the linear vorticity equation (61.138) becomes

$$(\partial_t + u_{\mathrm{b}}\,\partial_x)(\partial_{xx} + \partial_{zz})\psi - \partial_x\psi\,\partial_{zz} u_{\mathrm{b}} = -\partial_x b', \tag{61.141}$$

where the meridional component to the vorticity is given by the Laplacian of the streamfunction

$$\hat{\boldsymbol{y}} \cdot (\nabla \times \boldsymbol{v}') = (\partial_{xx} + \partial_{zz})\psi. \tag{61.142}$$

Likewise, the linear buoyancy equation (61.136c) becomes

$$(\partial_t + u_{\mathrm{b}}\,\partial_x) b' = \partial_x\psi\,N^2. \tag{61.143}$$

Since the fluid is contained by a top and bottom boundary as per Figure 61.11, the no-normal flow condition for the vertical velocity,

$$w' = 0 \quad \text{at } z = 0, H, \tag{61.144}$$

means that the streamfunction is a spatial constant along the top and bottom boundaries

$$\partial_x\psi = 0 \quad \text{at } z = 0, H. \tag{61.145}$$

Without loss of generality we take these constant streamfunction values to be zero, thus rendering the homogeneous Dirichlet boundary conditions

$$\psi = 0 \quad \text{at } z = 0, H. \tag{61.146}$$

61.7.3 Taylor-Goldstein equation

The vorticity equation (61.141) and buoyancy equation (61.143) are two coupled linear partial differential equations with independent variables, (x, z, t), and with z-dependent coefficients via $\mathrm{d}^2 u_\mathsf{b}(z)/\mathrm{d}z^2$ and $N^2(z)$. To study the stability of this flow, we pursue a modal analysis based on the wave ansatz

$$\psi(x, z, t) = \tilde{\psi}(z)\, \mathrm{e}^{\mathrm{i}\, k\, (x - c\, t)} \quad \text{and} \quad b'(x, z, t) = \tilde{b}(z)\, \mathrm{e}^{\mathrm{i}\, k\, (x - c\, t)}, \tag{61.147}$$

which accords with the wave ansatz (61.147) used to study stability of meridionally sheared flows in Section 61.4. In particular, the phase velocity,

$$\boldsymbol{c}_\mathsf{p} = c\, \hat{\boldsymbol{x}} = (\omega/k)\, \hat{\boldsymbol{x}}, \tag{61.148}$$

follows the conventions in Section 61.4.1. Use of the ansatz (61.147) brings the vorticity equation (61.141) and buoyancy equation (61.143) to

$$(-\omega + u_\mathsf{b}\, k)(-k^2 + \partial_{zz})\tilde{\psi} - k\, \tilde{\psi}\, \partial_{zz} u_\mathsf{b} = -k\, \tilde{b} \tag{61.149a}$$

$$(-\omega + u_\mathsf{b}\, k)\tilde{b} = -k\, \tilde{\psi}\, N^2. \tag{61.149b}$$

Substituting the buoyancy equation (61.149b) into the vorticity equation (61.149a) leads to the *Taylor-Goldstein equation* for the streamfunction

$$(u_\mathsf{b} - c)\, \left[\frac{\mathrm{d}^2}{\mathrm{d}z^2} - k^2\right] \tilde{\psi} + \left[\frac{N^2}{u_\mathsf{b} - c} - \frac{\mathrm{d}^2 u_\mathsf{b}}{\mathrm{d}z^2}\right] \tilde{\psi} = 0. \tag{61.150}$$

In the special case of $N^2 = 0$ and with z swapped to y, the Taylor-Goldstein equation reduces to the Rayleigh equation (61.35).

61.7.4 Richardson number and the stability conditions

An inspired transformation of the Taylor-Goldstein equation

To develop conditions for stability/instability, we make the inspired transformation of the streamfunction to

$$\tilde{\psi} = \tilde{\phi}\, \sqrt{u_\mathsf{b} - c} \quad \text{and} \quad \tilde{\phi}(0) = \tilde{\phi}(H) = 0. \tag{61.151}$$

A bit of algebra yields the second derivative

$$(u_\mathsf{b} - c)\, \frac{\mathrm{d}^2 \tilde{\psi}}{\mathrm{d}z^2} = \left[-\frac{1}{4\, (u_\mathsf{b} - c)^{1/2}} \left(\frac{\mathrm{d}u_\mathsf{b}}{\mathrm{d}z}\right)^2 + \frac{(u_\mathsf{b} - c)^{1/2}}{2}\, \frac{\mathrm{d}^2 u_\mathsf{b}}{\mathrm{d}z^2}\right] \tilde{\phi} + (u_\mathsf{b} - c)^{1/2}\, \frac{\mathrm{d}}{\mathrm{d}z}\left[(u_\mathsf{b} - c)\, \frac{\mathrm{d}\tilde{\phi}}{\mathrm{d}z}\right], \tag{61.152}$$

and the consequent transformation of the Taylor-Goldstein equation (61.150)

$$\left[\frac{1}{u_\mathsf{b} - c}\, \left[N^2 - \frac{1}{4}\left(\frac{\mathrm{d}u_\mathsf{b}}{\mathrm{d}z}\right)^2\right] - (u_\mathsf{b} - c)\, k^2 - \frac{1}{2}\, \frac{\mathrm{d}^2 u_\mathsf{b}}{\mathrm{d}z^2}\right] \tilde{\phi} + \frac{\mathrm{d}}{\mathrm{d}z}\left[(u_\mathsf{b} - c)\, \frac{\mathrm{d}\tilde{\phi}}{\mathrm{d}z}\right] = 0. \tag{61.153}$$

This form of the Taylor-Goldstein equation is actually a bit less compact than the original form (61.150). Even so, as we now show, it offers an elegant stability condition in terms of the gradient Richardson number.

Sufficient condition for stability and necessary condition for instability

To develop an integral stability theorem, multiply equation (61.153) by the complex conjugate, $\tilde{\phi}^*$, and integrate over the depth range $0 \le z \le H$. Performing this integral on the derivative term in equation (61.153) leads to

$$\int_0^H \tilde{\phi}^* \frac{\mathrm{d}}{\mathrm{d}z}\left[(u_\mathrm{b}-c)\,\frac{\mathrm{d}\tilde{\phi}}{\mathrm{d}z}\right]\mathrm{d}z = \int_0^H \frac{\mathrm{d}}{\mathrm{d}z}\left[\tilde{\phi}^*\,(u_\mathrm{b}-c)\,\frac{\mathrm{d}\tilde{\phi}}{\mathrm{d}z}\right]\mathrm{d}z - \int_0^H (u_\mathrm{b}-c)\left|\frac{\mathrm{d}\tilde{\phi}}{\mathrm{d}z}\right|^2\mathrm{d}z, \quad (61.154)$$

with the total derivative term vanishing through use of the homogeneous Dirichlet boundary conditions in equation (61.151). Rearrangement thus renders

$$\int_0^H \frac{|\tilde{\phi}|^2}{u_\mathrm{b}-c}\left[N^2 - \frac{1}{4}\left(\frac{\mathrm{d}u_\mathrm{b}}{\mathrm{d}z}\right)^2\right]\mathrm{d}z = \int_0^H (u_\mathrm{b}-c)\left[k^2\,|\tilde{\phi}|^2 + \left|\frac{\mathrm{d}\tilde{\phi}}{\mathrm{d}z}\right|^2\right]\mathrm{d}z + \frac{1}{2}\int_0^H \frac{\mathrm{d}^2 u_\mathrm{b}}{\mathrm{d}z^2}\,|\tilde{\phi}|^2\,\mathrm{d}z. \quad (61.155)$$

This integral condition provides the basis for developing a sufficient condition for stability and, conversely, a necessary condition for instability.

The final term on the right hand side of equation (61.155) is real, so that the imaginary part of this equation is given by

$$c_\mathrm{i}\int_0^H \frac{|\tilde{\phi}|^2\,(\mathrm{d}u_\mathrm{b}/\mathrm{d}z)^2\,(\mathrm{Ri}-1/4)}{|u_\mathrm{b}-c|^2}\,\mathrm{d}z = -c_\mathrm{i}\int_0^H \left[k^2\,|\tilde{\phi}|^2 + \left|\frac{\mathrm{d}\tilde{\phi}}{\mathrm{d}z}\right|^2\right]\mathrm{d}z, \quad (61.156)$$

where we used the identity

$$\frac{1}{u_\mathrm{b}-c} = \frac{u_\mathrm{b}-c^*}{(u_\mathrm{b}-c)\,(u_\mathrm{b}-c^*)} = \frac{u_\mathrm{b}-c_\mathrm{r}+\mathrm{i}\,c_\mathrm{i}}{|u_\mathrm{b}-c|^2}, \quad (61.157)$$

and introduced the *gradient Richardson number* (assuming nonzero vertical shear)

$$\mathrm{Ri} = \frac{N^2}{(\mathrm{d}u_\mathrm{b}/\mathrm{d}z)^2}. \quad (61.158)$$

Evidently, if the Richardson number is greater than the critical value,

$$\mathrm{Ri}_\mathrm{crit} = 1/4, \quad (61.159)$$

throughout the vertical column, then the only way to satisfy equation (61.156) is for $c_\mathrm{i} = 0$, which establishes a sufficient condition for stratified shear stability

$$\mathrm{Ri}(z) > \mathrm{Ri}_\mathrm{crit} = 1/4 \quad \forall\, z \in [0,H] \Longrightarrow \text{sufficient condition for stability.} \quad (61.160)$$

Conversely, a necessary condition for stratified shear instability is for the Richardson number to be less than 1/4 somewhere in the vertical column

$$\mathrm{Ri}(z) < \mathrm{Ri}_\mathrm{crit} = 1/4 \quad \text{for some } z \in [0,H] \Longrightarrow \text{necessary condition for instability.} \quad (61.161)$$

We emphasize that a Richardson number less than the critical value is necessary but not sufficient for stratified shear instability. Although for many purposes it is sufficient, there are examples

where it is not. For example, flows near boundaries generally require a smaller Richardson number to go unstable. Even so, for most geophysical applications, $\mathrm{Ri}_{\mathrm{crit}} = 1/4$ is a very good indicator for stratified shear instability.

Comparison to barotropic shear instability

The gradient Richardson number (61.158) is the ratio of the buoyancy stratification to the vertical shear of the horizontal flow. It is notable that the necessary condition for instability, $\mathrm{Ri} < 1/4$, does not depend on the curvature of the background flow, which contrasts to the case of barotropic shear instability studied in Section 61.5. For stratified shear instability, there is a direct struggle by the vertical shear to overcome the stabilizing effects from the background buoyancy stratification.

61.7.5 Richardson number and mixing energetics

The gradient Richardson number (61.158) provides a measure of the struggle between stabilizing effects from vertical stratification to the destabilizing effects from vertical shear. Here we provide an interpretation of the Richardson number in terms of mixing energetics, with mixing induced by the stratified shear instability. For this purpose we examine the thought experiment illustrated in Figure 61.12, with the analysis emulating that in Section 60.3.6 for mixing induced by Kelvin-Helmholtz instability.

Initial and final states of the thought experiment

Consider a Boussinesq ocean whose initial flow has a linear shear and a linear density profile

$$u_{\mathrm{b}}(z) = U_0 + (z/H)\,\delta U \quad \text{and} \quad \rho_{\mathrm{b}}(z) = \rho_{\circ} - (z/H)\,\delta\rho, \tag{61.162}$$

where U_0 is the velocity at $z = 0$, $\rho_{\circ}$ is the Boussinesq reference density, $\delta\rho > 0$ is a constant that sets the strength of the vertical stratification, and δU is a constant that sets the strength of the vertical shear. The initial Richardson number is assumed to be less than the critical value of 1/4,

$$\mathrm{Ri} = \frac{N^2}{(\partial_z u_{\mathrm{b}})^2} = \frac{g}{\rho_{\circ}} \frac{(\delta\rho/H)}{(\delta U/H)^2} < 1/4, \tag{61.163}$$

thus satisfying the necessary condition for stratified shear instability. For the final state, assume the fluid completely mixes to produce a uniform density and uniform velocity, which are taken to be the vertical average of the initial values

$$\overline{\rho} = U_0 + \delta U/2 \quad \text{and} \quad \overline{\rho} = \rho_{\circ} - \delta\rho/2. \tag{61.164}$$

We might think of this configuration as a tiny region where the shear and density are well approximated with a linear vertical profile, and where shear induced mixing homogenizes the density and velocity.

Change in the potential and kinetic energies per area

The difference in the potential energy (per horizontal area) between the final and initial states is given by

$$P_{\mathsf{final}} - P_{\mathsf{init}} = g \int_0^H z\,[\overline{\rho} - \rho_{\mathrm{b}}(z)]\,\mathrm{d}z = g\,\delta\rho\,H^2/12. \tag{61.165}$$

An increase in potential energy upon mixing is anticipated by the study in Section 60.3.6 of Kelvin-Helmholtz induced mixing, and from the more general examination of potential energy

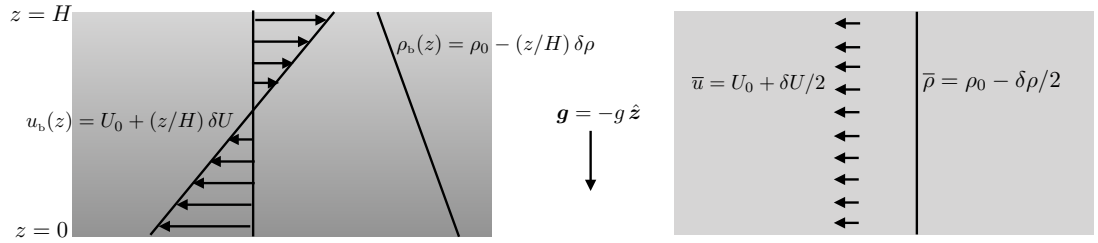

FIGURE 61.12: Left panel: initial conditions for a linearly stratified flow specified by a constant density parameter, $\delta\rho > 0$, that sets the strength of the linear stratification, and a constant shear parameter, δU, that sets the strength of the linear vertical shear. Right panel: a homogenized final state in which the density equals to the average of the initial density, $\overline{\rho} = \rho_0 - \delta\rho/2$, and the velocity equals to the average of the initial velocity, $\overline{u} = U_0 + \delta U/2$. The ratio of the potential energy change to the kinetic energy change is proportional to the gradient Richardson number as given by equation (61.167).

in Section 26.2.6. The basic idea is that vertical mixing raises the center of mass of the fluid, thus increasing the gravitational potential energy.

Where does the energy come from to raise the center of mass? For this thought experiment it must come from the kinetic energy, as that is the only other energy source. We thus anticipate that the kinetic energy decreases upon mixing. Indeed, the change in the kinetic energy (per horizontal area) is given by

$$K_{\text{final}} - K_{\text{init}} = \frac{\rho_0}{2}\int_0^H (\overline{u}^2 - u_b^2)\,\mathrm{d}z = -\frac{\rho_0}{2}\int_0^H (u_b - \overline{u})^2\,\mathrm{d}z = -\rho_0\, H\,(\delta U)^2/24. \tag{61.166}$$

A decrease in kinetic energy follows since the square of a spatially variable velocity is always greater than the square of its spatial average.

Taking the absolute ratio of the change in potential energy to the change in kinetic energy renders

$$\left|\frac{P_{\text{final}} - P_{\text{init}}}{K_{\text{final}} - K_{\text{init}}}\right| = \frac{2\,g}{\rho_0}\,\frac{\delta\rho/H}{(\delta U/H)^2} = 2\,\text{Ri}, \tag{61.167}$$

where the second equality introduced the Richardson number (61.163) of the initial state. Evidently, the Richardson number in this thought experiment is directly proportional to the absolute ratio of the potential energy change upon mixing to the kinetic energy change upon mixing. In Exercise 61.3 we find a similar result for a two-layer system, yet with a different proportionality constant. These two thought experiments support the general connection between the Richardson number and the energy ratio. Namely, the numerator is proportional to the potential energy increase due to mixing (presenting a barrier to mixing), and the denominator is proportional to the kinetic energy available from the shear to overcome the potential energy barrier.

61.7.6 Constraining the phase velocity of unstable waves

The inspired transformation (61.151) is not the only one that can extract useful information about stability from the Taylor-Goldstein equation (61.150). Another transformation, following *Howard* (1961), is motivated by considering the vertical displacement of a fluid particle under small amplitude linear waves, with this approach following that given in Section 61.4.5, where we considered meridional displacements of fluid particles. The particle following approach motivates a transformation of the Taylor-Goldstein equation that then leads to constraints on the real and imaginary part of the phase velocity for unstable waves. That is, we derive conditions that must be satisfied for a wave to grow when placed in an unstable background flow. The development leads to the *critical height theorem* as well as *Howard's semi-circle theorem*, which are generalizations of the critical latitude theorem from Section 61.5.3.

Taylor-Goldstein equation in terms of a fluid particle's vertical displacement

Introduce the field, $\eta(x,z,t)$, which measures the vertical displacement of a fluid particle that has its rest vertical position at z. As such, this field satisfies

$$w' = [\partial_t + (u' + u_\mathsf{b})\,\partial_x]\eta \approx (\partial_t + u_\mathsf{b}\,\partial_x)\eta, \tag{61.168}$$

with the linearization step following from the assumed small displacements. As defined, $\eta(x,z,t)$ is the vertical displacement of a fluid particle that has its rest position at z. Now assume the displacements are generated by small amplitude waves of the form

$$\eta(x,z,t) = \tilde{\eta}(z)\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)}. \tag{61.169}$$

The corresponding wave ansatz for the vertical velocity,

$$w' = -\partial_x\psi = -\mathrm{i}\,k\,\tilde{\psi}(z)\,\mathrm{e}^{\mathrm{i}\,k\,(x-c\,t)}, \tag{61.170}$$

leads to the relation between the streamfunction amplitude and the particle displacement amplitude

$$\tilde{\psi} = -(u_\mathsf{b} - c)\tilde{\eta}. \tag{61.171}$$

The corresponding relation between second derivatives

$$-(u_\mathsf{b} - c)\,\frac{\mathrm{d}^2\tilde{\psi}}{\mathrm{d}z^2} = \frac{\mathrm{d}}{\mathrm{d}z}\left[(u_\mathsf{b} - c)^2\,\frac{\mathrm{d}\tilde{\eta}}{\mathrm{d}z}\right] + \tilde{\eta}\,(u_\mathsf{b} - c)\,\frac{\mathrm{d}^2 u_\mathsf{b}}{\mathrm{d}z^2} \tag{61.172}$$

leads to the Taylor-Goldstein equation (61.150) written in terms of the vertical particle displacement

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[(u_\mathsf{b} - c)^2\,\frac{\mathrm{d}\tilde{\eta}}{\mathrm{d}z}\right] = [-N^2 + k^2\,(u_\mathsf{b} - c)^2]\,\tilde{\eta} \quad \text{with } \tilde{\eta}(0) = \tilde{\eta}(H) = 0. \tag{61.173}$$

Multiplying by $\tilde{\eta}^*$, then integrating over the vertical extent of the domain and using the homogeneous Dirichlet boundary conditions, $\tilde{\eta}(0) = \tilde{\eta}(H) = 0$, leads to the identity

$$\int_0^H N^2\,|\tilde{\eta}|^2\,\mathrm{d}z = \int_0^H \left[k^2\,|\tilde{\eta}|^2 + \left|\frac{\mathrm{d}\tilde{\eta}}{\mathrm{d}z}\right|^2\right](u_\mathsf{b} - c)^2\,\mathrm{d}z. \tag{61.174}$$

The critical height theorem

The imaginary part of the integral condition (61.174) leads to the constraint

$$2\,c_\mathsf{i}\int_0^H \left[k^2\,|\tilde{\eta}|^2 + \left|\frac{\mathrm{d}\tilde{\eta}}{\mathrm{d}z}\right|^2\right](u_\mathsf{b} - c_\mathsf{r})\,\mathrm{d}z = 0, \tag{61.175}$$

where we used

$$(u_\mathsf{b} - c)^2 = (u_\mathsf{b} - c_\mathsf{r})^2 - c_\mathsf{i}^2 - 2\,\mathrm{i}\,c_\mathsf{i}\,(u_\mathsf{b} - c_\mathsf{r}). \tag{61.176}$$

The constraint (61.175) holds in the presence of an instability ($c_\mathsf{i} \neq 0$) only if the real part of the phase velocity lives within the bounds of the background flow

$$u_\mathsf{b}^{\min} < c_\mathsf{r} < u_\mathsf{b}^{\max} \Longrightarrow u_\mathsf{b}(z_{\mathrm{crit}}) = c_\mathsf{r}. \tag{61.177}$$

That is, for a wave to grow in the presence of an unstable background flow, its phase velocity must have a real part within the bounds of the background flow. It follows that there is a vertical

position, $z = z_{\text{crit}}$, where the background flow and the real part of the phase velocity are equal,

$$u_{\text{b}}(z_{\text{crit}}) = c_{\text{r}}. \tag{61.178}$$

This *critical height theorem* is the vertical analog to the critical latitude theorem from Section 61.5.3. Evidently, for a wave to grow, the real part of its phase velocity must match that of the background flow at no less than one vertical position. Otherwise, if c_{r} is outside of the bound (61.177), then the wave simply moves too fast for it to extract energy from the background flow.

Howard's semi-circle theorem

The real part of the integral condition (61.174) leads to the constraint

$$\int_0^H \mathcal{Q}\,[(u_{\text{b}} - c_{\text{r}})^2 - c_{\text{i}}^2]\,\mathrm{d}z \geq 0, \tag{61.179}$$

where we introduced the shorthand for the non-negative quantity

$$\mathcal{Q} = k^2\,|\tilde{\eta}|^2 + \left|\frac{\mathrm{d}\tilde{\eta}}{\mathrm{d}z}\right|^2 \geq 0. \tag{61.180}$$

For the case with $c_{\text{i}} \neq 0$, which means there is an unstable wave, then equation (61.175) implies

$$2\int_0^H \mathcal{Q}\,(u_{\text{b}} - c_{\text{r}})\,\mathrm{d}z = 0. \tag{61.181}$$

We can thus add this term to the constraint (61.179) to render

$$\int_0^H \mathcal{Q}\,[(u_{\text{b}} - c_{\text{r}})^2 - c_{\text{i}}^2]\,\mathrm{d}z = \int_0^H \mathcal{Q}\,[(u_{\text{b}} - c_{\text{r}})^2 - c_{\text{i}}^2 + 2\,c_{\text{r}}\,(u_{\text{b}} - c_{\text{r}})]\,\mathrm{d}z \geq 0, \tag{61.182}$$

which then leads to

$$\int_0^H \mathcal{Q}\,u_{\text{b}}^2\,\mathrm{d}z \geq \int_0^H \mathcal{Q}\,(c_{\text{r}}^2 + c_{\text{i}}^2)\,\mathrm{d}z \Longrightarrow (c_{\text{r}}^2 + c_{\text{i}}^2) \leq \frac{\int_0^H \mathcal{Q}\,u_{\text{b}}^2\,\mathrm{d}z}{\int_0^H \mathcal{Q}\,\mathrm{d}z}. \tag{61.183}$$

This inequality places a constraint on the real and imaginary part of the phase velocity. However, it is not so practical since we need to specify $\mathcal{Q}$ from equation (61.180), which requires information about the wavenumber and particle displacements.

A more useful practical constraint can be derived by starting from the inequality

$$\int_0^H \mathcal{Q}\,(u_{\text{b}} - u_{\text{b}}^{\min})\,(u_{\text{b}} - u_{\text{b}}^{\max})\,\mathrm{d}z = \int_0^H \mathcal{Q}\,[u_{\text{b}}^2 - u_{\text{b}}\,u_{\text{b}}^{\min} - u_{\text{b}}\,u_{\text{b}}^{\max} + u_{\text{b}}^{\min}\,u_{\text{b}}^{\max}]\,\mathrm{d}z \leq 0, \tag{61.184}$$

which follows from the definition of the $u_{\text{b}}^{\min}$ and $u_{\text{b}}^{\max}$, and recalling that $\mathcal{Q} \geq 0$. Making use of equation (61.183) allows us to replace u_{b}^2 with $c_{\text{r}}^2 + c_{\text{i}}^2$ and still maintain the inequality, so that

$$\int_0^H \mathcal{Q}\,[c_{\text{r}}^2 + c_{\text{i}}^2 - u_{\text{b}}\,(u_{\text{b}}^{\min} + u_{\text{b}}^{\max}) + u_{\text{b}}^{\min}\,u_{\text{b}}^{\max}]\,\mathrm{d}z \leq 0, \tag{61.185}$$

and use of the constraint (61.181) then allows us to replace u_{b} with c_{r} to have

$$\int_0^H \mathcal{Q}\,[c_{\text{r}}^2 + c_{\text{i}}^2 - c_{\text{r}}\,(u_{\text{b}}^{\min} + u_{\text{b}}^{\max}) + u_{\text{b}}^{\min}\,u_{\text{b}}^{\max}]\,\mathrm{d}z \leq 0. \tag{61.186}$$

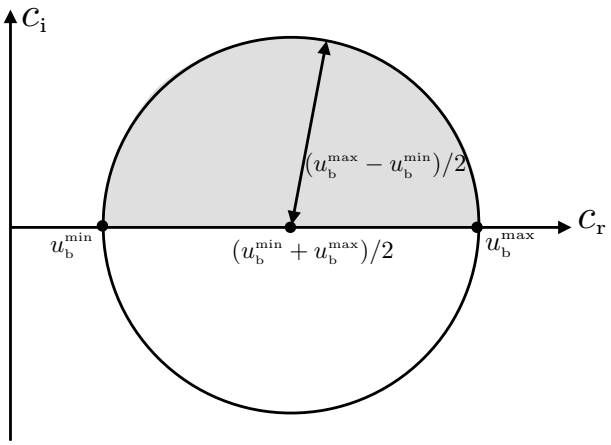

FIGURE 61.13: Illustrating Howard's semi-circle theorem (61.188) in the complex plane defined by the phase velocity. The semi-circle theorem says that growing waves (with $c_\mathrm{i} > 0$) in a sheared flow have their phase velocity within the gray region, with radius $(u_\mathrm{b}^\mathrm{max} - u_\mathrm{b}^\mathrm{min})/2$ and center along the real axis at $c_\mathrm{r} = (u_\mathrm{b}^\mathrm{min} + u_\mathrm{b}^\mathrm{max})/2$.

This constraint is more practical since it only involves the phase velocity and the maximum and minimum values of the background velocity, each of which are independent of z. Evidently, since $\mathcal{Q}$ is positive, we must have

$$c_\mathrm{r}^2 + c_\mathrm{i}^2 - c_\mathrm{r}\,(u_\mathrm{b}^\mathrm{min} + u_\mathrm{b}^\mathrm{max}) + u_\mathrm{b}^\mathrm{min}\,u_\mathrm{b}^\mathrm{max} \leq 0, \tag{61.187}$$

which can be rearranged to

$$[c_\mathrm{r} - (u_\mathrm{b}^\mathrm{min} + u_\mathrm{b}^\mathrm{max})/2]^2 + c_\mathrm{i}^2 \leq [(u_\mathrm{b}^\mathrm{max} - u_\mathrm{b}^\mathrm{min})/2]^2. \tag{61.188}$$

This constraint is depicted in Figure 61.13, where we see that unstable waves (with $c_\mathrm{i} > 0$) have phase velocities that sit within the semi-circle in the upper half of the complex plane whose center is along the real axis with $c_\mathrm{r} = (u_\mathrm{b}^\mathrm{min} + u_\mathrm{b}^\mathrm{max})/2$ and whose radius is $(u_\mathrm{b}^\mathrm{max} - u_\mathrm{b}^\mathrm{min})/2$.

The semi-circle theorem is particularly useful when designing numerical algorithms to find unstable waves. Also note that we derived this theorem starting from the case of a stratified shear layer. However, the same result holds for unstable waves in the presence of a meridionally sheared barotropic flow discussed as earlier in this chapter.

61.7.7 Further study

The $\mathrm{Ri} = 1/4$ stability argument was first presented by *Miles* (1961) and soon thereafter it was extended by *Howard* (1961). Our derivation of Howard's semi-circle theorem (61.188) follows Section 11.7 of *Kundu et al.* (2016).

61.8 A vertically sheared homogeneous fluid with a free surface

In this chapter we studied horizontal sheared flow in a homogeneous fluid, and then rotated the geometry to consider vertically sheared flow in a gravitationally stratified fluid. Here we consider a vertically sheared homogeneous fluid moving over a flat surface at $z = 0$ and with a free surface at $z = \eta$, as depicted in Figure 61.14. Directly translating the analysis of stratified shear instability from Section 61.7 to the present case, we might presume that since the Richardson number vanishes here, then any flow satisfies the necessary condition for vertical shear instability. However, besides having a vanishing buoyancy (since the fluid is homogeneous), the free upper surface further distinguishes this configuration from the vertically stratified shear instability studied in Section 61.7 (where we assumed the flow to occur between two rigid boundaries). The

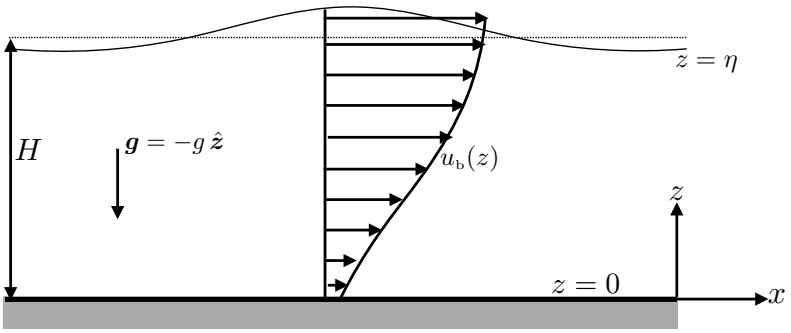

FIGURE 61.14: Schematic of the flow configuration used to examine vertical shear instability in a homogeneous inviscid flow with a free upper surface. The background flow is zonal with a vertical shear, $u_\mathrm{b}(z)\,\hat{\boldsymbol{x}}$. The fluid domain has a rigid lower bound at $z = 0$, where the bottom kinematic boundary condition means that $w(0) = 0$. The upper surface is free at $z = \eta = H + \eta'(x,t)$, so that the linearized upper kinematic boundary condition is $(\partial_t + u_\mathrm{b}\,\partial_x)\,\eta' = w'$, and this boundary condition is evaluated at $z = H$ rather than $z = \eta$.

presence of a free surface removes the ability to make general statements about the stability, thus illustrating the importance of boundary conditions when studying modal instabilities. This section also serves to highlight the role of non-hydrostatic pressure for enabling vertical shear instability.

61.8.1 Linearized governing equations

The linearized governing equations are given by equations (61.136a)-(61.136d) with identically zero buoyancy

$$\partial_t u' + u_\mathrm{b}\,\partial_x u' + w'\,\partial_z u_\mathrm{b} = -\partial_x \varphi' \tag{61.189a}$$
$$\partial_t w' + u_\mathrm{b}\,\partial_x w' = -\partial_z \varphi' \tag{61.189b}$$
$$\partial_x u' + \partial_z w' = 0, \tag{61.189c}$$

along with the bottom kinematic boundary condition and the linearized kinematic free surface boundary condition

$$w' = 0 \quad \text{at } z = 0 \tag{61.190a}$$
$$(\partial_t + u_\mathrm{b}\,\partial_x)\,\eta' = w' \quad \text{at } z = H. \tag{61.190b}$$

Since the x-z flow is non-divergent we can introduce a streamfunction as in equation (61.140)

$$u'\,\hat{\boldsymbol{x}} + w'\,\hat{\boldsymbol{z}} = \hat{\boldsymbol{y}} \times \nabla\psi = \partial_z \psi\,\hat{\boldsymbol{x}} - \partial_x \psi\,\hat{\boldsymbol{z}}, \tag{61.191}$$

which yields the governing equations

$$(\partial_t + u_\mathrm{b}\,\partial_x)\,\partial_z \psi - \partial_x \psi\,\partial_z u_\mathrm{b} = -\partial_x \varphi' \quad \text{for } 0 < z < H \tag{61.192a}$$
$$(\partial_t + u_\mathrm{b}\,\partial_x)\,\partial_x \psi = \partial_z \varphi' \quad \text{for } 0 < z < H \tag{61.192b}$$
$$\psi = 0 \quad \text{at } z = 0 \tag{61.192c}$$
$$(\partial_t + u_\mathrm{b}\,\partial_x)\eta' = -\partial_x \psi \quad \text{at } z = H. \tag{61.192d}$$

61.8.2 Hydrostatic fluctuations are stable

If we assume the fluctuations are hydrostatic then the zonal pressure gradient is given by the zonal derivative of the free surface (as in the case of a hydrostatic shallow water fluid),

$$\partial_x \varphi' = g\, \partial_x \eta', \tag{61.193}$$

so that the zonal velocity equation (61.192a) becomes

$$(\partial_t + u_{\mathrm{b}}\, \partial_x)\, \partial_z \psi - \partial_x \psi\, \partial_z u_{\mathrm{b}} = -g\, \partial_x \eta'. \tag{61.194}$$

Now assume the small amplitude fluctuations of the streamfunction and free surface take the propagating plane wave form

$$\psi(x,z,t) = \widetilde{\psi}(z)\, \mathrm{e}^{\mathrm{i}\, k\,(x-c\,t)} \quad \text{and} \quad \eta'(x,t) = \widetilde{\eta}\, \mathrm{e}^{\mathrm{i}\, k\,(x-c\,t)}. \tag{61.195}$$

For these fluctuations the kinematic boundary conditions (61.192c) and (61.192d) become

$$\widetilde{\psi} = 0 \qquad \text{at } z = 0 \tag{61.196a}$$

$$(u_{\mathrm{b}} - c)\widetilde{\eta} = -\widetilde{\psi} \quad \text{at } z = H. \tag{61.196b}$$

Similarly, the zonal velocity equation (61.194) renders the relations between the amplitude functions

$$(u_{\mathrm{b}} - c)\partial_z \widetilde{\psi} - \widetilde{\psi}\, \partial_z u_{\mathrm{b}} = -g\, \widetilde{\eta} \quad \text{for } 0 < z < H. \tag{61.197}$$

Dividing by $(u_{\mathrm{b}} - c)^2$ brings about

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[\frac{\widetilde{\psi}}{u_{\mathrm{b}} - c}\right] = -\frac{g\, \widetilde{\eta}}{(u_{\mathrm{b}} - c)^2}, \tag{61.198}$$

whose vertical integral renders

$$\left.\frac{\widetilde{\psi}}{u_{\mathrm{b}} - c}\right|_{z=H} - \left.\frac{\widetilde{\psi}}{u_{\mathrm{b}} - c}\right|_{z=0} = -g\, \widetilde{\eta} \int_0^H \frac{\mathrm{d}z}{(u_{\mathrm{b}} - c)^2}, \tag{61.199}$$

where we evaluated the upper integral limit at $z = H$ as per the linear theory. Making use of the kinematic boundary conditions (61.196a) and (61.196b) brings this equation into the form

$$g \int_0^H \frac{\mathrm{d}z}{(u_{\mathrm{b}} - c)^2} = 1. \tag{61.200}$$

This identity can only be satisfied if the phase velocity, c, has zero imaginary part, in which case we conclude that the fluctuations are stable to vertical shear instability. In particular, for u_{b} a constant we recover the case considered in Exercise 55.4 for gravity waves moving on a constant background flow, in which the phase velocity is $c = u_{\mathrm{b}} \pm \sqrt{g\, H} = u_{\mathrm{b}} \pm c_{\mathsf{grav}}$.

We understand why the hydrostatic fluctuations are stable by appealing to the discussion of shallow water dynamics in Section 35.2. In that section we observed that a homogeneous fluid layer with a hydrostatic pressure (i.e., a shallow water fluid layer) renders a horizontal pressure gradient that is depth independent, which in turn leads to a depth independent horizontal velocity. That is, the homogeneous hydrostatic fluid cannot support a vertical shear in the horizontal flow, so that there can be no vertical shear instability. That is, when studying stability of a vertically sheared homogeneous fluid layer, hydrostatic fluctuations are depth independent and so they cannot lead to a vertical shear instability.

61.8.3 Taylor-Goldstein equation

Accepting that unstable fluctuations must involve a non-hydrostatic pressure, we make use of the analysis in Section 61.7.3 for stratified shear instability, in which we formed the linearized vorticity equation and introduced the streamfunction to render the Taylor-Goldstein equation (61.150). Specializing Taylor-Goldstein to the case of zero buoyancy ($N^2 = 0$) yields

$$(u_\mathrm{b} - c)\left[\frac{\mathrm{d}^2}{\mathrm{d}z^2} - k^2\right]\tilde{\psi} = \frac{\mathrm{d}^2 u_\mathrm{b}}{\mathrm{d}z^2}\,\tilde{\psi} \tag{61.201a}$$

$$\widetilde{\psi} = 0 \qquad \text{at } z = 0 \tag{61.201b}$$

$$(u_\mathrm{b} - c)\widetilde{\eta} = -\widetilde{\psi} \qquad \text{at } z = H. \tag{61.201c}$$

In deriving the necessary condition for vertical shear instability in Section 61.7.4, we made use of the assumed rigid top and bottom boundaries to eliminate the two boundary contributions appearing in equation (61.154). Yet with a free surface the $z = H$ boundary contribution no longer vanishes, instead it satisfies the kinematic condition (61.201c).

61.8.4 Necessary conditions for instability

To develop an integral condition, rather than introduce the ansatz (61.151), we work directly with the Taylor-Goldstein equation (61.201a). Since $N^2 = 0$, the manipulations are quite similar to those used to derive the Rayleigh-Kuo inflection point theorem in Section 61.5.1. For this purpose, multiply the Taylor-Goldstein equation (61.151) by $\widetilde{\psi}^*$ and rearrange to yield

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[\widetilde{\psi}^*\,\frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z}\right] = \left[k^2 + \frac{1}{u_\mathrm{b} - c}\,\frac{\mathrm{d}^2 u_\mathrm{b}}{\mathrm{d}z^2}\right]|\widetilde{\psi}|^2 + \left|\frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z}\right|^2 \tag{61.202}$$

Vertical integration and use of the kinematic boundary conditions leads to

$$\widetilde{\psi}^*\,\frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z}\bigg|_{z=H} = \int_0^H \left[k^2\,|\widetilde{\psi}|^2 + \left|\frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z}\right|^2\right]\mathrm{d}z + \int_0^H \frac{\mathrm{d}^2 u_\mathrm{b}}{\mathrm{d}z^2}\,\frac{|\widetilde{\psi}|^2}{u_\mathrm{b} - c}\,\mathrm{d}z. \tag{61.203}$$

Taking the imaginary part of this equation and exposing the amplitude and phase for $\widetilde{\psi}$,

$$\widetilde{\psi} = |\widetilde{\psi}(z)|\,\mathrm{e}^{\mathrm{i}\,\alpha(z)}, \tag{61.204}$$

leads to

$$\left[|\widetilde{\psi}|^2\,\frac{\mathrm{d}\alpha}{\mathrm{d}z}\right]_{z=H} = c_\mathrm{i}\int_0^H \frac{\mathrm{d}^2 u_\mathrm{b}}{\mathrm{d}z^2}\,\frac{|\widetilde{\psi}|^2}{|u_\mathrm{b} - c|^2}\,\mathrm{d}z. \tag{61.205}$$

The left hand side vanishes for a rigid upper boundary, in which case we recover the Rayleigh-Kuo inflection point theorem (61.59). But with a free surface there are other situations that support instability since the left hand side is no longer zero. That is, allowing for a free surface opens up further avenues for instabilities. When developing necessary conditions for baroclinic instability in Section 62.8, we also find a fundamental role for boundary processes.

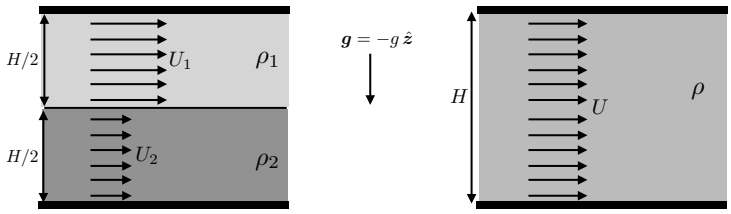

FIGURE 61.15: Initial (left) and final (right) conditions for a two-layer stratified flow that completely mixes its density and velocity. In Exercise 61.3 we work through the energetics of mixing and show that the ratio of the potential energy change to the kinetic energy change is proportional to a discrete version of the gradient Richardson number.

61.9 Exercises

EXERCISE 61.1: COMPLEX CONJUGATE FORMULA
In equations (61.45c) and (61.48) we made use of the identity

$$\mathrm{Im}\left[\widetilde{\psi}^* \, \partial_y \widetilde{\psi}\right] = -\,\mathrm{Im}\left[\widetilde{\psi} \, \partial_y \widetilde{\psi}^*\right]. \tag{61.206}$$

Derive this identity. Hint: make use of equation (61.49) for the streamfunction.

EXERCISE 61.2: FJØRTOFT'S THEOREM WITH SINH PROFILE AND $\beta \neq 0$
Consider the sinh velocity profile from Section 61.5.4. Show that with $\beta \neq 0$ the flow remains stable according to Fjørtoft's theorem.

EXERCISE 61.3: RICHARDSON NUMBER AND ENERGETICS OF MIXING
Rework the energetics from Section 61.7.5, only now with the two-layer stratified shear profile shown in Figure 61.15. In particular, compute the ratio of the potential energy increase to the kinetic energy decrease and show that this ratio is proportional to a discrete version of the gradient Richardson number

$$\frac{P_{\text{final}} - P_{\text{init}}}{K_{\text{init}} - K_{\text{final}}} \propto \mathrm{Ri}. \tag{61.207}$$

Assume a Boussinesq ocean for purposes of computing the kinetic energy. Hint: the solution to this exercise is detailed in Section 14.1 of *Cushman-Roisin and Beckers* (2011).

Chapter 62

QUASI-GEOSTROPHIC WAVES AND BAROCLINIC INSTABILITY

In this chapter we study waves and *baroclinic instability* in a continuously stratified quasi-geostrophic flow within a vertically bounded domain. The vertically bounded domain is more relevant to the ocean, with the atmosphere top boundary more suitably assumed to be at infinity. However, beyond the ocean case, we are motivated to consider the vertically bounded domain since it is assumed for the *Eady model* of baroclinic instability (*Eady*, 1949), which is a particularly elegant example of baroclinic instability. We furthermore find it is convenient to study waves in combination with baroclinic instability since baroclinic instability follows a *wave resonance* mechanism, much like that considered for shear instability in Chapter 61.

The waves we encounter in this chapter include *planetary Rossby waves*, *topographic Rossby waves*, and *Eady edge waves*. Recall that we encountered Rossby waves and edge waves in the horizontally non-divergent barotropic model of Chapter 54, as well as Rossby waves and topographic waves for the shallow water model in Chapter 55. In the present chapter, we work fully within the quasi-geostrophic theory and allow for continuous stratification. In addition to Rossby waves, we here consider a thermal wind background state, in which the quasi-geostrophic flow supports Eady edge waves. As shown here, Eady edge waves rely on the presence of a buoyancy gradient along the top and/or bottom boundaries of the domain. Eady waves are the primary actors in the Eady model of baroclinic instability.

The study of baroclinic instability is motivated by asking whether a thermal wind flow is stable to small amplitude geostrophic perturbations. Under certain circumstances, there are unstable wave modes whose energy grows by feeding off the potential energy of the thermal wind state. The Eady model considers the constructive interference of edge waves that leads to wave resonance. This resonance then drives the mutual growth of the edge waves, which constitutes baroclinic instability. Baroclinic instability dominates the fluctuations of the large-scale (order deformation radius) flows in the middle latitude atmosphere (*synoptic scale*) and the *mesoscale* ocean.

READER'S GUIDE FOR THIS CHAPTER

In this chapter we make use of the governing equations of continuously stratified quasi-geostrophic flow from Chapter 45, as well as the Rossby wave discussions in Chapter 54 (horizontally non-divergent barotropic model) and Section 55.9 (shallow water layer). The wave resonance interpretation of Eady's model of baroclinic instability closely follows that given for shear instability in Chapter 61.

62.1 Loose threads

62.2 Equations of quasi-geostrophy

As developed in Chapter 45, quasi-geostrophy is concerned with the evolution of hydrostatic and nearly geostrophic flow in the presence of a prescribed and gravitationally stable background state that is itself in hydrostatic and geostrophic balance. In this section we summarize salient features of continuously stratified quasi-geostrophy that are useful in the study of quasi-geostrophic waves and baroclinic instability.

62.2.1 Equations in the fluid interior

Within the interior of the fluid domain, the quasi-geostrophic buoyancy equation (45.42), relative vorticity equation (45.47), and potential vorticity equation (45.54), are given by

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\, b = -w\, N^2 \qquad \text{buoyancy equation} \tag{62.1a}$$

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\, \zeta = -\beta\, v + f_{\circ}\, \partial_z w \qquad \text{relative vorticity equation} \tag{62.1b}$$

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\, q = 0, \qquad \text{quasi-geostrophic potential vorticity equation,} \tag{62.1c}$$

in which

$$\psi = p/(\rho_{\circ}\, f_{\circ}) \qquad \text{quasi-geostrophic streamfunction } (p = \text{pressure}) \tag{62.2a}$$

$$\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi \qquad \text{non-divergent geostrophic velocity} \tag{62.2b}$$

$$b = f_{\circ}\, \partial_z \psi \qquad \text{buoyancy} \tag{62.2c}$$

$$\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) = \nabla_{\mathrm{h}}^2 \psi \qquad \text{geostrophic relative vorticity} \tag{62.2d}$$

$$q = f_{\circ} + \beta\, y + \zeta + f_{\circ}\, \partial_z (b/N^2) \qquad \text{quasi-geostrophic potential vorticity} \tag{62.2e}$$

$$q = f_{\circ} + \beta\, y + \nabla_{\mathrm{h}}^2 \psi + f_0^2\, \partial_z (\partial_z \psi / N^2) \qquad \text{potential vorticity in terms of streamfunction.} \tag{62.2f}$$

The prescribed time-independent parameters are given by

$$N^2(z) > 0 \qquad \text{background stratification} \tag{62.3a}$$

$$f(y) = f_{\circ} + \beta\, y \qquad \beta\text{-plane Coriolis frequency.} \tag{62.3b}$$

Quasi-geostrophy is based on the following scale assumptions

$$\begin{aligned}
&\mathrm{Ro} = U/f_\circ L \ll 1 && \text{small Rossby number} && (62.4a)\\
&\beta\, L/f_\circ \ll 1 && \beta\text{-plane approximation} && (62.4b)\\
&\mathrm{Bu}(z) = [L_\mathsf{d}(z)/L]^2 = [N(z)\, H/f_\circ]^2\, L^{-2} \sim 1 && \text{order unity Burger number} && (62.4c)\\
&\mathrm{Ri}(z) = \mathrm{Ro}^{-2}\, \mathrm{Bu}(z) \gg 1 && \text{very large Richardson number.} && (62.4d)
\end{aligned}$$

The small Rossby number, Ro, means that the flow is strongly affected by the Coriolis acceleration, which furthermore means it is in near geostrophic balance. This scaling holds for both the background flow, which is prescribed, and perturbations to the background. The order unity Burger number says that the horizontal length scale of the flow, L, is comparable to the deformation radius, L_d, with the deformation radius a function of the vertical scale of motion, H (also the vertical size of the Eady model domain), the f-plane Coriolis parameter, $f_\circ$, and the prescribed background buoyancy frequency, $N(z)$. The large Richardson number, Ri, means that the flow is stable with respect to stratified shear instability (Chapter 61). Note that when writing the potential vorticity, the constant $f_\circ$ can be dropped since it plays no role in the potential vorticity equation.

The evolution of buoyancy (equation (62.1a)) and relative vorticity (equation (62.1b)) are both impacted by the ageostrophic vertical velocity, w. However, we do not need to explicity compute w to evolve the flow within the domain interior. The reason is that we can instead evolve the quasi-geostrophic potential vorticity through equation (62.1c). Thereafter, we solve the Poisson equation (with boundary conditions) for the geostrophic streamfunction

$$\nabla_\mathsf{h}^2 \psi + f_\circ^2\, \partial_z(\partial_z \psi / N^2) = q - (f_\circ + \beta\, y). \tag{62.5}$$

Upon updating the streamfunction we then update the velocity, buoyancy, and relative vorticity. Even though w is unnecessary for updating the flow state, it can be useful for a variety of diagnostic purposes. In Section 45.4.2 we derive a diagnostic equation for this ageostrophic velocity component.

62.2.2 Boundary conditions for vertically bounded domain

For the lateral boundaries, we assume either an infinite horizontal domain with all fields assumed to be finite or vanishing at spatial infinity, or assume doubly periodic domains. In this manner, the lateral boundaries play no fundamental role in the dynamics of concern in this chapter. In contrast, we are concerned with vertically bounded domains in which the top and bottom boundaries are central to the dynamics. To establish the corresponding boundary conditions, we make use of the buoyancy equation (62.1a), given the presence of the vertical velocity. Furthermore, we are concerned with perfect fluid quasi-geostrophy, so consider just the kinematic boundary conditions. The dynamic boundary conditions involve frictional stresses and are not considered here.

The top and bottom boundary conditions for quasi-geostrophy were studied in Sections 45.6 and 45.7. For the upper surface (top) boundary, the vertical velocity is vanishingly small relative to interior vertical motion, thus prompting the rigid lid approximation. Evaluating the buoyancy equation (62.1a) at the rigid lid top boundary means that the boundary buoyancy is materially invariant

$$(\partial_t + \boldsymbol{u} \cdot \nabla_\mathsf{h})\, b = 0 \implies (\partial_t + \boldsymbol{u} \cdot \nabla_\mathsf{h})\, \partial_z \psi = 0 \quad \text{at } z = \overline{\eta}. \tag{62.6}$$

To within the accuracy of quasi-geostrophy, this boundary condition is evaluated at the resting position of the top boundary, $z = \overline{\eta}$, which is typically taken as $\overline{\eta} = 0$.

The analogous boundary condition at the domain bottom, $z = \eta_b(x, y)$, is given by

$$(\partial_t + \boldsymbol{u} \cdot \nabla_h)\, b = -N^2\, \boldsymbol{u} \cdot \nabla \eta_b \quad \text{at } z = \overline{\eta_b}. \tag{62.7}$$

which takes on the following form with the streamfunction

$$(\partial_t + \boldsymbol{u} \cdot \nabla_h)\, (f_o\, \partial_z \psi) = -N^2\, \boldsymbol{u} \cdot \nabla \eta_b \quad \text{at } z = \overline{\eta_b}. \tag{62.8}$$

The bottom boundary condition is evaluated at the horizontally averaged position, $z = \overline{\eta_b}$, since the more precise boundary location, $z = \eta_b(x, y)$, is one order higher in Rossby number and so is dropped from quasi-geostrophic theory. Correspondingly, quasi-geostrophic theory is formally valid only for very gently sloping bottom boundaries. Note that when η_b is a constant, then $\nabla_h \eta_b = 0$, so that the bottom boundary condition reduces to the material invariance of the boundary buoyancy, just like the top boundary condition.

Quasi-geostrophic theory based on studies of just the top and/or bottom boundary conditions is known as *surface quasi-geostrophy* (e.g., *Held et al.* (1995), *Yassin and Griffies* (2022)), where the interior potential vorticity is assumed to be a constant, which can be set to zero without loss of generality. Surface quasi-geostrophy shares mathematically elements with the study of surface gravity waves in Chapter 52. Namely, surface quasi-geostrophy supports edge waves that are exponentially trapped at the boundaries and with a vertical length scale inversely proportional to the horizontal wavelength (i.e., shorter edge waves are more trapped next to the boundary than longer edge waves). As we see later in this chapter, edge waves are central to baroclinic instability as realized in the Eady model.

62.3 Linear fluctuations on a zonal geostrophic background flow

We here formulate equations for a zonal background flow state and the linear fluctuations relative to that flow. The static and prescribed background state is assumed to be in thermal wind balance, and all perturbations to that background state satisfy the scalings of quasi-geostrophy. All background fields have a "b" subscript to remind us that these fields are prescribed.

The linear analysis in this section forms the baseline for subsequent sections that specialize these results. In particular, in Section 62.4 we specialize to the case of zero thermal wind flow with planetary beta, thus considering planetary Rossby waves. In Section 62.5, we set planetary beta to zero but allow for a topographic slope, thus considering topographic Rossby waves. In Section 62.6, we maintain the thermal wind state but assume zero planetary beta and zero topographic beta, thus focusing on the mechanics of *Eady edge waves*, whose existence along either the top or bottom boundary relies on the presence of a horizontal buoyancy gradient along that boundary. In Section 62.7 we study the unstable Eady edge waves arising in the Eady model, thus forming the wave mechanism for baroclinic instability.

62.3.1 Zonal geostrophic background flow

Consider a geostrophic background state described by a streamfunction, $\Psi_b(y, z)$, with a corresponding zonal flow and thermal wind shear

$$u_b(y, z) = -\partial_y \Psi_b \quad \text{and} \quad \partial_z u_b = -\partial_{yz} \Psi_b = -f_o^{-1}\, \partial_y b_b, \tag{62.9}$$

where $b_b(y, z)$ is the prescribed background buoyancy field supporting the background geostrophic flow.

A particular example of buoyancy supporting a geostrophic flow with a constant thermal

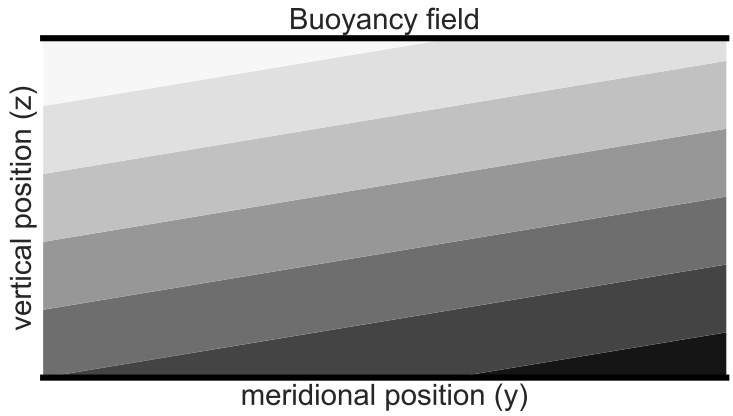

FIGURE 62.1: Example background buoyancy field written as the linear function, $b_b = N^2\,[z - y\,(\mathrm{d}z/\mathrm{d}y)_{b_b}]$, as per equation (62.13). The squared buoyancy frequency is positive, $N^2 = \partial_z b_b > 0$, whereas the northward buoyancy gradient is negative, $\partial_y b_b < 0$. Correspondingly, the buoyancy slope, $(\mathrm{d}z/\mathrm{d}y)_{b_b} = -\partial_y b_b/\partial_z b_b = f_o\,\partial_z u_b/N^2 > 0$, is positive to the north (north is to the right). There are no lateral boundaries, so that the fluid is assumed to be unbounded in the horizontal directions. However, the top and bottom are rigid.

wind shear is given by the sloped and planar buoyancy surfaces

$$b_b = N^2\,z + (\partial_y b_b)\,y = N^2\,z - f_o\,(\partial_z u_b)\,y, \quad \text{with } N^2,\ \partial_y b_b, \text{ and } \partial_z u_b \text{ constants.} \tag{62.10}$$

We consider this special case when studying Eady waves in Section 62.6 and the Eady model of baroclinic instability in Section 62.7. Although very idealized, it provides the core features of Eady waves and baroclinic instability, and it does so in an analytically tractable manner.

The buoyancy (62.10) can be written in a geometric form by introducing the meridional slope of the background buoyancy surfaces. To derive an expression for the slope, note that constant buoyancy surfaces are defined by[1]

$$b_b = \text{constant} \implies \mathrm{d}b_b = 0 = (\partial b_b/\partial y)\,\mathrm{d}y + (\partial b_b/\partial z)\,\mathrm{d}z, \tag{62.11}$$

which means that the slope of constant buoyancy surfaces is given by

$$\left[\frac{\mathrm{d}z}{\mathrm{d}y}\right]_{b_b} = -\frac{\partial_y b_b}{\partial_z b_b} = -\frac{\partial_y b_b}{N^2} = \frac{f_o\,\partial_z u_b}{N^2}, \tag{62.12}$$

so that the buoyancy (62.10) is

$$b_b = N^2\,[z - y\,(\mathrm{d}z/\mathrm{d}y)_{b_b}] \quad \text{with } (\mathrm{d}z/\mathrm{d}y)_{b_b} \text{ a constant slope.} \tag{62.13}$$

Figure 62.1 illustrates such a buoyancy field with a constant and positive meridional slope, $(\mathrm{d}z/\mathrm{d}y)_{b_b} > 0$.

It is common to forget the minus signs appearing in the first and second expressions for the slope in equation (62.12). Examination of Figure 62.1 quickly remedies this mistake. Namely, this figure depicts a buoyancy field that has a positive slope towards the north, $(\mathrm{d}z/\mathrm{d}y)_{b_b} > 0$. This slope arises due to the reduction in buoyancy moving north ($\partial_y b_b < 0$) in the presence of a vertically stable stratification ($\partial_z b_b > 0$).

62.3.2 Background state is an exact quasi-geostrophic solution

We here show that the thermal wind flow (62.9) identically satisfies the quasi-geostrophic equations, thus constituting an exact solution to quasi-geostrophy. For this purpose, introduce

[1] See Section 63.12.2 for mathematical details on the treatment of generalized vertical coordinates.

the quasi-geostrophic potential vorticity for the background flow

$$q_\mathsf{b} = f_\circ + \beta\, y + \zeta_\mathsf{b} + f_\circ^2\, \partial_z(N^{-2}\, \partial_z \Psi_\mathsf{b}) = f_\circ + \beta\, y - \partial_y u_\mathsf{b} + f_\circ^2\, \partial_z(N^{-2}\, \partial_z \Psi_\mathsf{b}), \tag{62.14}$$

where we introduced the relative vorticity of the background zonal geostrophic flow

$$\zeta_\mathsf{b} = -\partial_y u_\mathsf{b}. \tag{62.15}$$

Since q_b is static and a spatial function just of (y, z), it trivially satisfies the potential vorticity equation

$$(\partial_t + u_\mathsf{b}\, \hat{\boldsymbol{x}} \cdot \nabla_\mathsf{h})\, q_\mathsf{b} = u_\mathsf{b}\, \partial_x\, q_\mathsf{b} = 0. \tag{62.16}$$

Likewise, the background buoyancy field, $b_\mathsf{b}(y, z)$, trivially satisfies the top boundary condition (62.6) since

$$(\partial_t + u_\mathsf{b}\, \hat{\boldsymbol{x}} \cdot \nabla_\mathsf{h})\, b_\mathsf{b} = u_\mathsf{b}\, \partial_x\, b_\mathsf{b} = 0 \quad \text{at } z = \overline{\eta}. \tag{62.17}$$

For the bottom boundary condition (62.8) we have

$$(\partial_t + u_\mathsf{b}\, \partial_x)\, b_\mathsf{b} + u_\mathsf{b}\, \partial_x(N^2\, \eta_\mathsf{b}) = 0 \quad \text{at } z = \overline{\eta_\mathsf{b}}, \tag{62.18}$$

which is satisfied if the topography is a function only of latitude, $\eta_\mathsf{b} = \eta_\mathsf{b}(y)$. Hence, the background thermal wind flow, $u_\mathsf{b}(y, z)$, and corresponding buoyancy, $b_\mathsf{b}(y, z)$, are exact solutions to quasi-geostrophy if the bottom is either flat or has a meridional slope.

62.3.3 Fluctuating streamfunction, potential vorticity, and buoyancy

Now consider fluctuations relative to the zonal geostrophic flow, with streamfunction and buoyancy decomposed as

$$\psi(x, y, z, t) = \Psi_\mathsf{b}(y, z) + \psi'(x, y, z, t) \quad \text{and} \quad b(x, y, z, t) = b_\mathsf{b}(y, z) + b'(x, y, z, t). \tag{62.19}$$

The corresponding quasi-geostrophic potential vorticity is decomposed according to

$$q(x, y, z, t) = q_\mathsf{b}(y, z) + q'(x, y, z, t), \tag{62.20}$$

with q_b given by equation (62.14). The fluctuating potential vorticity arises from relative vorticity and stretching

$$q' = \nabla_\mathsf{h}^2 \psi' + f_\circ^2\, \partial_z(N^{-2}\, \partial_z \psi'). \tag{62.21}$$

Substituting these expressions into the quasi-geostrophic potential vorticity equation (62.1c) leads to

$$[\partial_t + (\boldsymbol{u}' + \boldsymbol{u}_\mathsf{b}) \cdot \nabla]\, (q_\mathsf{b} + q') = [\partial_t + (\boldsymbol{u}' + \boldsymbol{u}_\mathsf{b}) \cdot \nabla]\, q' + \boldsymbol{u}' \cdot \nabla q_\mathsf{b} = 0, \tag{62.22}$$

where we set

$$\partial_t q_\mathsf{b} + \boldsymbol{u}_\mathsf{b} \cdot \nabla q_\mathsf{b} = 0, \tag{62.23}$$

since q_b is an exact solution to quasi-geostrophy (Section 62.3.2). Rearranging equation (62.22), and setting $\boldsymbol{u}_\mathsf{b} = u_\mathsf{b}\, \hat{\boldsymbol{x}}$, leads to

$$[\partial_t + (u_\mathsf{b}\, \hat{\boldsymbol{x}} + \boldsymbol{u}') \cdot \nabla_\mathsf{h}]\, q' + v'\, \partial_y q_\mathsf{b} = 0. \tag{62.24}$$

We are concerned in this chapter with linear theory, with the linearized equation for the perturbation potential vorticity given by

$$(\partial_t + u_\mathsf{b}\, \partial_x)\, q' = -v'\, \partial_y q_\mathsf{b} \Longrightarrow (\partial_t + u_\mathsf{b}\, \partial_x)\, [\nabla_\mathsf{h}^2 \psi' + f_\circ^2\, \partial_z(N^{-2}\, \partial_z \psi')] = -\partial_x \psi'\, \partial_y q_\mathsf{b}. \tag{62.25}$$

Evidently, in the linear theory we find that q' is advected by the zonal background flow, u_b, and it has a source determined by the anomalous meridional advection of the background quasi-geostrophic potential vorticity, q_b.

For the buoyancy, $b(x, y, z, t) = b_\mathrm{b}(y, z) + b'(x, y, z, t)$, we linearize the buoyancy equation (62.1a) to find

$$(\partial_t + u_\mathrm{b}\,\partial_x)\,b' = -v'\,\partial_y b_\mathrm{b} - w'\,N^2. \tag{62.26}$$

The right hand side source terms can be written in terms of the slope of the buoyancy surfaces (62.12)

$$(\partial_t + u_\mathrm{b}\,\partial_x)\,b' = -N^2\,[w' - v'\,(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}}]. \tag{62.27}$$

62.3.4 Linearized upper boundary condition

The upper surface boundary condition (62.6) is

$$\partial_t b' + (u_\mathrm{b}\,\partial_x + \boldsymbol{u}'\cdot\nabla_\mathrm{h})(b_\mathrm{b} + b') = 0, \tag{62.28}$$

which linearizes to

$$(\partial_t + u_\mathrm{b}\,\partial_x)\,b' = -v'\,\partial_y b_\mathrm{b} \Longrightarrow (\partial_t + u_\mathrm{b}\,\partial_x)\,\partial_z\psi' = \partial_x\psi'\,\partial_z u_\mathrm{b}. \tag{62.29}$$

As we see in Section 62.6, advection by the zonal geostrophic flow provides a frequency shift to the linear waves, whereas the source, $\partial_x\psi'\,\partial_z u_\mathrm{b}$, supports the propagation of surface trapped edge waves relative to the flow.

62.3.5 Linearized bottom boundary condition

The bottom boundary condition (62.8), with $\eta_\mathrm{b} = \eta_\mathrm{b}(y)$, is given by

$$f_\circ\,(\partial_t + u_\mathrm{b}\,\partial_x + \boldsymbol{u}'\cdot\nabla_\mathrm{h})\,\partial_z\psi' = v'\,(f_\circ\,\partial_z u_\mathrm{b} - N^2\,\partial_y\eta_\mathrm{b}), \tag{62.30}$$

which linearizes to

$$f_\circ\,(\partial_t + u_\mathrm{b}\,\partial_x)\,\partial_z\psi' = \partial_x\psi'\,(f_\circ\,\partial_z u_\mathrm{b} - N^2\,\partial_y\eta_\mathrm{b}). \tag{62.31}$$

The right hand side can be written in a geometric manner by introducing the slope of the background buoyancy as per equation (62.12), so that

$$(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} = -\partial_y b_\mathrm{b}/\partial_z b_\mathrm{b} = f_\circ\,\partial_z u_\mathrm{b}/N^2. \tag{62.32}$$

The bottom boundary condition (62.31) can thus be written as

$$f_\circ\,(\partial_t + u_\mathrm{b}\,\partial_x)\,\partial_z\psi' = \partial_x\psi'\,N^2\,[(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} - \partial_y\eta_\mathrm{b}], \tag{62.33}$$

in which the forcing on the right hand side is proportional to the difference between the buoyancy slope and bottom topography slope. When the bottom topography is flat then the bottom boundary condition reduces to the same condition as the top

$$(\partial_t + u_\mathrm{b}\,\partial_x)\,\partial_z\psi' = \partial_x\psi'\,\partial_z u_\mathrm{b}. \tag{62.34}$$

62.4 Vertically bounded planetary Rossby waves

In this section we simplify the background state by assuming zero background flow with flat top and bottom boundaries, yet affected by a nonzero planetary beta. That is, we here study continuously stratified planetary Rossby waves in a vertically bounded domain. We already

encountered planetary Rossby waves in Section 54.3 for the horizontally non-divergent barotropic model, and in Section 55.9 for the shallow water model. The goal here is to extend those earlier discussions to the case of continuous stratification.

62.4.1 Governing linear equations

Again, we assume the background state has a flat bottom with zero background thermal wind flow, so that the background consists solely of planetary beta. Hence, the background potential vorticity equals to the planetary vorticity

$$q_{\mathsf{b}} = f_{\circ} + \beta\, y \Longrightarrow \nabla q_{\mathsf{b}} = \beta\, \hat{\boldsymbol{y}}. \tag{62.35}$$

The linearized potential vorticity equation (62.25) and linearized boundary conditions (62.29) and (62.31), each with zero background flow, are given by

$$\partial_t q' + \beta\, v' = 0 \Longrightarrow \partial_t[\nabla_{\mathsf{h}}^2 \psi' + f_0^2\, \partial_z(N^{-2}\, \partial_z \psi')] + \beta\, \partial_x \psi' = 0 \tag{62.36a}$$

$$\partial_{tz} \psi' = 0 \quad \text{at } z = \overline{\eta} \text{ and } z = \overline{\eta_{\mathsf{b}}}. \tag{62.36b}$$

In the presence of a horizontally homogeneous vertical stratification, $N^2(z) > 0$, we can introduce a wave ansatz consisting of horizontally traveling free plane waves that are modulated by a vertically dependent (generally complex) amplitude

$$\psi'(x,y,z,t) = \widetilde{\psi}(z)\, \mathrm{e}^{\mathrm{i}\,(k_x\, x + k_y\, y - \omega\, t)} \Longrightarrow \boldsymbol{u} = (\hat{\boldsymbol{z}} \times \mathrm{i}\, \boldsymbol{k})\, \widetilde{\psi}(z)\, \mathrm{e}^{\mathrm{i}\,(k_x\, x + k_y\, y - \omega\, t)}. \tag{62.37}$$

As we will see when analytically calculating the vertical structure for constant N^2 in Section 62.4.3, the vertical structure takes the form of vertically standing waves, which accords with our prior experience of waves in a bounded domain (e.g., acoustic waves in a rectangular cavity in Exercise 51.1; surface gravity waves in Section 52.8). Plugging the ansatz (62.37) into the streamfunction equation (62.36a) and boundary condition equation (62.36b) leads to the *Sturm-Liouville* eigenvalue problem[2]

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[\frac{f_{\circ}^2}{N^2}\, \frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z}\right] = -\lambda\, \widetilde{\psi} \tag{62.38a}$$

$$\frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z} = 0 \quad \text{at } z = \overline{\eta}, \overline{\eta_{\mathsf{b}}} \tag{62.38b}$$

$$\lambda = -(|\boldsymbol{k}|^2 + \beta\, k_x/\omega). \tag{62.38c}$$

We refer to solutions $\widetilde{\psi}$ as *eigenmodes* with λ the corresponding *eigenvalues*. From the Sturm-Liouville theory we know there are a countably infinite number of eigenmodes, with the higher eigenvalues corresponding to modes with more zero crossings.

62.4.2 Barotropic mode and baroclinic modes

Multiplying the eigenvalue equation (62.38a) by $\widetilde{\psi}^*$, integrating over the depth of the fluid, and making use of the Neumann boundary conditions (62.38b), leads to the expression for the eigenvalue in terms of the eigenmodes

$$\lambda = -(|\boldsymbol{k}|^2 + \beta\, k_x/\omega) = \frac{\int_{\overline{\eta_{\mathsf{b}}}}^{\overline{\eta}} |(f_{\circ}/N)\, \mathrm{d}\widetilde{\psi}/\mathrm{d}z|^2\, \mathrm{d}z}{\int_{\overline{\eta_{\mathsf{b}}}}^{\overline{\eta}} |\widetilde{\psi}|^2\, \mathrm{d}z}, \tag{62.39}$$

[2] Sturm-Liouville eigenvalue problems have a well established theory in differential equations and mathematical physics. Chapter 11 of *Boyce and DiPrima* (2009) is a classic reference, now in its 9th edition!

which proves that the eigenvalues are non-negative

$$\lambda \geq 0. \tag{62.40}$$

Barotropic mode

The case with zero eigenvalue, $\lambda = 0$, has a dispersion relation given by

$$\omega = -k_x \, \beta / |\boldsymbol{k}|^2 \quad \text{barotropic mode}, \tag{62.41}$$

and a corresponding depth independent eigenmode ($\mathrm{d}\widetilde{\psi}/\mathrm{d}z = 0$), with this mode referred to as the *barotropic mode*. Notice that the barotropic mode's frequency is unbounded as the wavenumber gets smaller (longer waves). That is, the longer wavelength modes have higher frequency. Also note that the phase velocity (equation (49.26))

$$\boldsymbol{c}_{\mathsf{p}} = (\omega/|\boldsymbol{k}|) \, \hat{\boldsymbol{k}} = (\omega/|\boldsymbol{k}|^2) \, \boldsymbol{k}, \tag{62.42}$$

has a westward component

$$(\boldsymbol{c}_{\mathsf{p}} \cdot \hat{\boldsymbol{x}})^{\text{barotropic}} = (\omega/|\boldsymbol{k}|^2) \, \boldsymbol{k} \cdot \hat{\boldsymbol{x}} = -k_x^2 \, \beta / |\boldsymbol{k}|^2 < 0. \tag{62.43}$$

This westward phase velocity accords with our earlier studies of Rossby waves. Even though this barotropic mode appears in a stratified fluid, its properties are equivalent to that of the Rossby waves appearing in a horizontally non-divergent barotropic model as studied in Section 54.3, further supporting this mode being referred to it as the barotropic mode.

Baroclinic modes

Equation (62.39) shows that all nonzero eigenvalues are positive

$$\lambda = -(|\boldsymbol{k}|^2 + \beta \, k_x/\omega) > 0. \tag{62.44}$$

Furthermore, upon vertically integrating the eigenvalue equation (62.38a) and using the boundary conditions (62.38b) we find that all higher modes have zero depth integral

$$\int_{\overline{\eta_{\mathsf{b}}}}^{\overline{\eta}} \widetilde{\psi} \, \mathrm{d}z = 0. \tag{62.45}$$

We refer to these as *baroclinic modes* since they are depth dependent, with the baroclinic modes having eigenvalues that form a monotonically increasing and countably infinite sequence. Each successive baroclinic mode has one more zero crossing, and thus more vertical structure. We display this behavior in Section 62.4.3 when analytically determing the eigenmodes with a constant N^2.

62.4.3 Planetary Rossby waves with constant N^2

An analytic solution to the eigenvalue problem (62.38a)-(62.38b) for vertically bounded Rossby waves can be found for the case of constant N^2, whereby the eigenmode is given by the cosine function

$$\widetilde{\psi} = \widetilde{\psi}_{\circ} \cos[n \, \pi \, (z - \overline{\eta_{\mathsf{b}}})/H] \quad \text{with } H = \overline{\eta} - \overline{\eta_{\mathsf{b}}}, \tag{62.46}$$

with $\widetilde{\psi}_{\circ}$ a constant real amplitude. The eigenvalues can be found through equation (62.39),

$$\lambda = (n \, \pi / L_{\mathsf{d}})^2 \quad \text{with } n = 0, 1, 2, 3... \text{ and } L_{\mathsf{d}} = N \, H / f_{\circ}, \tag{62.47}$$

which then lead to the dispersion relation for the baroclinic modes

$$\omega = -\frac{\beta\, k_x}{(n\,\pi/L_\mathsf{d})^2 + k_x^2 + k_y^2}. \tag{62.48}$$

Since the angular frequency is non-negative (Section 49.2.3), all planetary Rossby wave modes have a westward, $k_x < 0$, phase propagation, just like we saw for the barotropic planetary wave with $n = 0$. We display this property by writing the zonal component of the phase velocity

$$\boldsymbol{c}_\mathsf{p} \cdot \hat{\boldsymbol{x}} = (\omega/|\boldsymbol{k}|^2)\, k_x = -\frac{\beta\, k_x^2/|\boldsymbol{k}|^2}{(n\,\pi/L_\mathsf{d})^2 + k_x^2 + k_y^2} < 0. \tag{62.49}$$

Observe that a useful way to non-dimensionalize the dispersion relation (62.48) is to write

$$\omega/(\beta\, L_\mathsf{d}) = -\frac{k_x\, L_\mathsf{d}}{(n\,\pi)^2 + (k_x\, L_\mathsf{d})^2 + (k_y\, L_\mathsf{d})^2}, \tag{62.50}$$

with this expression plotted in Figure 62.2 for the $n = 0, 1, 2$ Rossby wave modes with $k_y = 0$.

A packet of Rossby waves with carrier wavevector $\boldsymbol{k}$ moves with the group velocity

$$\boldsymbol{c}_\mathsf{g} = \nabla_{\boldsymbol{k}}\omega = \frac{\beta\,[\hat{\boldsymbol{x}}\,(k_x^2 - k_y^2 - (n\,\pi/L_\mathsf{d})^2) + 2\,k_x\,k_y\,\hat{\boldsymbol{y}}]}{[(n\,\pi/L_\mathsf{d})^2 + k_x^2 + k_y^2]^2}. \tag{62.51}$$

In Section 54.3 we studied Rossby waves in the horizontally non-divergent barotropic model, and then in Section 55.9 we studied Rossby waves in a single shallow water layer. Both of those discussions share much with the present case, in particular the shallow water Rossby waves since they have a finite deformation radius whereas the deformation radius is formally infinite in the barotropic model. Hence, each baroclinic mode found in the continuously stratified case can be understood as a Rossby wave in a single shallow water layer whose deformation radius,

$$L_\mathsf{d} = c_\mathsf{grav}/f_\circ = \sqrt{g\,H}/f_\circ, \tag{62.52}$$

is chosen to fit that of the baroclinic mode. By extension, we can understand the geometry of baroclinic Rossby wave packets, including their reflection from surfaces, by referring to the earlier shallow water discussion.

62.5 Topographic Rossby waves

Now set $\beta = 0$, to eliminate planetary Rossby waves, but maintain a background potential vorticity gradient by allowing the bottom to have a nonzero slope. In so doing we extend the study of topographic Rossby waves from the shallow water in Section 55.4.6 to the continuously stratified case. The resulting linearized potential vorticity equation and boundary conditions are

$$\partial_t q' = 0 \Longrightarrow \partial_t[\nabla_\mathsf{h}^2\psi' + f_0^2\,\partial_z(N^{-2}\,\partial_z\psi')] = 0 \tag{62.53a}$$

$$\partial_{tz}\psi' = 0 \quad \text{at } z = \overline{\eta}. \tag{62.53b}$$

$$f_\circ\,\partial_{tz}\psi' + N^2\,\hat{\boldsymbol{z}}\cdot(\nabla\psi'\times\nabla\eta_\mathsf{b}) = 0 \quad \text{at } z = \overline{\eta_\mathsf{b}}. \tag{62.53c}$$

To study plane waves in the horizontal, assume the special case of a gentle and constant linear slope, $\partial_y\eta_\mathsf{b}$, in the meridional direction so that

$$\eta_\mathsf{b} = \eta_\text{const} + y\,\partial_y\eta_\mathsf{b} \quad \text{with } |\partial_y\eta_\mathsf{b}| \ll 1, \tag{62.54}$$

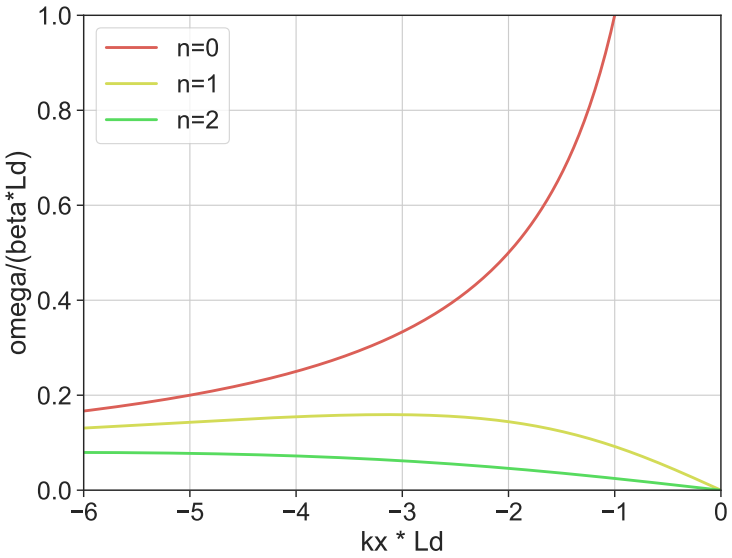

FIGURE 62.2: Dispersion relation for planetary Rossby waves according to equation (62.50), $\omega/(\beta\, L_\mathrm{d}) = -k_x\, L_\mathrm{d}/[(n\,\pi)^2 + (k_x\, L_\mathrm{d})^2 + (k_y\, L_\mathrm{d})^2]$, showing the $n = 0$ barotropic mode and $n = 1, 2$ baroclinic modes, each with $k_y = 0$. A positive angular frequency is realized with $k_x < 0$, so that the phase propagates to the west. The frequency for the barotropic mode is unbounded approaching the origin, so that long barotropic Rossby waves are high frequency waves. Both the barotropic and baroclinic wave modes have a vanishing frequency as the waves become shorter ($|\boldsymbol{k}| \to \infty$).

in which case the bottom boundary condition (62.53c) becomes

$$f_\circ\, \partial_{tz}\psi' + N^2\, \partial_y \eta_\mathrm{b}\, \partial_x \psi' = 0 \quad \text{at } z = \overline{\eta_\mathrm{b}}. \tag{62.55}$$

62.5.1 Eigenvalue problem for $\widetilde{\psi}$

Taking the linear bottom slope (62.54) allows us to consider the same wave ansatz (62.37) as used for planetary Rossby waves in Section 62.4.1, which then converts equations (62.53a), (62.53b), and (62.55) into the eigenvalue problem

$$\omega \frac{\mathrm{d}}{\mathrm{d}z}\left[\frac{f_\circ^2}{N^2}\frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z}\right] = \omega\, |\boldsymbol{k}|^2\, \widetilde{\psi} \qquad \overline{\eta_\mathrm{b}} < z < \overline{\eta} \tag{62.56a}$$

$$\omega \frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z} = 0 \qquad \text{at } z = \overline{\eta}, \tag{62.56b}$$

$$f_\circ\, \omega \frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z} = N^2\, \partial_y \eta_\mathrm{b}\, k_x\, \widetilde{\psi} \quad \text{at } z = \overline{\eta_\mathrm{b}}. \tag{62.56c}$$

The differential equation (62.56a) and surface boundary condition (62.56b) can be satisfied with a zero frequency wave, $\omega = 0$, in which case there is no propagating wave. However, the bottom boundary condition (62.56c) cannot be satisfied with $\omega = 0$ in the presence of a nonzero bottom slope and nonzero Coriolis frequency. Evidently, the Coriolis frequency plays a fundamental role in supporting a propagating topographic Rossby waves in the presence of a sloping bottom.

Cancelling the angular frequency in equation (62.56a) (since $\omega \neq 0$ for topographic waves), then multiplying by $\widetilde{\psi}^*$ and integrating over the depth of the domain leads to

$$\int_{\overline{\eta_\mathrm{b}}}^{\overline{\eta}} \frac{\mathrm{d}}{\mathrm{d}z}\left[\widetilde{\psi}^*\, \frac{f_\circ^2}{N^2}\frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z}\right] \mathrm{d}z = \int_{\overline{\eta_\mathrm{b}}}^{\overline{\eta}} \left[|\boldsymbol{k}|^2\, |\widetilde{\psi}|^2 + \frac{f_\circ^2}{N^2}\left|\frac{\mathrm{d}\widetilde{\psi}}{\mathrm{d}z}\right|^2\right] \mathrm{d}z. \tag{62.57}$$

Use of the surface boundary condition (62.56b) and bottom boundary condition (62.56c) render

$$f_o \, \partial_y \eta_b \, k_x = -\frac{\omega}{|\widetilde{\psi}(\overline{\eta_b})|^2} \int_{\overline{\eta_b}}^{\overline{\eta}} \left[|\boldsymbol{k}|^2 \, |\widetilde{\psi}|^2 + \frac{f_o^2}{N^2} \left| \frac{d\widetilde{\psi}}{dz} \right|^2 \right] dz. \tag{62.58}$$

The right hand side is a negative number (recall $\omega > 0$), which then orients the zonal component to the phase velocity according to the sign of $f_o \, \partial_y \eta_b$. For example, in the northern hemisphere with a bottom slope rising to the north, so that $f_o \, \partial_y \eta_b > 0$, then $k_x < 0$, which means that the zonal phase velocity is to the west. Likewise, for the southern hemisphere, a bottom slope that is rising to the south has $f_o \, \partial_y \eta_b > 0$, which also yields $k_x < 0$.

62.5.2 Topographic Rossby waves with constant N^2

Following our approach for planetary Rossby waves in Section 62.4.3, assume the buoyancy frequency is constant so that the eigenvalue problem (62.56a)-(62.56c) reduces to

$$\frac{d^2\widetilde{\psi}}{dz^2} = k_R^2 \, \widetilde{\psi} \qquad \overline{\eta_b} < z < \overline{\eta} \tag{62.59a}$$

$$f_o \, \omega \, \frac{d\widetilde{\psi}}{dz} = N^2 \, \partial_y \eta_b \, k_x \, \widetilde{\psi} \quad \text{at } z = \overline{\eta_b} \tag{62.59b}$$

$$\omega \, \frac{d\widetilde{\psi}}{dz} = 0 \qquad \text{at } z = \overline{\eta}, \tag{62.59c}$$

where we introduced the inverse *Rossby height*

$$k_R = |\boldsymbol{k}| \, N / f_o = |\boldsymbol{k}| \, L_d / H \quad \text{with } L_d = N \, H / f_o. \tag{62.60}$$

As we see below, k_R^{-1} defines an exponential scale height over which the wave decays moving away from the bottom boundary.

Bottom trapped streamfunction

To further simplify the analysis, assume the upper boundary, at $z = \overline{\eta}$, is far enough away that it can be ignored. In this case the streamfunction takes on the bottom trapped form

$$\widetilde{\psi} = \widetilde{\psi}_o \, e^{-k_R \, (z - \overline{\eta_b})}. \tag{62.61}$$

To determine what is "far enough away", evaluate the streamfunction at $z = \overline{\eta}$, whereby

$$\widetilde{\psi}(z = \overline{\eta}) = \widetilde{\psi}_o \, e^{-k_R \, H} = \widetilde{\psi}_o \, e^{-|\boldsymbol{k}| \, L_d}. \tag{62.62}$$

This streamfunction is exponentially small for wavenumbers satisfying

$$|\boldsymbol{k}| \gg L_d^{-1}. \tag{62.63}$$

That is, the topographic Rossby waves do not feel the upper boundary if their horizontal wavelength is small compared to the deformation radius

$$\Lambda \ll 2\pi \, L_d. \tag{62.64}$$

Dispersion relation

Inserting the streamfunction (62.61) into the bottom boundary condition (62.59b) leads to the dispersion relation

$$\omega = -N\, \partial_y \eta_{\mathsf{b}}\, k_x / |\boldsymbol{k}|. \tag{62.65}$$

Since the angular frequency is positive, the wave vector is constrained so that $\partial_y \eta_{\mathsf{b}}\, k_x < 0$. That is, if the bottom slope is rising to the north ($\partial_y \eta_{\mathsf{b}} > 0$) then the phase velocity has a westward component ($k_x < 0$), whereas a slope rising to the south ($\partial_y \eta_{\mathsf{b}} < 0$) has an eastward phase velocity ($k_x > 0$). We can also see this orientation by looking at the zonal component to the phase velocity

$$\boldsymbol{c}_{\mathsf{p}} \cdot \hat{\boldsymbol{x}} = (\omega/|\boldsymbol{k}|^2)\, k_x = -N\, \partial_y \eta_{\mathsf{b}}\, k_x^2 / |\boldsymbol{k}|^3, \tag{62.66}$$

with the sign of $\partial_y \eta_{\mathsf{b}}$ determining the orientation of the zonal phase velocity.

Evidently, the topographic slope acts as a background potential vorticity gradient just like planetary beta. To further this correspondence, define *topographic beta*

$$\beta_{\text{topo}} = f_{\mathsf{o}}\, \partial_y \eta_{\mathsf{b}} / H, \tag{62.67}$$

so that the dispersion relation (62.65) takes on the form

$$\omega = -\frac{\beta_{\text{topo}}\, k_x\, L_{\mathsf{d}}}{|\boldsymbol{k}|}, \tag{62.68}$$

which shares features with the planetary Rossby wave from Section 62.4.1. However, in contrast to planetary beta, the topographic beta can be either sign.

62.6 Non-interacting Eady waves

The geometric expression for the bottom boundary condition (62.33) suggests that sloping buoyancy surfaces support waves in a manner akin to sloping bottom topography. Whereas a sloping bottom in the presence of flat buoyancy surfaces supports topographic Rossby waves, a sloping buoyancy surface in the presence of a flat bottom or rigid lid top supports *Eady waves*. More precisely, a nonzero gradient of boundary buoyancy supports Eady edge waves.

62.6.1 Assumptions for Eady waves

We make the following assumptions to support an analytic derivation of the dispersion relation for Eady waves.

- Disable planetary Rossby waves by setting $\beta = 0$.
- Disable topographic Rossby waves by setting $\nabla \eta_{\mathsf{b}} = 0$.
- The flow occurs between a flat bottom at $z = \overline{\eta_{\mathsf{b}}} = 0$ and flat top at $z = \overline{\eta} = H$.
- A linear thermal wind front is supported by the buoyancy in equation (62.10), in which N^2, $\partial_y b_{\mathsf{b}}$, and $\partial_z u_{\mathsf{b}}$ are constants, thus implying that the buoyancy slope, $(\mathrm{d}z/\mathrm{d}y)_{b_{\mathsf{b}}}$, is also a constant;
- The background zonal geostrophic flow is a linear function of vertical position so that

$$u_{\mathsf{b}} = u_{\mathsf{b}}(z) = U_0 + \partial_z u_{\mathsf{b}}\, (z - \overline{\eta_{\mathsf{b}}}), \tag{62.69}$$

  where

$$\partial_z u_{\mathsf{b}} = \text{constant}. \tag{62.70}$$

In turn, the corresponding geostrophic streamfunction is

$$\Psi_\mathsf{b} = -y\,[U_0 + \partial_z u_\mathsf{b}\,(z - \overline{\eta_\mathsf{b}})]. \tag{62.71}$$

- With these assumptions the background potential vorticity (62.14) is a constant throughout the fluid interior

$$q_\mathsf{b} = f_\circ \Longrightarrow \nabla q_\mathsf{b} = 0, \tag{62.72}$$

and thus it plays no dynamical role.

Each of the above assumptions is rather restrictive. Indeed, the use of a top boundary is not very relevant to the atmosphere. However, these assumptions offer a streamlined means to analytically reveal the core physics of Eady waves, and in turn the interaction of such waves to produce baroclinic instability (Section 62.7). It is for this reason that the Eady model has proven so compelling pedagogically.

62.6.2 Streamfunction equation

The linearized potential vorticity equation (62.25) and corresponding boundary conditions (62.29) and (62.33) take on the form

$$[\partial_t + u_\mathsf{b}(z)\,\partial_x]\,q' = 0 \qquad \overline{\eta_\mathsf{b}} < z < \overline{\eta} \tag{62.73a}$$

$$[\partial_t + u_\mathsf{b}(\overline{\eta})\,\partial_x]\,\partial_z\psi' = \partial_x\psi'\,\partial_z u_\mathsf{b} \quad z = \overline{\eta} \tag{62.73b}$$

$$(\partial_t + u_\mathsf{b}(\overline{\eta_\mathsf{b}})\,\partial_x)\,\partial_z\psi' = \partial_x\psi'\,\partial_z u_\mathsf{b} \quad z = \overline{\eta_\mathsf{b}}, \tag{62.73c}$$

with the bottom boundary condition resulting from the meridional gradient of the background buoyancy, or equivalently the zonal thermal wind shear

$$N^2\,(\mathrm{d}z/\mathrm{d}y)_{b_\mathsf{b}} = -\partial_y b_\mathsf{b} = f_\circ\,\partial_z u_\mathsf{b}. \tag{62.74}$$

The simplifying assumptions from Section 62.6.1 have led to a linear boundary value problem in which the only spatial dependence is in the vertical. Hence, we can consider the familiar wave ansatz (62.37) for the streamfunction, in which fluctuations are organized into horizontally propagating free plane waves that are modulated by a vertically dependent amplitude function

$$\psi'(x, y, z, t) = \widetilde{\psi}(z)\,\mathrm{e}^{\mathrm{i}\,(k_x\,x + k_y\,y - \omega\,t)}. \tag{62.75}$$

With this ansatz we find the fluctuating potential vorticity (62.21) is given by

$$q' = (f_\circ/N)^2\,(\partial_{zz} - k_\mathsf{R}^2)\,\psi', \tag{62.76}$$

and the linear potential vorticity equation (62.73a) is

$$(-\omega + u_\mathsf{b}\,k_x)\,(\partial_{zz} - k_\mathsf{R}^2)\,\widetilde{\psi} = 0, \tag{62.77}$$

where

$$k_\mathsf{R} = |\boldsymbol{k}|\,N/f_\circ = |\boldsymbol{k}|\,L_\mathsf{d}/H \tag{62.78}$$

is the inverse Rossby height originally introduced for topographic waves in equation (62.60).

Throughout the analysis we assume the angular frequency satisfies

$$\omega \neq u_\mathsf{b}\,k_x, \tag{62.79}$$

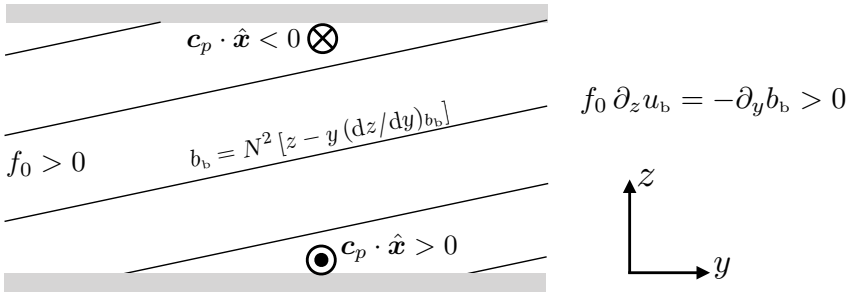

FIGURE 62.3: Depicting the orientation for the intrinsic phase velocity of Eady edge waves for a northern hemisphere thermal wind balanced base state with buoyancy decreasing northward. Relative to the local background flow, the upper boundary has westward propagating Eady waves whereas the Eady waves are eastward at the lower boundary (see Section 62.6.5).

which then means that the streamfunction equation (62.77) reduces to

$$\frac{\mathrm{d}^2 \widetilde{\psi}}{\mathrm{d}z^2} = k_\mathsf{R}^2 \, \widetilde{\psi}, \tag{62.80}$$

which is the same equation as satisfied by the topographic Rossby wave (62.59a). As seen below, the angular frequency assumption (62.79) indeed holds for Eady waves.

62.6.3 Bottom trapped Eady waves

As in our discussion of topographic Rossby waves in Section 62.5, assume here that the upper boundary is far from the lower boundary, with "far" determined by a horizontal wavenumber satisfying equation (62.63), i.e.,

$$|\boldsymbol{k}| \gg L_\mathsf{d}^{-1}. \tag{62.81}$$

In this case, the bottom trapped streamfunction solution to equation (62.80) is given by

$$\widetilde{\psi} = \widetilde{\psi}_\mathrm{bot} \, \mathrm{e}^{-k_\mathsf{R} \, (z - \overline{\eta_\mathsf{b}})}, \tag{62.82}$$

which is, as expected, the same as for the topographic Rossby wave (62.61). Even though they have the same form for their streamfunctions, the Eady wave dispersion relation differs from that of the topographic Rossby wave. Here, we derive the dispersion relation through use of the bottom boundary condition (62.73c), which takes the form

$$(-\omega + u_\mathsf{b}(\overline{\eta_\mathsf{b}}) \, k_x)(-k_\mathsf{R}) = k_x \, \partial_z u_\mathsf{b}, \tag{62.83}$$

thus leading to the dispersion relation

$$\omega_\mathrm{bot} = k_x \, u_\mathsf{b}(\overline{\eta_\mathsf{b}}) + (k_x / k_\mathsf{R}) \, \partial_z u_\mathsf{b}. \tag{62.84}$$

The vertical shear portion of the right hand side can be written in the following equivalent forms (again, each evaluated at $z = \overline{\eta_\mathsf{b}}$)

$$\frac{f_\circ \, \partial_z u_\mathsf{b}}{N} = \frac{H}{L_\mathsf{d}} \frac{\partial u_\mathsf{b}}{\partial z} = -N^{-1} \, \partial_y b_\mathsf{b} = N \, (\mathrm{d}z/\mathrm{d}y)_{b_\mathsf{b}}, \tag{62.85}$$

where the final equality introduced the meridional buoyancy slope (62.12). We are thus led to the dispersion relation for the bottom trapped edge waves

$$\omega_{\rm bot} = k_x \left[u_{\rm b} + k_{\rm R}^{-1} \, \partial_z u_{\rm b} \right]_{z=\overline{\eta_{\rm b}}} = k_x \left[u_{\rm b} + \frac{N}{|\boldsymbol{k}|} \left(\frac{{\rm d}z}{{\rm d}y} \right)_{b_{\rm b}} \right]_{z=\overline{\eta_{\rm b}}} . \tag{62.86}$$

The $k_x \, u_{\rm b}(\overline{\eta_{\rm b}})$ term provides a Doppler shifted frequency due to motion of the background zonal flow at the bottom. The next term arises from thermal wind shear in the presence of rotation and stratification, with the zonal thermal wind shear reliant on the meridionally sloped buoyancy surfaces that intersect the bottom.

62.6.4 Upper surface trapped Eady waves

Proceeding just like for the bottom, we now focus on the upper (top) boundary and assume the bottom boundary is far away. In this case the upper surface trapped streamfunction is given by

$$\widetilde{\psi} = \psi_{\rm top} \, {\rm e}^{k_{\rm R} \, (z - \overline{\eta})}, \tag{62.87}$$

which, when used in the upper boundary condition (62.29), leads to the dispersion relation

$$\omega_{\rm top} - k_x \, u_{\rm b}(\overline{\eta}) = -(k_x / k_{\rm R}) \, \partial_z u_{\rm b}. \tag{62.88}$$

This relation can be written just like equation (62.86) for the bottom boundary condition, only with a swapped sign on the buoyancy slope term

$$\omega_{\rm top} = k_x \left[u_{\rm b} - k_{\rm R}^{-1} \, \partial_z u_{\rm b} \right]_{z=\overline{\eta}} = k_x \left[u_{\rm b} - \frac{N}{|\boldsymbol{k}|} \left(\frac{{\rm d}z}{{\rm d}y} \right)_{b_{\rm b}} \right]_{z=\overline{\eta}} . \tag{62.89}$$

As for the bottom trapped Eady waves, the term $k_x \, u_{\rm b}(\overline{\eta})$ is a Doppler shift in the frequency arising from the zonal velocity at the upper boundary that couples to the zonal component of the phase velocity. The other term arises from the thermal wind shear coupled to rotation and stratification, which itself relies on the slope of the buoyancy surfaces that intersect the upper boundary.

62.6.5 Comparing the top and bottom dispersion relations

It is useful to compare the dispersion relations (62.86) and (62.89), rewritten here as the $\hat{\boldsymbol{x}}$ component of the phase velocity

$$\boldsymbol{c}_{\rm p} \cdot \hat{\boldsymbol{x}} = (\omega / |\boldsymbol{k}|^2) \, k_x, \tag{62.90}$$

which are given by

$$(\boldsymbol{c}_{\rm p} \cdot \hat{\boldsymbol{x}})_{\rm bot} = \frac{k_x^2}{|\boldsymbol{k}|^2} \left[u_{\rm b} + \frac{H \, \partial_z u_{\rm b}}{L_{\rm d} \, |\boldsymbol{k}|} \right]_{z=\overline{\eta_{\rm b}}} = \frac{k_x^2}{|\boldsymbol{k}|^2} \left[u_{\rm b} + \frac{N}{|\boldsymbol{k}|} \left(\frac{{\rm d}z}{{\rm d}y} \right)_{b_{\rm b}} \right]_{z=\overline{\eta_{\rm b}}} \tag{62.91a}$$

$$(\boldsymbol{c}_{\rm p} \cdot \hat{\boldsymbol{x}})_{\rm top} = \frac{k_x^2}{|\boldsymbol{k}|^2} \left[u_{\rm b} - \frac{H \, \partial_z u_{\rm b}}{L_{\rm d} \, |\boldsymbol{k}|} \right]_{z=\overline{\eta}} = \frac{k_x^2}{|\boldsymbol{k}|^2} \left[u_{\rm b} - \frac{N}{|\boldsymbol{k}|} \left(\frac{{\rm d}z}{{\rm d}y} \right)_{b_{\rm b}} \right]_{z=\overline{\eta}} . \tag{62.91b}$$

The first difference between these expressions arises from the differences in the background zonal flow at $z = \overline{\eta_{\rm b}}$ versus $z = \overline{\eta}$. Assuming $\partial_z u_{\rm b} > 0$, the background flow at the top has a larger eastward value than the background flow at the bottom, as given by

$$u_{\rm b}(\overline{\eta}) = u_{\rm b}(\overline{\eta_{\rm b}}) + (\overline{\eta} - \overline{\eta_{\rm b}}) \, \partial_z u_{\rm b} = u_{\rm b}(\overline{\eta_{\rm b}}) + H \, \partial_z u_{\rm b}. \tag{62.92}$$

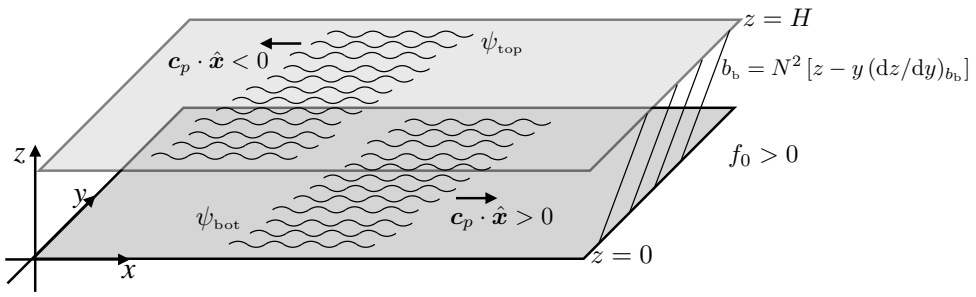

FIGURE 62.4: A perspective view of the intrinsic phase velocity of Eady edge waves for a northern hemisphere thermal wind balanced base state with buoyancy increasing northward. The upper boundary has westward propagating Eady waves whereas the Eady waves are eastward at the lower boundary. The top and bottom boundaries are flat, and so we write $z = \overline{\eta} = H$ for the upper boundary and $z = \overline{\eta_{\rm b}} = 0$ for the lower boundary.

The second difference between the bottom dispersion relation (62.91a) and top dispersion relation (62.91b) arises from the swapped signs for the buoyancy slope term. This term represents the *intrinsic frequency* for the two edge waves (i.e., the frequency seen by an observer moving with the background flow)

$$\omega^{\rm intrinsic}_{\rm bot} = \frac{N\,k_x^{\rm bot}}{|\boldsymbol{k}|}\left(\frac{{\rm d}z}{{\rm d}y}\right)_{b_{\rm b}} \quad \text{and} \quad \omega^{\rm intrinsic}_{\rm top} = -\frac{N\,k_x^{\rm top}}{|\boldsymbol{k}|}\left(\frac{{\rm d}z}{{\rm d}y}\right)_{b_{\rm b}}. \tag{62.93}$$

For surfaces of constant buoyancy that slope upward to the north, $({\rm d}z/{\rm d}y)_{b_{\rm b}} > 0$, the intrinsic frequency for the bottom wave is positive if the phase velocity is eastward relative to the background flow ($k_x^{\rm bot} > 0$), whereas a positive frequency for the top wave requires a westward phase velocity ($k_x^{\rm top} < 0$). We also see this orientation by writing the intrinsic components to the zonal phase velocities

$$(\boldsymbol{c}_{\rm p} \cdot \hat{\boldsymbol{x}})^{\rm intrinsic}_{\rm bot} = \frac{N\,k_x^2}{|\boldsymbol{k}|^2}\left(\frac{{\rm d}z}{{\rm d}y}\right)_{b_{\rm b}} > 0 \quad \text{and} \quad (\boldsymbol{c}_{\rm p} \cdot \hat{\boldsymbol{x}})^{\rm intrinsic}_{\rm top} = -\frac{N\,k_x^2}{|\boldsymbol{k}|^2}\left(\frac{{\rm d}z}{{\rm d}y}\right)_{b_{\rm b}} < 0. \tag{62.94}$$

The zonal component to the phase velocity in equations (62.91a) and (62.91b) are equal for that wavevector whose magnitude satisfies

$$L_{\rm d}\,|\boldsymbol{k}| = 2, \tag{62.95}$$

in which case

$$(\boldsymbol{c}_{\rm p} \cdot \hat{\boldsymbol{x}})_{\rm top} = (k_x^2/|\boldsymbol{k}|^2)\,[u_{\rm b}(\overline{\eta}) - (H/2)\,\partial_z u_{\rm b}] = (k_x^2/|\boldsymbol{k}|^2)\,[u_{\rm b}(\overline{\eta_{\rm b}}) + (H/2)\,\partial_z u_{\rm b}] = (\boldsymbol{c}_{\rm p} \cdot \hat{\boldsymbol{x}})_{\rm bot}. \tag{62.96}$$

Evidently, waves with $L_{\rm d}\,|\boldsymbol{k}| = 2$ have the opportunity to phase lock and thus to interact. This possibility motivates the work in Section 62.7 whereby we include interactions in the formulation.

62.6.6 Meridional and vertical motion within an Eady wave

To help understand fluid particle motion in a stable Eady wave, we compute the meridional velocity, v', and vertical velocity, w', for a wave moving along the bottom boundary, with a similar calculation holding along the top. Recall that since the flow is quasi-geostrophic that the vertical velocity is much smaller than the horizontal. Even so, it is nonzero and we can compute it for the Eady wave, thus revealing motion in the meridional-depth plane. For this calculation we use the streamfunction for a bottom trapped Eady wave

$$\psi'(x, y, z, t) = \widetilde{\psi}_{\rm o}\, {\rm e}^{-k_{\rm R}\,(z - \overline{\eta_{\rm b}})}\, {\rm e}^{{\rm i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega_{\rm bot}\,t)}, \tag{62.97}$$

with ω_{bot} given by the dispersion relation (62.86).

The meridional velocity of fluid particles within the bottom Eady wave is given by

$$v' = \partial_x \psi' = \mathrm{i}\, k_x\, \widetilde{\psi}_{\mathsf{o}}\, \mathrm{e}^{-k_{\mathsf{R}}\,(z-\overline{\eta_{\mathsf{b}}})}\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega_{\text{bot}}\,t)}, \tag{62.98}$$

whose real part is

$$v' = -k_x\, \widetilde{\psi}_{\mathsf{o}}\, \mathrm{e}^{-k_{\mathsf{R}}\,(z-\overline{\eta_{\mathsf{b}}})} \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega_{\text{bot}}\,t). \tag{62.99}$$

A similar calculation leads to the zonal velocity within the wave

$$u' = k_y\, \widetilde{\psi}_{\mathsf{o}}\, \mathrm{e}^{-k_{\mathsf{R}}\,(z-\overline{\eta_{\mathsf{b}}})} \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega_{\text{bot}}\,t). \tag{62.100}$$

Calculating the vertical velocity takes a bit more work, for which we make use of the linearized buoyancy equation (62.26) so that

$$w'\, N^2 = -(\partial_t + u_{\mathsf{b}}\,\partial_x) b' - v'\,\partial_y b_{\mathsf{b}}. \tag{62.101}$$

The first term is given by

$$-(\partial_t + u_{\mathsf{b}}\,\partial_x) b' = \mathrm{i}\, k_{\mathsf{R}}\, f_{\mathsf{o}}\, (-\omega_{\text{bot}} + k_x\, u_{\mathsf{b}})\, \psi', \tag{62.102}$$

whose real part is

$$-(\partial_t + u_{\mathsf{b}}\,\partial_x) b' = k_{\mathsf{R}}\, f_{\mathsf{o}}\, (\omega_{\text{bot}} - k_x\, u_{\mathsf{b}})\, \widetilde{\psi}_{\mathsf{o}}\, \mathrm{e}^{-k_{\mathsf{R}}\,(z-\overline{\eta_{\mathsf{b}}})} \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega_{\text{bot}}\,t), \tag{62.103}$$

and the meridional velocity term is

$$-v'\,\partial_y b_{\mathsf{b}} = k_x\,\partial_y b_{\mathsf{b}}\, \widetilde{\psi}_{\mathsf{o}}\, \mathrm{e}^{-k_{\mathsf{R}}\,(z-\overline{\eta_{\mathsf{b}}})} \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega_{\text{bot}}\,t), \tag{62.104}$$

so that

$$w'\, N^2 = \widetilde{\psi}_{\mathsf{o}}\, \mathrm{e}^{-k_{\mathsf{R}}\,(z-\overline{\eta_{\mathsf{b}}})} \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega_{\text{bot}}\,t)[k_x\,\partial_y b_{\mathsf{b}} + k_{\mathsf{R}}\, f_{\mathsf{o}}\, (\omega_{\text{bot}} - k_x\, u_{\mathsf{b}})]. \tag{62.105}$$

Making use of the dispersion relation (62.86) for the bottom trapped Eady edge waves leads to

$$\begin{aligned} k_x\,\partial_y b_{\mathsf{b}} + k_{\mathsf{R}}\, f_{\mathsf{o}}\, (\omega_{\text{bot}} - k_x\, u_{\mathsf{b}}) &= k_x\,\partial_y b_{\mathsf{b}} + k_{\mathsf{R}}\, f_{\mathsf{o}}\, k_x\, (k_{\mathsf{R}}^{-1} - z)\,\partial_z u_{\mathsf{b}} && \text{(62.106a)} \\ &= k_{\mathsf{R}}\, k_x\, z\,\partial_y b_{\mathsf{b}}, && \text{(62.106b)} \end{aligned}$$

so that the vertical velocity component is

$$w' = -k_{\mathsf{R}}\, k_x\, z\, (\mathrm{d}z/\mathrm{d}y)_{b_{\mathsf{b}}}\, \widetilde{\psi}_{\mathsf{o}}\, \mathrm{e}^{-k_{\mathsf{R}}\,(z-\overline{\eta_{\mathsf{b}}})} \sin(\boldsymbol{k}\cdot\boldsymbol{x} - \omega_{\text{bot}}\,t) \tag{62.107}$$

and its ratio with the meridional velocity is

$$w'/v' = z\, k_{\mathsf{R}}\, (\mathrm{d}z/\mathrm{d}y)_{b_{\mathsf{b}}} = z\, |\boldsymbol{k}|\, (N/f_{\mathsf{o}})\, (\mathrm{d}z/\mathrm{d}y)_{b_{\mathsf{b}}}. \tag{62.108}$$

For vertical positions less than the Rossby height, k_{R}^{-1}, the fluid particle motion is more horizontal than the buoyancy slope, whereas the motion is more vertical than the slope for positions higher than k_{R}^{-1}. Also note that the amplitude of the motion exponentially decays moving away from the bottom boundary with an efolding height k_{R}^{-1} Figure 62.5 provides a schematic of this motion.

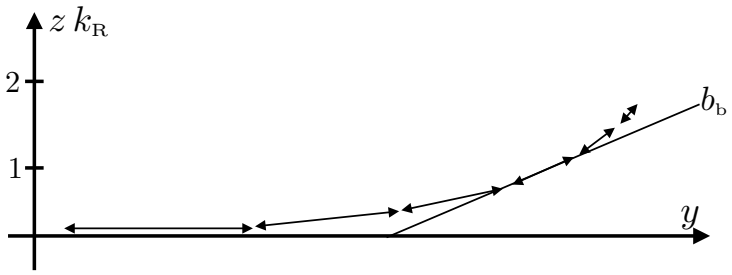

FIGURE 62.5: A meridional-vertical view of fluid particle velocity within a stable bottom trapped Eady wave, as given by equation (62.108). The particle velocity is parallel to the bottom when at $z = \overline{\eta_{\mathrm{b}}} = 0$, and parallel to the buoyancy surface at vertical position $z\,k_{\mathrm{R}} = 1$, and further steepens when moving higher in the column. The amplitude of the oscillatory motion exponentially decays away from the bottom with an e-folding scale given by the Rossby height, k_{R}^{-1}. This figure is adapted from Figure 13.1(e) in *Gill* (1982).

62.6.7 Further study

The treatment in this section is compatible with Section 13.2 of *Gill* (1982), Chapter 19 of *Pedlosky* (2003) and Section 8.7 of *Smyth and Carpenter* (2019).

62.7 Interacting Eady waves and baroclinic instability

The analysis from Section 62.6 revealed the presence of Eady edge waves that are exponentially trapped next to the rigid top and bottom boundaries, with the wave supported by the thermal wind shear intersecting the boundaries. Furthermore, the zonal component to the phase velocity of the two waves is equal (equation (62.6.5)) for a horizontal wavenumber

$$\omega_{\mathrm{top}} = \omega_{\mathrm{bot}} \implies |\boldsymbol{k}| = 2\,L_{\mathrm{d}}^{-1}. \tag{62.109}$$

For this wave, and for longer waves (smaller wavenumbers), we cannot ignore wave interactions. Under specific circumstances detailed in this section, the waves constructively interact to support mutual exponential growth, thus signaling *baroclinic instability*. The treatment is directly analogous to our study in Section 61.6 of interacting vortex edge waves in a horizontally sheared fluid.

62.7.1 Streamfunction solution

As before, we take the streamfunction ansatz (62.75), which builds in an assumption that the Eady waves at the two boundaries move with the same phase velocity to thus allow them to interact. We are thus led to the differential equation (62.80) and boundary conditions (62.73c) and (62.83)

$$\mathrm{d}^2\widetilde{\psi}/\mathrm{d}z^2 = k_{\mathrm{R}}^2\,\widetilde{\psi} \qquad 0 < z < H \tag{62.110a}$$

$$[-\omega + u_{\mathrm{b}}(H)\,k_x]\,\partial_z\widetilde{\psi} = k_x\,\partial_z u_{\mathrm{b}}\,\widetilde{\psi} \qquad z = H \tag{62.110b}$$

$$[-\omega + u_{\mathrm{b}}(0)\,k_x]\,\partial_z\widetilde{\psi} = k_x\,\partial_z u_{\mathrm{b}}\,\widetilde{\psi} \qquad z = 0, \tag{62.110c}$$

where we made use of the inverse Rossby height (62.60)

$$k_{\mathrm{R}} = |\boldsymbol{k}|\,N/f_{\mathrm{o}} = |\boldsymbol{k}|\,L_{\mathrm{d}}/H \quad \text{with } L_{\mathrm{d}} = N\,H/f_{\mathrm{o}}. \tag{62.111}$$

Additionally, we set

$$\overline{\eta} = H \quad \text{and} \quad \overline{\eta_{\mathrm{b}}} = 0, \tag{62.112}$$

to help reduce notational clutter (see Figure 62.4).

Solution to the boundary value problem

The solution to the differential equation (62.110a) is given by the hyperbolic functions

$$\widetilde{\psi} = C_1 \cosh(k_\mathsf{R}\, z) + C_2 \sinh(k_\mathsf{R}\, z), \tag{62.113}$$

where the coefficients C_1 and C_2, are specified from the boundary conditions. Making use of the upper surface boundary condition (62.110b) and bottom boundary condition (62.110c) leads to the coupled linear equations

$$(-\tilde{c} + H\,\partial_z u_\mathsf{b})\, k_\mathsf{R}\, [C_1 \sinh(k_\mathsf{R}\, H) + C_2 \cosh(k_\mathsf{R}\, H)] = \partial_z u_\mathsf{b}\, [C_1 \cosh(k_\mathsf{R}\, H) + C_2 \sinh(k_\mathsf{R}\, H)] \tag{62.114a}$$

$$-\tilde{c}\, k_\mathsf{R}\, C_2 = C_1\, \partial_z u_\mathsf{b}, \tag{62.114b}$$

where we introduced the shorthand

$$\tilde{c} \equiv \omega/k_x - u_\mathsf{b}(0), \tag{62.115}$$

and noted that the constant thermal wind shear means that

$$u_\mathsf{b}(H) = u_\mathsf{b}(0) + H\,\partial_z u_\mathsf{b}. \tag{62.116}$$

62.7.2 Dispersion relation

Equations (62.114a) and (62.114b) are two homogeneous linear equations for the two unknowns, C_1 and C_2. A nontrivial solution exists if the determinant of the 2×2 coefficient matrix vanishes. This condition leads to the quadratic equation for $\tilde{c}$

$$\tilde{c}^2 - \tilde{c}\, H\, \partial_z u_\mathsf{b} + (\partial_z u_\mathsf{b}/k_\mathsf{R})^2\, (H\, k_\mathsf{R} \coth(k_\mathsf{R}\, H) - 1) = 0, \tag{62.117}$$

which has two roots given by the quadratic formula

$$\tilde{c} = \frac{H\,\partial_z u_\mathsf{b}}{2} \pm \frac{\partial_z u_\mathsf{b}}{k_\mathsf{R}} \left[\frac{(k_\mathsf{R}\, H)^2}{4} - k_\mathsf{R}\, H \coth(k_\mathsf{R}\, H) + 1 \right]^{1/2}. \tag{62.118}$$

A further simplification arises from use of the identity

$$2 \coth x = \tanh(x/2) + \coth(x/2), \tag{62.119}$$

in which case we have the roots

$$\omega/k_x = u_\mathsf{b}(z=0) + \frac{H\,\partial_z u_\mathsf{b}}{2} \pm \frac{\partial_z u_\mathsf{b}}{k_\mathsf{R}} \left[\left(\frac{k_\mathsf{R}\, H}{2} - \coth(k_\mathsf{R}\, H/2) \right) \left(\frac{k_\mathsf{R}\, H}{2} - \tanh(k_\mathsf{R}\, H/2) \right) \right]^{1/2}. \tag{62.120}$$

Since

$$x \geq \tanh x, \tag{62.121}$$

the only way to realize a negative discriminant is for

$$k_\mathsf{R}\, H \leq 2 \coth(k_\mathsf{R}\, H/2). \tag{62.122}$$

A graphical solution to the equality finds the critical nondimensional wavenumber

$$k_{\mathsf{R}}\, H = |\boldsymbol{k}|\, L_{\mathsf{d}} \approx 2.399. \tag{62.123}$$

Longer waves that satisfy the inequality are baroclinically unstable

$$k_{\mathsf{R}}\, H = |\boldsymbol{k}|\, L_{\mathsf{d}} < 2.399 \Longrightarrow \text{unstable} \tag{62.124}$$

Note how $|\boldsymbol{k}|\, L_{\mathsf{d}} \approx 2.399$ is rather close to the $|\boldsymbol{k}|\, L_{\mathsf{d}} = 2$ value from equation (62.109), computed by setting the frequencies equal for two non-interacting Eady edge waves.

62.7.3 Growth rate

For unstable waves, the growth rate is given by the imaginary part of the angular frequency

$$\sigma = \frac{|k_x\, \partial_z u_{\mathsf{b}}|}{k_{\mathsf{R}}} \left[\left| \frac{k_{\mathsf{R}}\, H}{2} - \coth(k_{\mathsf{R}}\, H/2) \right| \left| \frac{k_{\mathsf{R}}\, H}{2} - \tanh(k_{\mathsf{R}}\, H/2) \right| \right]^{1/2}. \tag{62.125}$$

Due to the k_x factor in the front, we see that for any given horizontal wavenumber,

$$|\boldsymbol{k}| = \sqrt{k_x^2 + k_y^2}, \tag{62.126}$$

the growth rate is maximized for waves with a zonal phase velocity, in which case

$$|\boldsymbol{k}| = |k_x|. \tag{62.127}$$

That is, the most unstable waves whose phase velocity is aligned with the background flow[3]

$$\sigma(\boldsymbol{k} = \hat{\boldsymbol{x}}\, k_x) = \frac{H\, |\partial_z u_{\mathsf{b}}|}{L_{\mathsf{d}}} \left[\left| \frac{|\boldsymbol{k}|\, L_{\mathsf{d}}}{2} - \coth(|\boldsymbol{k}|\, L_{\mathsf{d}}/2) \right| \left(\frac{|\boldsymbol{k}|\, L_{\mathsf{d}}}{2} - \tanh(|\boldsymbol{k}|\, L_{\mathsf{d}}/2) \right) \right]^{1/2}. \tag{62.128}$$

Since the horizontal flow is non-divergent, Eady waves are horizontally transverse so that fluid particle movement is perpendicular to the phase velocity. With a zonal phase velocity, fluid particles move in the meridional direction.

Maximum growth rate

To determine the maximum growth rate we compute the wavenumber, $|\boldsymbol{k}| = |k_x|$, that satisfies

$$\frac{\mathrm{d}\sigma^2}{\mathrm{d}k_x} = 0, \tag{62.129}$$

which yields

$$|\boldsymbol{k}|_{\max} = |k_x|_{\max} \approx 1.6/L_{\mathsf{d}} \Longrightarrow \Lambda_{\max} \approx (2\pi/1.6)\, L_{\mathsf{d}} \approx 3.9\, L_{\mathsf{d}}. \tag{62.130}$$

Evidently, the fastest growing Eady waves are purely zonal and have wavelength about four times the deformation radius. It is this connection to the deformation radius that directly connects these unstable Eady waves to synoptic eddies in the atmosphere and mesoscale eddies in the ocean.

[3] This is a version of Squires theorem described at the start of Chapter 61.

Eady growth rate

The growth rate (62.128) is the product of an inverse time scale, T_{Eady}^{-1}, and a non-dimensional function, where the Eady time scale is given by

$$T_{\text{Eady}} = \frac{L_{\text{d}}}{H\,\partial_z u_{\text{b}}} = \frac{1}{f_{\circ}}\,\frac{N}{\partial_z u_{\text{b}}} = \frac{\sqrt{\text{Ri}}}{f_{\circ}} = [N\,|(\text{d}z/\text{d}y)_{b_{\text{b}}}|]^{-1}. \tag{62.131}$$

We here introduced the *balanced Richardson number* from Section 43.7.5

$$\text{Ri} = N^2/(\partial_z u_{\text{b}})^2 = f_{\circ}^2\,[N\,(\text{d}z/\text{d}y)_{b_{\text{b}}}]^{-2}. \tag{62.132}$$

For quasi-geostrophic flows, the balanced Richardson number is normally quite large. Evaluating the growth rate expression (62.128) with the fastest growing wave (62.130) renders

$$\sigma_{\max} = 0.31\,T_{\text{Eady}}^{-1} = 0.31\,|\partial_z u_{\text{b}}\,(f_{\circ}/N)| = 0.31\,\frac{|f_{\circ}|}{\sqrt{\text{Ri}}}. \tag{62.133}$$

This maximum growth rate is sometimes generically called *the Eady growth rate*. For a background state with $\text{Ri} = 100$ and $f_{\circ} = 10^{-4}$ s^{-1}, we find the growth rate of the most unstable Eady wave

$$\sigma_{\max} \approx (3.7 \text{ days})^{-1}, \tag{62.134}$$

which accords with the growth rate of middle latitude atmospheric cyclones. For the ocean, the Eady growth rate is roughly ten times slower than the atmosphere (e.g., see Figure 1 in *Treguier et al.* (1997)).

62.7.4 Further study

Our presentation of the Eady model is consistent with that found in *Pedlosky* (2003) and *Vallis* (2017). Although maths and pictures are revealing, it is also useful to observe laboratory rotating tank experiments to further ones understanding of the Eady model and baroclinic instability.

62.8 Necessary conditions for instability

In Section 61.5 we established the Rayleigh-Kuo inflection point theorem as well as Fjørtoft's theorem, each establishing necessary conditions for shear instability. Here we pursue a similar approach for baroclinic instability of a zonal background flow

$$u_{\text{b}} = u_{\text{b}}(y, z), \tag{62.135}$$

and maintain nonzero planetary β so that

$$f = f_{\circ} + \beta\, y. \tag{62.136}$$

The analysis of non-zonal flows greatly adds to the technical overhead, largely since the flow is no longer perpendicular to the planetary vorticity gradient. We thus restrict attention to zonal background flows.

As for the shear instability case, the necessary conditions for instability identifies cases whereby instabilities are possible. However, the integral conditions are not sufficient conditions. Hence, detailed calculations are required to determine if the flow is indeed unstable even if it satisfies the necessary conditions. Both the derivation of the necessary conditions, and their form, offer insights into the mechanics of baroclinic instability.

62.8.1 Summary of the governing linear equations

From Section 62.3.3, we have the governing linear equation (62.25) for the geostrophic streamfunction and the boundary conditions (62.29) and (62.33)

$$(\partial_t + u_\mathsf{b}\,\partial_x)\,[\nabla_\mathsf{h}^2\psi' + f_\circ^2\,\partial_z(N^{-2}\,\partial_z\psi')] = -\partial_x\psi'\,\partial_y q_\mathsf{b} \qquad \overline{\eta_\mathsf{b}} < z < \overline{\eta} \tag{62.137a}$$

$$(\partial_t + u_\mathsf{b}\,\partial_x)\,\partial_z\psi' = \partial_x\psi'\,\partial_z u_\mathsf{b} \qquad z = \overline{\eta} \tag{62.137b}$$

$$f_\circ\,(\partial_t + u_\mathsf{b}\,\partial_x)\,\partial_z\psi' = \partial_x\psi'\,N^2\,[(\mathrm{d}z/\mathrm{d}y)_{b_\mathsf{b}} - \partial_y\eta_\mathsf{b}] \qquad z = \overline{\eta_\mathsf{b}}, \tag{62.137c}$$

where the meridional derivative of the background potential vorticity is given by equation (62.14)

$$\partial_y q_\mathsf{b} = \partial_y[f_\circ + \beta\,y - \partial_y u_\mathsf{b} + f_\circ^2\,\partial_z(N^{-2}\,\partial_z\Psi_\mathsf{b})] = \beta - \partial_{yy}u_\mathsf{b} + f_\circ^2\,\partial_{yz}(N^{-2}\,\partial_z\Psi_\mathsf{b}). \tag{62.138}$$

The background flow is a function of (y,z), which means it only supports freely propagating plane waves in the zonal direction. We thus consider the following wave ansatz for the streamfunction

$$\psi'(x,y,z,t) = \widetilde{\psi}(y,z)\,\mathrm{e}^{\mathrm{i}\,(k_x\,x - \omega\,t)}. \tag{62.139}$$

Use of this ansatz in the boundary value problem (62.137a)-(62.137c) yields

$$(u_\mathsf{b} - c)\,[(\partial_{yy} - k_x^2)\,\widetilde{\psi} + f_\circ^2\,\partial_z(N^{-2}\,\partial_z\widetilde{\psi})] = -\widetilde{\psi}\,\partial_y q_\mathsf{b} \qquad \overline{\eta_\mathsf{b}} < z < \overline{\eta} \tag{62.140a}$$

$$(u_\mathsf{b} - c)\,\partial_z\widetilde{\psi} = \widetilde{\psi}\,\partial_z u_\mathsf{b} \qquad z = \overline{\eta} \tag{62.140b}$$

$$f_\circ\,(u_\mathsf{b} - c)\,\partial_z\widetilde{\psi} = N^2\,\widetilde{\psi}\,[(\mathrm{d}z/\mathrm{d}y)_{b_\mathsf{b}} - \partial_y\eta_\mathsf{b}] \qquad z = \overline{\eta_\mathsf{b}}, \tag{62.140c}$$

where the zonal phase velocity is written

$$\boldsymbol{c}_\mathsf{p} = (\omega/|\boldsymbol{k}|)\,\hat{\boldsymbol{k}} = (\omega/k_x)\,\hat{\boldsymbol{x}} = c\,\hat{\boldsymbol{x}}. \tag{62.141}$$

Note that the phase velocity, c, is generally complex, which means that the streamfunction, $\widetilde{\psi}$, is also complex. Just like for the horizontal shear case in Section 61.6, if c and $\widetilde{\psi}$ satisfy the boundary value problem (62.140a)-(62.140c), then so do their complex conjugates, c^* and $\widetilde{\psi}^*$.

62.8.2 Steps for deriving the necessary conditions

To develop a necessary condition for instability, multiply the differential equation (62.140a) by $\widetilde{\psi}^*$ and integrate over the full domain

$$\int \left[\widetilde{\psi}^*\,(\partial_{yy} - k_x^2)\,\widetilde{\psi} + \widetilde{\psi}^*\,f_\circ^2\,\partial_z(N^{-2}\,\partial_z\widetilde{\psi}) + \frac{|\widetilde{\psi}|^2\,\partial_y q_\mathsf{b}}{U - c}\right]\mathrm{d}y\,\mathrm{d}z = 0. \tag{62.142}$$

Meridional derivative term

Consider the meridional derivative term, in which we have

$$\int \widetilde{\psi}^*\,\partial_{yy}\widetilde{\psi}\,\mathrm{d}y = \int [\partial_y(\widetilde{\psi}^*\,\partial_y\widetilde{\psi}) - |\partial_y\widetilde{\psi}|^2]\,\mathrm{d}y. \tag{62.143}$$

Assuming either meridionally periodic conditions, or fields that decay at infinity, allows us to drop the total derivative term to have

$$\int \widetilde{\psi}^*\,\partial_{yy}\widetilde{\psi}\,\mathrm{d}y = -\int |\partial_y\widetilde{\psi}|^2\,\mathrm{d}y. \tag{62.144}$$

Vertical derivative term

For the vertical derivative term we have

$$\int \widetilde{\psi}^* \, \partial_z (N^{-2} \, \partial_z \widetilde{\psi}) \, \mathrm{d}z = \int [\partial_z (\widetilde{\psi}^* \, N^{-2} \, \partial_z \widetilde{\psi}) - N^{-2} \, |\partial_z \widetilde{\psi}|^2] \, \mathrm{d}z. \tag{62.145}$$

The boundary conditions (62.140b) and (62.140c) lead to

$$[\widetilde{\psi}^* \, N^{-2} \, \partial_z \widetilde{\psi}]_{z=\overline{\eta}} = \left[\frac{|\widetilde{\psi}|^2 \, \partial_z u_\mathrm{b}}{N^2 \, (u_\mathrm{b} - c)} \right]_{z=\overline{\eta}} \tag{62.146a}$$

$$[\widetilde{\psi}^* \, N^{-2} \, \partial_z \widetilde{\psi}]_{z=\overline{\eta_\mathrm{b}}} = \left[\frac{|\widetilde{\psi}|^2 \, [(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} - \partial_y \eta_\mathrm{b}]}{f_\circ \, (u_\mathrm{b} - c)} \right]_{z=\overline{\eta_\mathrm{b}}} \tag{62.146b}$$

It is important to note that these boundary terms are generally nonzero, and so they play a role in determining the necessary conditions for instability.

62.8.3 Necessary conditions based on the imaginary part

The various pieces bring the integral (62.142) into the form

$$\begin{aligned} &\int \left[k_x^2 \, |\widetilde{\psi}|^2 + |\partial_y \widetilde{\psi}|^2 + (f_\circ/N)^2 \, |\partial_z \widetilde{\psi}|^2 \right] \mathrm{d}y \, \mathrm{d}z \\ &\quad = \int \frac{|\widetilde{\psi}|^2 \, \partial_y q_\mathrm{b}}{u_\mathrm{b} - c} \, \mathrm{d}y \, \mathrm{d}z + \int_{z=\overline{\eta}} \frac{f_\circ^2 \, |\widetilde{\psi}|^2 \, \partial_z u_\mathrm{b}}{N^2 \, (u_\mathrm{b} - c)} \, \mathrm{d}y - \int_{z=\overline{\eta_\mathrm{b}}} \frac{f_\circ \, |\widetilde{\psi}|^2 \, [(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} - \partial_y \eta_\mathrm{b}]}{(u_\mathrm{b} - c)} \, \mathrm{d}y. \end{aligned} \tag{62.147}$$

The left hand side is a real and non-negative number. For consistency, the imaginary part of the right hand side must vanish. Making use of the identity

$$\frac{1}{u_\mathrm{b} - c} = \frac{u_\mathrm{b} - c_\mathrm{r} - \mathrm{i} \, c_\mathrm{i}}{|u_\mathrm{b} - c|^2} \tag{62.148}$$

leads to the constraint

$$c_\mathrm{i} \left[\int \frac{|\widetilde{\psi}|^2 \, \partial_y q_\mathrm{b}}{|u_\mathrm{b} - c|^2} \, \mathrm{d}y \, \mathrm{d}z + \int_{z=\overline{\eta}} \frac{f_\circ^2 \, |\widetilde{\psi}|^2 \, \partial_z u_\mathrm{b}}{N^2 \, |u_\mathrm{b} - c|^2} \, \mathrm{d}y - \int_{z=\overline{\eta_\mathrm{b}}} \frac{f_\circ \, |\widetilde{\psi}|^2 \, [(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} - \partial_y \eta_\mathrm{b}]}{|u_\mathrm{b} - c|^2} \, \mathrm{d}y \right] = 0. \tag{62.149}$$

An instability exists only if $c_\mathrm{i} \neq 0$. We thus see that if the sum of the integrals does not vanish, then there can be no instability. That is, a sufficient condition for baroclinic stability of a zonal geostrophic flow, $u_\mathrm{b}(y, z)$, is that the sum of the integrals is nonzero. Conversely, a necessary condition for baroclinic instability of the zonal flow is that the sum of the three integrals in equation (62.149) vanishes. This necessary condition is known as the *Charney-Stern-Pedlosky* condition (*Charney and Stern*, 1962; *Pedlosky*, 1964).

In summary, the necessary conditions for instability are that the following three functions must not have the same sign everywhere

$$\partial_y q_\mathrm{b} \quad \text{must change sign within } \overline{\eta_\mathrm{b}} < z < \overline{\eta} \tag{62.150a}$$

$$f_\circ \, \partial_y u_\mathrm{b} = -\partial_y b_\mathrm{b} \quad \text{must change sign along } z = \overline{\eta} \tag{62.150b}$$

$$(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} - \partial_y \eta_\mathrm{b} \quad \text{must change sign along } z = \overline{\eta_\mathrm{b}}. \tag{62.150c}$$

Conversely, if each of these conditions fails, then that is sufficient to conclude that the flow is stable to baroclinic instability.

62.8.4 Necessary conditions based on the real part

Following from Fjørtoft's theorem for shear instability in Section 61.5.2, consider the real part of equation (62.147), which says

$$\Gamma = \int \frac{(u_\mathrm{b} - c_\mathrm{r})\,|\widetilde{\psi}|^2\,\partial_y q_\mathrm{b}}{|u_\mathrm{b} - c|^2}\,\mathrm{d}y\,\mathrm{d}z + \int_{z=\overline{\eta}} \frac{(u_\mathrm{b} - c_\mathrm{r})\,f_\circ^2\,|\widetilde{\psi}|^2\,\partial_z u_\mathrm{b}}{N^2\,|u_\mathrm{b} - c|^2}\,\mathrm{d}y - \int_{z=\overline{\eta_\mathrm{b}}} \frac{(u_\mathrm{b} - c_\mathrm{r})\,f_\circ\,|\widetilde{\psi}|^2\,[(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} - \partial_y \eta_\mathrm{b}]}{|u_\mathrm{b} - c|^2}\,\mathrm{d}y, \quad (62.151)$$

where we introduced the non-negative number

$$\Gamma = \int \left[k_x^2\,|\widetilde{\psi}|^2 + |\partial_y \widetilde{\psi}|^2 + (f_\circ/N)^2\,|\partial_z \widetilde{\psi}|^2\right]\mathrm{d}y\,\mathrm{d}z \geq 0. \quad (62.152)$$

Given that the condition (62.149) is maintained (with $c_\mathrm{i} \neq 0$), then we can replace c_r in equation (62.151) with an arbitrary constant, referred to as U_s in Fjørtoft's theorem from Section 61.5.2. We conclude that a sufficient condition for stability is if there is any constant, U_s, whereby all of the following conditions hold

$$(u_\mathrm{b} - c_\mathrm{r})\,\partial_y q_\mathrm{b} < 0 \qquad \overline{\eta_\mathrm{b}} < z < \overline{\eta} \quad (62.153a)$$

$$(u_\mathrm{b} - U_s)\,\partial_z u_\mathrm{b} < 0 \qquad z = \overline{\eta} \quad (62.153b)$$

$$-(u_\mathrm{b} - U_s)\,[(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} - \partial_y \eta_\mathrm{b}] < 0 \qquad z = \overline{\eta_\mathrm{b}}. \quad (62.153c)$$

62.8.5 Necessary condition for instability of the Eady model

To help understand features of the necessary condition (62.149), and the summary statements (62.150a)–(62.150c), we consider some special cases, starting with the Eady model from Sections 62.6 and 62.7. In this case, there is a constant interior potential vorticity of the background state, so that $\partial_y q_\mathrm{b} = 0$. Hence, the necessary condition for instability (62.149) reduces to a condition on the boundary integrals

$$\int_{z=\overline{\eta}} \frac{|\widetilde{\psi}|^2\,\partial_z u_\mathrm{b}}{N^2\,|u_\mathrm{b} - c|^2}\,\mathrm{d}y = \int_{z=\overline{\eta_\mathrm{b}}} \frac{|\widetilde{\psi}|^2\,\partial_z u_\mathrm{b}}{N^2\,|u_\mathrm{b} - c|^2}\,\mathrm{d}y, \quad (62.154)$$

where we set $\partial_y \eta_\mathrm{b} = 0$ as per the Eady model, and the buoyancy slope is

$$(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} = -\partial_y b_\mathrm{b}/\partial_z b_\mathrm{b} = f_\circ\,\partial_z u_\mathrm{b}/N^2. \quad (62.155)$$

Furthermore, N^2 and $\partial_z u_\mathrm{b}$ are constants in the Eady model, and the zonal flow is a function only of vertical, $u_\mathrm{b}(z)$, so that the necessary condition for instability (62.154) reduces to

$$\left[\frac{|\widetilde{\psi}|^2}{|u_\mathrm{b} - c|^2}\right]_{z=\overline{\eta}} = \left[\frac{|\widetilde{\psi}|^2}{|u_\mathrm{b} - c|^2}\right]_{z=\overline{\eta_\mathrm{b}}}. \quad (62.156)$$

For this condition to hold requires the streamfunction to be nonzero at both boundaries. We are ensured that the streamfunction is not exponentially small at the boundaries when the edge waves have small enough wavenumber that the waves can overlap and have a nontrivial presence at both boundaries

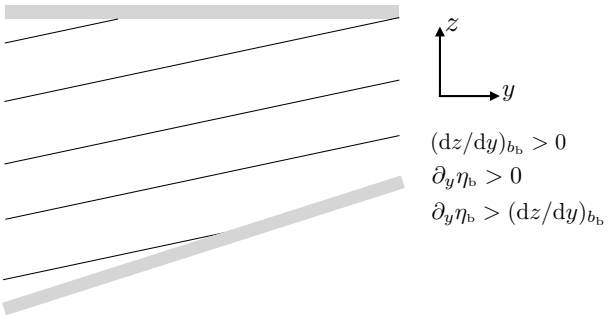

FIGURE 62.6: The Eady model with constant sloping buoyancy surfaces and with a bottom slope that is steeper than the buoyancy surfaces. This flow state is baroclinically stable according to equation (62.157) since the slope of the topography is steeper than the buoyancy surface.

62.8.6 Effects from adding a bottom slope to the Eady model

Consider the Eady model but with a sloping bottom, in which case the necessary condition for instability, equation (62.149), becomes

$$\int_{z=\overline{\eta}} \frac{|\widetilde{\psi}|^2 \, (\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}}}{|u_\mathrm{b} - c|^2} \, \mathrm{d}y = \int_{z=\overline{\eta_\mathrm{b}}} \frac{|\widetilde{\psi}|^2 \, [(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} - \partial_y \eta_\mathrm{b}]}{|u_\mathrm{b} - c|^2} \, \mathrm{d}y. \tag{62.157}$$

For the Eady model the buoyancy slope is constant, and let us assume it is positive. If the bottom topography slope has the same sign as the buoyancy slope, but is larger in magnitude, then the right hand side of equation (62.157) is negative whereas the left hand side is positive. We reach a contradiction, which means this necessary condition for instability cannot be satisfied. Evidently, the flow is baroclinically stable if the bottom slope is steeper than the buoyancy slope. We depict this situation in Figure 62.6.

62.8.7 Flat bottom with constant buoyancy along the two boundaries

The Eady model has horizontally varying buoyancy along the top and bottom boundaries, and stability of the Eady waves is determined by the boundary buoyancy. But what if there is a constant buoyancy along the two boundaries (so $(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} = 0$) and with the bottom boundary flat ($\partial_y \eta_\mathrm{b} = 0$)? In this case there are no topographic waves nor Eady waves along the boundaries, and both boundary integrals in the necessary condition (62.149) vanish. The necessary condition for instability (62.149) reduces to

$$\int \frac{|\widetilde{\psi}|^2 \, \partial_y q_\mathrm{b}}{|u_\mathrm{b} - c|^2} \, \mathrm{d}y \, \mathrm{d}z = 0. \tag{62.158}$$

We thus find that in the absence of boundary contributions, the necessary condition for baroclinic instability holds so long as the meridional derivative of the background potential vorticity changes sign somewhere in the domain. This condition is reminiscent of the Rayleigh-Kuo inflection point theorem for horizontal shear instability (Section 61.5).

62.9 Energetics of small amplitude fluctuations

In this section we offer another means to help understand the mechanics of quasi-geostrophic waves and baroclinic instability, as well as conditions required for a fluctuation to grow. Elements of this section are shared with Section 62.8, yet here we focus on the mechanical energy budget of the fluctuating fields. As with Section 62.8, the results here are more general than those found

for the Eady model in Section 62.7, since we allow for the general linear theory from Sections 62.3 and 62.8.

Recall the energetics of quasi-geostrophy as studied in Section 45.9, where we identify the mechanical energy per mass of the fluctuations

$$E = [\nabla_h \psi' \cdot \nabla_h \psi' + (f_o \, \partial_z \psi' / N)^2]/2, \tag{62.159}$$

which is the sum of the kinetic energy per mass

$$\nabla_h \psi' \cdot \nabla_h \psi' / 2 = \boldsymbol{u}' \cdot \boldsymbol{u}' / 2, \tag{62.160}$$

plus the available potential energy per mass

$$(f_o \, \partial_z \psi' / N)^2 / 2 = (b'/N)^2 / 2. \tag{62.161}$$

To derive the energy budget equation, we follow the standard procedure in quasi-geostrophy by multiplying the potential vorticity equation (62.25) by ψ'

$$\psi' \, (\partial_t + u_b \, \partial_x) \, [\nabla_h^2 \psi' + f_o^2 \, \partial_z (N^{-2} \, \partial_z \psi')] = -\psi' \, \partial_x \psi' \, \partial_y q_b. \tag{62.162}$$

We now move derivatives around, with the manipulations relatively straightforward with $u_b = 0$, but somewhat more tedious with $u_b \neq 0$.

62.9.1 Time derivative terms

The time derivative can be written

$$\begin{aligned} \psi' \, \partial_t (\nabla_h^2 \psi') &= \psi' \, \nabla_h \cdot \nabla_h (\partial_t \psi') && \text{(62.163a)} \\ &= \nabla_h \cdot [\psi' \, \nabla_h (\partial_t \psi')] - \nabla_h \psi' \cdot \nabla_h (\partial_t \psi') && \text{(62.163b)} \\ &= \nabla_h \cdot [\psi' \, \nabla_h (\partial_t \psi')] - \partial_t (\nabla_h \psi' \cdot \nabla_h \psi')/2, && \text{(62.163c)} \end{aligned}$$

along with

$$\begin{aligned} \psi' \, \partial_t \partial_z [(f_o^2/N^2) \, \partial_z \psi'] &= \psi' \, \partial_z [(f_o^2/N^2) \, \partial_{zt} \psi'] && \text{(62.164a)} \\ &= \partial_z [\psi' \, (f_o^2/N^2) \, \partial_{zt} \psi'] - \partial_z \psi' \, (f_o^2/N^2) \, \partial_{zt} \psi' && \text{(62.164b)} \\ &= \partial_z [\psi' \, (f_o^2/N^2) \, \partial_{zt} \psi'] - \partial_t (f_o \, \partial_z \psi' / N)^2 / 2, && \text{(62.164c)} \end{aligned}$$

which yields

$$\psi' \, \partial_t [\nabla_h^2 \psi' + f_o^2 \, \partial_z (N^{-2} \, \partial_z \psi')] = -\partial_t E + \nabla_h \cdot [\psi' \, \nabla_h (\partial_t \psi')] + \partial_z [\psi' \, (f_o^2/N^2) \, \partial_{zt} \psi']. \tag{62.165}$$

62.9.2 Advection by the background zonal flow

To account for advection by the zonal background geostrophic flow, it is important to remember that $u_b = u_b(y, z)$, so that

$$\begin{aligned} \psi' \, u_b \, \partial_x (\nabla_h^2 \psi') &= \psi' \, u_b \, \nabla_h \cdot \nabla_h (\partial_x \psi') && \text{(62.166a)} \\ &= \nabla_h \cdot [\psi' \, u_b \, \nabla_h (\partial_x \psi')] - \nabla_h (\psi' \, u_b) \cdot \nabla_h (\partial_x \psi') && \text{(62.166b)} \\ &= \nabla_h \cdot [\psi' \, u_b \, \nabla_h (\partial_x \psi')] - \psi' \, \nabla_h u_b \cdot \nabla_h (\partial_x \psi') - u_b \, \nabla_h \psi' \cdot \nabla_h (\partial_x \psi') && \text{(62.166c)} \\ &= \nabla_h \cdot [\psi' \, u_b \, \nabla_h (\partial_x \psi')] - \psi' \, \partial_y u_b \, \partial_{xy} \psi' - u_b \, \partial_x (\nabla_h \psi' \cdot \nabla_h \psi')/2. && \text{(62.166d)} \end{aligned}$$

One further step is key, whereby we write

$$\psi' \, \partial_y u_\mathsf{b} \, \partial_{xy} \psi' = \partial_x (\psi' \, \partial_y u_\mathsf{b} \, \partial_y \psi') - \partial_x \psi' \, \partial_y u_\mathsf{b} \, \partial_y \psi', \tag{62.167}$$

so that

$$\psi' \, u_\mathsf{b} \, \partial_x (\nabla_\mathsf{h}^2 \psi') = \nabla_\mathsf{h} \cdot [\psi' \, u_\mathsf{b} \, \nabla_\mathsf{h} (\partial_x \psi')] - \partial_x (\psi' \, \partial_y u_\mathsf{b} \, \partial_y \psi') + \partial_x \psi' \, \partial_y u_\mathsf{b} \, \partial_y \psi' \\ - u_\mathsf{b} \, \partial_x (\nabla_\mathsf{h} \psi' \cdot \nabla_\mathsf{h} \psi')/2. \tag{62.168}$$

A similar set of steps for the stretching term (temporarily dropping the constant f_o^2 for brevity) leads to

$$\psi' \, u_\mathsf{b} \, \partial_x \partial_z (N^{-2} \, \partial_z \psi') = \psi' \, u_\mathsf{b} \, \partial_z (N^{-2} \, \partial_{xz} \psi') \tag{62.169a}$$
$$= \partial_z [\psi' \, u_\mathsf{b} \, N^{-2} \, \partial_{xz} \psi'] - \partial_z (\psi' \, u_\mathsf{b}) \, N^{-2} \, \partial_{xz} \psi' \tag{62.169b}$$
$$= \partial_z [\psi' \, u_\mathsf{b} \, N^{-2} \, \partial_{xz} \psi'] - \psi' \, \partial_z u_\mathsf{b} \, N^{-2} \, \partial_{xz} \psi' - u_\mathsf{b} \, \partial_z \psi' \, N^{-2} \, \partial_{xz} \psi' \tag{62.169c}$$
$$= \partial_z [\psi' \, u_\mathsf{b} \, N^{-2} \, \partial_{xz} \psi'] - \psi' \, \partial_z u_\mathsf{b} \, N^{-2} \, \partial_{xz} \psi' - u_\mathsf{b} \, \partial_x (\partial_z \psi'/N)^2/2. \tag{62.169d}$$

As for the relative vorticity terms, write

$$\psi' \, \partial_z u_\mathsf{b} \, N^{-2} \, \partial_{xz} \psi' = \partial_x (\psi' \, \partial_z u_\mathsf{b} \, N^{-2} \, \partial_z \psi') - \partial_x \psi' \, \partial_z u_\mathsf{b} \, N^{-2} \, \partial_z \psi', \tag{62.170}$$

which then leads to

$$\psi' \, u_\mathsf{b} \, \partial_{xz} (f_\mathsf{o}^2 \, N^{-2} \, \partial_z \psi') = \partial_z (\psi' \, u_\mathsf{b} \, f_\mathsf{o}^2 \, N^{-2} \, \partial_{xz} \psi') - \partial_x (\psi' \, \partial_z u_\mathsf{b} \, f_\mathsf{o}^2 \, N^{-2} \, \partial_z \psi') \\ + \partial_x \psi' \, \partial_z u_\mathsf{b} \, f_\mathsf{o}^2 \, N^{-2} \, \partial_z \psi' - u_\mathsf{b} \, \partial_x (f_\mathsf{o} \, \partial_z \psi'/N)^2/2. \tag{62.171}$$

62.9.3 Summary of the energy equation

Bringing terms together gives

$$0 = \psi' \, (\partial_t + u_\mathsf{b} \, \partial_x) \, [\nabla_\mathsf{h}^2 \psi' + f_\mathsf{o}^2 \, \partial_z (N^{-2} \, \partial_z \psi')] + \psi' \, \partial_x \psi' \, \partial_y q_\mathsf{b} \\ = -(\partial_t + u_\mathsf{b} \, \partial_x) E - \nabla_\mathsf{h} \cdot \boldsymbol{F}^\mathsf{h} - \partial_z F^z + \partial_x \psi' \, \partial_y u_\mathsf{b} \, \partial_y \psi' + \partial_x \psi' \, \partial_z u_\mathsf{b} \, f_\mathsf{o}^2 \, N^{-2} \, \partial_z \psi', \tag{62.172}$$

where we introduced the horizontal and vertical components to the energy flux vector

$$\boldsymbol{F}^\mathsf{h} = -\psi' \, (\partial_t + u_\mathsf{b} \, \partial_x) \nabla_\mathsf{h} \psi' + \hat{\boldsymbol{x}} \, \psi' \, (-\psi' \, \partial_y q_\mathsf{b}/2 + \partial_y u_\mathsf{b} \, \partial_y \psi' + \partial_z u_\mathsf{b} \, f_\mathsf{o}^2 \, N^{-2} \, \partial_z \psi') \tag{62.173a}$$
$$F^z = -\psi' \, f_\mathsf{o}^2 \, N^{-2} \, (\partial_t + u_\mathsf{b} \, \partial_x) \partial_z \psi' = -\psi' \, f_\mathsf{o} \, N^{-2} \, (\partial_t + u_\mathsf{b} \, \partial_x) b', \tag{62.173b}$$

which gives the energy equation

$$(\partial_t + u_\mathsf{b} \, \partial_x) E = -\nabla_\mathsf{h} \cdot \boldsymbol{F}^\mathsf{h} - \partial_z F^z + \partial_x \psi' \, \partial_y u_\mathsf{b} \, \partial_y \psi' + \partial_x \psi' \, \partial_z u_\mathsf{b} \, f_\mathsf{o}^2 \, N^{-2} \, \partial_z \psi'. \tag{62.174}$$

Since u_b is independent of x, one may choose to place the zonal advection term inside of the horizontal flux by noting that

$$u_\mathsf{b} \, \partial_x E = \partial_x (u_\mathsf{b} \, E), \tag{62.175}$$

so that

$$\partial_t E = -\nabla_\mathsf{h} \cdot (E \, u_\mathsf{b} \, \hat{\boldsymbol{x}} + \boldsymbol{F}^\mathsf{h}) - \partial_z F^z + \partial_x \psi' \, \partial_y u_\mathsf{b} \, \partial_y \psi' + \partial_x \psi' \, \partial_z u_\mathsf{b} \, f_\mathsf{o}^2 \, N^{-2} \, \partial_z \psi'. \tag{62.176}$$

62.9.4 Horizontal and thermal wind shear production

Equation (62.176) indicates that time changes to the mechanical energy contained in the small amplitude fluctuations is driven by the convergence of an energy flux, plus two source terms arising from shears in the background zonal geostrophic flow. The flux convergence acts to move energy around, and its domain integral provides possible sources for energy at the boundaries. We do not study this term in this section since it is quite dependent on assumptions about the boundaries, though we comment on this limitation in the analysis in Section 62.9.7.

Instead, we focus here on the two source terms in equation (62.176). The source arising from horizontal shear can be written

$$\partial_x \psi' \, \partial_y u_{\mathrm{b}} \, \partial_y \psi' = -v' \, u' \, \partial_y u_{\mathrm{b}}, \tag{62.177}$$

and the source arising from vertical shear is

$$\partial_x \psi' \, \partial_z u_{\mathrm{b}} \, f_{\mathrm{o}}^2 \, N^{-2} \, \partial_z \psi' = v' \, b' \, (f_{\mathrm{o}} \, \partial_z u_{\mathrm{b}} / N^2) = v' \, b' \, (\mathrm{d}z/\mathrm{d}y)_{b_{\mathrm{b}}}, \tag{62.178}$$

where the final step introduced the slope of the background buoyancy surface according to equation (62.12).

Horizontal shear production and thermal wind shear production

As in the study of horizonal shear instability in Section 61.4.6, we identify

$$-v' \, u' \, \partial_y u_{\mathrm{b}} = \text{horizontal shear production}. \tag{62.179}$$

This shear production term is generally rather small for geostrophic flows in comparison to the ageostrophic flows considered in Chapter 61. In analogy, we introduce

$$v' \, b' \, (\mathrm{d}z/\mathrm{d}y)_{b_{\mathrm{b}}} = -v' \, b' \, \partial_y b_{\mathrm{b}} / N^2 = \text{thermal wind shear production}. \tag{62.180}$$

The thermal wind shear production is fundamentally distinct from horizontal shear production. The reason is that $v' \, b' \, (\mathrm{d}z/\mathrm{d}y)_{b_{\mathrm{b}}}$ arises from the potential energy in the background state that supports the thermal wind shear, rather than from the background kinetic energy that supports horizontal (or vertical) shear production described in Section 61.4.6. For quasi-geostrophic flows, kinetic energy sourced shear production is generally far smaller than potential energy sourced thermal wind shear production.

62.9.5 Meridional and vertical eddy buoyancy fluxes

As shown in the following, fluctuations that increase their energy through making use of the prescribed background potential energy have a tendency to flux buoyancy down the meridional gradient and upward. These two effects act in a manner that increases the total quasi-geostrophic mechanical energy (sum of kinetic plus available potential) of the fluctuations, while feeding off the available potential energy of the background flow.

Meridionally downgradient flux of buoyancy increases mechanical energy of the fluctuations

Mechanical energy of the fluctuations increases through the thermal wind shear production (62.180) if the meridional *eddy buoyancy flux* is down the meridional gradient of the background buoyancy

$$v' \, b' \, \partial_y b_{\mathrm{b}} = -v' \, b' \, f_{\mathrm{o}} \, \partial_z u_{\mathrm{b}} < 0 \quad \text{mechanical energy of fluctuations increases}. \tag{62.181}$$

In practice, this downgradient behavior occurs over a space and/or time and/or ensemble average, in which we use an overbar as a generic average so that

$$\overline{v'\,b'}\,\partial_y b_{\mathsf{b}} = -\overline{v'\,b'}\,f_{\mathsf{o}}\,\partial_z u_{\mathsf{b}} < 0 \quad \text{averaged mechanical energy of fluctuations increases.} \tag{62.182}$$

This downgradient meridional buoyancy flux leads to a poleward heat transport for flows where temperature dominates buoyancy. Furthermore, the poleward heat transport extracts potential energy from the background flow since it acts in a direction that flattens the background buoyancy surfaces. Such fluctuations increase their energy at the expense of the available potential energy of the background state.

Fluid particle motion leading to an increase in available potential energy of the fluctuations

Available potential energy contained in the fluctuations evolves according to

$$\begin{aligned}
(\partial_t + u_{\mathsf{b}}\,\partial_x)[(f_{\mathsf{o}}\,\partial_z\psi'/N)^2/2] &= (\partial_t + u_{\mathsf{b}}\,\partial_x)(b'/N)^2/2 && \text{(62.183a)}\\
&= (b'/N^2)\,(\partial_t + u_{\mathsf{b}}\,\partial_x)b' && \text{(62.183b)}\\
&= -b'\,[w' - v'\,(\mathrm{d}z/\mathrm{d}y)_{b_{\mathsf{b}}}] && \text{(62.183c)}\\
&= -b'\,(w' + v'\,\partial_y b_{\mathsf{b}}/N^2), && \text{(62.183d)}
\end{aligned}$$

where we used the linear buoyancy equation (62.27) for the penultimate step. The available potential energy of the fluctuations increases if

$$b'\,[w' - v'\,(\mathrm{d}z/\mathrm{d}y)_{b_{\mathsf{b}}}] = b'\,(w' + v'\,\partial_y b_{\mathsf{b}}/N^2) < 0 \quad \text{APE of the fluctuations increases.} \tag{62.184}$$

An increasing available potential energy in the fluctuations is expected for a growing disturbance, in which fluctuating buoyancy surfaces have growing amplitudes. The condition (62.184) takes on a geometric expression by cancelling the buoyancy fluctuation and writing

$$w'/v' < (\mathrm{d}z/\mathrm{d}y)_{b_{\mathsf{b}}} \implies \quad \text{APE of the fluctuations increases,} \tag{62.185}$$

whereas the fluctuations maintain a fixed available potential energy if the meridional and vertical velocity components align with the background buoyancy surfaces

$$w'/v' = (\mathrm{d}z/\mathrm{d}y)_{b_{\mathsf{b}}}] \implies \text{APE of the fluctuations remains constant.} \tag{62.186}$$

We have more to say on these geometric conditions in Section 62.9.7.

Kinetic energy of the fluctuations

Substituting the available potential energy equation (62.183d) into the mechanical energy equation (62.174) leads to the equation for the kinetic energy of the fluctuations

$$(\partial_t + u_{\mathsf{b}}\,\partial_x)(\boldsymbol{u}'\cdot\boldsymbol{u}'/2) = -\nabla_{\mathsf{h}}\cdot\boldsymbol{F}^{\mathsf{h}} - \partial_z F^z - v'\,u'\,\partial_y u_{\mathsf{b}} + w'\,b'. \tag{62.187}$$

Growth in the kinetic energy of the fluctuations arises if positive buoyancy anomalies are fluxed upward,

$$w'\,b' > 0 \quad \text{kinetic energy of the fluctuations increases.} \tag{62.188}$$

This flux lowers the center of mass for the fluid and so decreases the potential energy.

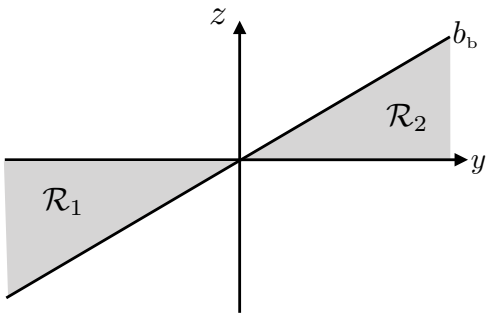

FIGURE 62.7: Depicting the wedge of instability for baroclinic instability. The background buoyancy is oriented with $\partial_y b_\mathrm{b} < 0$, so that less buoyant fluid sits to the north (to the right), as well as $\partial_z b_\mathrm{b} > 0$, so that the fluid is stably stratified in the vertical. A buoyancy fluctuation, b', in region $\mathcal{R}_1$ is more buoyant than b_b, so that $b' > 0$, whereas in region $\mathcal{R}_2$ we find $b' < 0$ relative to b_b. Hence, motion of fluid within a fluctuation that moves from region $\mathcal{R}_1$ to region $\mathcal{R}_2$ represents motion of relatively buoyant fluid ($b' > 0$) upward ($w' > 0$). This motion thus has $w'\,b' > 0$, which leads to an increase in kinetic energy of the fluctuation (equation (62.188)). This same motion also carries $v'\,b' > 0$ so that $v'\,b'\,\partial_y b_\mathrm{b} < 0$, meaning that the mechanical energy of the fluctuation increases (equation (62.181)). Finally, this motion ensures that $w'\,b' \le v'\,b'\,(\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}}$, so that the available potential energy of the fluctuation increases (equation (62.189)). Motion from region $\mathcal{R}_2$ to region $\mathcal{R}_1$ reverses all signs of the perturbations, so that their products remain the same, thus ensuring that energies increase for fluctuations moving from $\mathcal{R}_2$ to region $\mathcal{R}_1$.

Summary of the inequalities

We summarize the considerations thus far by noting that the mechanical energy, kinetic energy, and available potential energy of the fluctuating field increases for fluid particle displacements that are sloped between the horizontal plane and the constant buoyancy surface passing through the origin as in the *wedge of instability* in Figure 62.7

$$w'/v' \le (\mathrm{d}z/\mathrm{d}y)_{b_\mathrm{b}} \Longrightarrow N^2\,w'\,b' < -v'\,b'\,\partial_y b_\mathrm{b}. \tag{62.189}$$

Recall that $w'\,b' > 0$ means that kinetic energy in the fluctuating fields increases (equation (62.188)), and $v'\,b'\,\partial_y b_\mathrm{b} < 0$ means that the mechanical energy increases (equation (62.181)). Inequality (62.189) thus ensures that available potential energy for the fluctuations also increases.

62.9.6 Tilting phase lines of unstable baroclinic waves

In Section 61.4.7 we showed that phase lines of unstable barotropic waves tilt into the meridional shear of the zonal flow, with this orientation allowing the wave perturbations to grow by extracting kinetic energy from the background shear. Here we pursue a similar argument to reveal that unstable baroclinic waves tilt into the vertical shear of the zonal flow, with this orientation allowing the waves to extract potential energy from the background thermal wind flow.

Start with the phase average of the inequality (62.182) that provides a sufficient condition for wave fluctuations to increase their mechanical energy

$$\langle v'\,b' \rangle\, f_\circ\, \partial_z u_\mathrm{b} > 0 \quad \text{mechanical energy of fluctuations increases.} \tag{62.190}$$

Writing the streamfunction in the form

$$\psi'(x,y,z,t) = \tilde{\psi}(z)\, \mathrm{e}^{\mathrm{i}\,(k_x\,x + k_y\,y - \omega_\mathrm{r}\,t) + \omega_\mathrm{i}\,t} = |\tilde{\psi}(z)|\, \mathrm{e}^{\mathrm{i}\,(k_x\,x + k_y\,y + \alpha(z) - \omega_\mathrm{r}\,t) + \omega_\mathrm{i}\,t}, \tag{62.191}$$

leads to

$$v' = \partial_x \psi' = \mathrm{i}\,k_x\,|\tilde{\psi}|\, \mathrm{e}^{\mathrm{i}\,(k_x x + k_y y + \alpha - \omega_r t) + \omega_i t} \tag{62.192a}$$

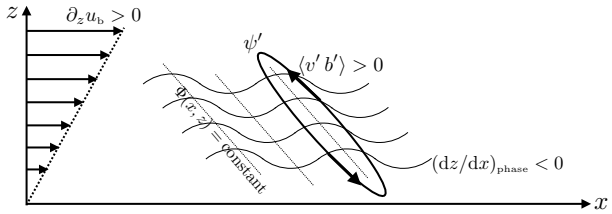

FIGURE 62.8: The lines of constant phase, $\Phi(x,z) = k\,x - \alpha(z)$, for the streamfunction (or the meridional velocity) in a northern hemisphere ($f_\circ > 0$) baroclinic wave. The wave depicted here has an increasing mechanical energy since the phase lines are tilted into the vertical shear of the zonal background flow, thus allowing for thermal wind shear production to increase the mechanical energy as per equation (62.197). This figure is directly analogous to the case of barotropic shear production as given by Figure 61.1.

$$b' = f_\circ\, \partial_z \psi' = f_\circ\, [\partial_z |\tilde{\psi}| + \mathrm{i}\, |\tilde{\psi}|\, \partial_z \alpha]\, \mathrm{e}^{\mathrm{i}\,(k_x x + k_y y + \alpha - \omega_\mathsf{r} t) + \omega_\mathsf{i} t}, \tag{62.192b}$$

and with the phase averaging identity (8.17e) yielding

$$\langle v'\, b' \rangle = (1/2)\ \mathrm{Re}[v'\, b^*] = (1/2)\, k_x\, f_\circ\, |\tilde{\psi}|^2\, \mathrm{e}^{2\omega_\mathsf{i} t}\, \partial_z \alpha. \tag{62.193}$$

We focus on phase lines in the x-z plane (so that $k_y = 0$), as that is the plane of the zonal flow with a vertical shear and so it is the plane of the most unstable wave as per *Squire's theorem*. We thus consider the spatial phase function

$$\Phi(x,z) \equiv k_x\, x + \alpha(z), \tag{62.194}$$

whose constant surfaces are defined by

$$\mathrm{d}\Phi = 0 = k_x\, \mathrm{d}x + (\partial_z \alpha)\, \mathrm{d}z \Longrightarrow (\mathrm{d}z/\mathrm{d}x)_{\text{phase}} = -k_x/\partial_z \alpha, \tag{62.195}$$

so that the instability condition (62.190) takes the form

$$(1/2)\, k_x^2\, f_\circ^2\, |\tilde{\psi}|^2\, \mathrm{e}^{2\omega_\mathsf{i} t}\, \frac{\partial_z u_\mathsf{b}}{(\mathrm{d}z/\mathrm{d}x)_{\text{phase}}} < 0 \Longrightarrow \text{sufficient condition for energy growth.} \tag{62.196}$$

Simplifying this equation leads to the condition for the ratio of the vertical shear to the phase slope

$$\frac{\partial_z u_\mathsf{b}}{(\mathrm{d}z/\mathrm{d}x)_{\text{phase}}} < 0 \Longrightarrow \text{sufficient condition for energy growth.} \tag{62.197}$$

This inequality says that mechanical energy of the wave grows when the wave's phase lines tilt into the background vertical shear, such as depicted in Figure 62.8. This condition is directly analogous to equation (61.56) and Figure 61.1, which hold for unstable barotropic waves on a meridional sheared zonal flow. Here, the tilt of the phase lines reflects the ability of the wave to extract potential energy from the background state, thus leading to growth of energy for the unstable wave. The geometric property (62.197) offers a visual indicator that the wave is acting on a baroclinically unstable background state, thus providing a valuable diagnostic tool for identifying when baroclinic instability is happening.

62.9.7 Caveats for extending the wedge of instability to parcels

Inequality (62.189) refers to the orientation of fluid particles affected by small amplitude wave fluctuations that lead to baroclinic instability, as illustrated in Figure 62.7. Even so, this figure is the basis for a parcel argument that goes beyond that of a small amplitude wave argument, with the parcel argument presented in many texts, such as Section 7.6 of *Pedlosky* (1987), Lecture 20 of *Pedlosky* (2003), Section 13.15 of *Kundu et al.* (2016), and Section 9.4.1 of *Vallis* (2017), and

originating from *Eady* (1949). Here we offer some caveats about this argument.

Baroclinic instability versus symmetric instability

The parcel arguments associated with the wedge of instability do not represent necessary conditions for baroclinic instability, and so they are no substitute for the integral statements in Section 62.8. This situation contrasts to parcel arguments considered for symmetric instability, where the necessary and sufficient condition for symmetric instability is summarized by its wedge of instability shown in Figure 59.8.

Furthermore, the parcel argument used for symmetric instability is based on a force balance, and so it incorporates accelerations from both buoyancy and Coriolis to account for the vertical and horizontal motion of the parcels. In contrast, the wedge of instability in Figure 62.7 is based on energetic arguments for baroclinic instability, with Coriolis acceleration absent from such arguments.

Baroclinic instability is a wave instability not a local instability

As explored in our study of the Eady model in Section 62.7, baroclinic instability mechanistically occurs through wave resonance. The realization of wave resonance relies on boundary conditions and phase locking of waves so that they can mutually reinforce one another. This mechanism is directly analogous to that considered for horizontal shear instability in Chapter 61.

In contrast, parcel arguments, such as used for symmetric instability, do not know about boundary conditions or phase locking. Instead, they are only concerned with local environmental conditions. Consider the following case in point for limitions of parcel arguments for baroclinic instability. Namely, observe that the wedge of instability does do not distinguish between flat bottom boundary or sloping bottom boundary. However, in Section 62.8.6 we found that the Eady model is stable in the presence of a bottom slope that is steeper than the buoyancy surfaces (Figure 62.6).

Additional points

Focusing specifically on the arguments leading up to inequality (62.189), note that these arguments have ignored all contributions from the convergence of energy fluxes that appear in the energy equation (62.174). These fluxes, particularly at domain boundaries, provide further influences on the domain integrated energetics and hence on stability of the flow (e.g., boundary terms are critical for the necessary instability conditions in Section 62.8). Additional caveats are raised by *Heifetz et al.* (1998) related to the problems with ignoring pressure fluctuations acting on the fluid particles. These caveats are analogous to those raised in Section 30.11 when studying effective buoyancy.

62.9.8 Further reading

Chapter 17 of *Cushman-Roisin and Beckers* (2011) offers qualifiers similar to those raised in Section 62.9.7 regarding the conceptual limitations of using parcel arguments for describing the mechanism of instabilities occuring via wave resonance.

Part XII

Generalized vertical coordinates

Generalized vertical coordinates (GVCs) offer a mathematical framework for describing fluid mechanics according to monotonically stacked surfaces that are a general function of space and time. For studying stratified fluid mechanics, the most common generalized vertical coordinate is based on Archimedean buoyancy or specific entropy. Generalized vertical coordinates appear in many guises throughout geophysical fluid mechanics, and they were introduced by *Starr* (1945) for atmospheric modeling and *Bleck* (1978) for ocean modeling. There is a growing use of GVC-based numerical ocean (e.g., *Griffies et al.* (2020)) and atmospheric models. This usage prompts the need to master their use for analysis, model formulation, and theory, thus providing motivation for this part of the book.

Time dependence of generalized vertical coordinates means that observers situated on a fixed generalized vertical coordinate surface are non-inertial, in a manner akin to the Lagrangian reference frame. Generalized vertical coordinates are also non-orthogonal, which contrasts to the static and locally orthogonal coordinates described in Sections 4.21, 4.22, and 4.23 (e.g., Cartesian, cylindrical, spherical). Both time dependence and non-orthogonality offer advantages for describing certain features of geophysical fluid motion. Yet there is a price to pay due to the added mathematical complexity that requires care beyond that needed with the coordinates in Chapter **??**.

The key reason we fravor a locally non-orthogonal coordinate set is that gravity plays a dominant role in orienting geophysical fluid motion. Hence, it is strategically useful to decompose the equations of motion so that lateral motions are perpendicular to gravity, just like with geopotential vertical coordinates. That is, we orient horizontal motions the same regardless whether we use geopotential coordinates or generalized vertical coordinates, since doing so removes the vertical pressure force from the horizontal equations of motion. If we were to instead locally rotate the components of the velocity vector to be parallel and perpendicular to the surface of constant generalized vertical coordinate, as per a locally orthogonal coordinate description, then that representation would introduce a portion of the vertical pressure gradient into the equations for lateral motion. Having the vertical pressure gradient appear in each of the three components to the equations of motion makes it very difficult to isolate the hydrostatic pressure force. In turn, it makes it difficult to describe nearly all of the basic features of geophysical flows, such as the geostrophic and hydrostatic balances.[4]

In this part of the book we develop the mathematics of generalized vertical coordinates, and then build up the kinematics and dynamics of stratified fluid mechanics using these coordinates. These chapters are written in the style of a monograph, with equations derived in detail and concepts explored. Here is a brief summary of these chapters.

- MATHEMATICAL FOUNDATIONS: Chapter 63 establishes the mathematics of generalized vertical coordinates. As noted already, their time dependence and their non-orthogonality present some complexity in both concept and detail. Even so, with practice, generalized vertical coordinates can become a versatile member of our theoretical and numerical toolkit.

- Chapters 64 and 65 describe elements of fluid kinematics and dynamics using generalized vertical coordinates.

- Chapter 66 formulates the hydrostatic Boussinesq equations using buoyancy as the vertical coordinate. This chapter specializes elements from the previous chapters, and in so doing provides a mathematical and physical basis for *isopycnal* models of the ocean and isentropic models of the atmosphere.

- Chapter 67 provides further insights into eddy and mean flow decomposition as viewed through the lens of thickness weighted averaging (TWA) for the shallow water model.

[4] The one case where locally orthogonal coordinate are useful concerns the tracer diffusion operator within the ocean interior, as discussed in Section 71.4.

We position this chapter in this part of this book since it makes use of the layered perspective of generalized vertical coordinates, particularly isopycnal coordinates. Indeed, the adiabatic stacked shallow water model is a discrete realization of the perfect fluid isopycnal equations. The TWA formalism of the shallow water equations offers a technically less difficult rendition of the formalism when applied to the continuously stratified isopycnal coordinates.

Chapter 63

Mathematical foundations

In this chapter we present the mathematics of generalized vertical coordinates (GVC), with Figure 63.1 offering a schematic of how these coordinates monotonically partition the vertical direction. Such coordinates are of particular use for stratified fluid mechanics, where it is often convenient to make use of a vertical coordinate distinct from, but uniquely related to, the geopotential vertical coordinate.

CHAPTER GUIDE

We make use of the general tensor analysis detailed in Chapter 4. We mostly consider just the spatial tensors in this chapter, consistent with the Newtonian perspective whereby time is universal. However, since the vertical coordinate is a function of time, we follow the space-time perspective from Section 4.9 for transforming the partial derivative operator. Chapters directly relying on the material from this chapter include the fluid kinematics discussed in Chapter 64, the general vertical coordinate dynamics discussed in Chapter 65, and the tracer equation diffusion and stirring operators discussed in Chapter 71.

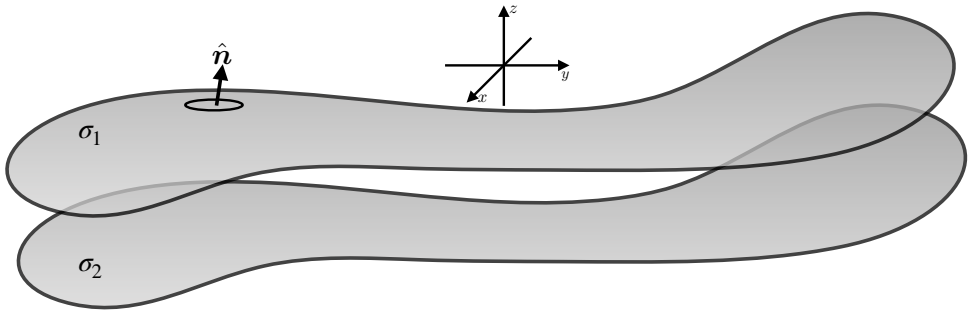

FIGURE 63.1: This stylized schematic illustrates the geometry of two surfaces of constant generalized vertical coordinate $\sigma(x, y, z, t) = \sigma_1$ and $\sigma(x, y, z, t) = \sigma_2$, here showing patches on two such surfaces. The surfaces are generally undulating in space and time yet are assumed to monotonically layer the fluid. Monotonic layering means that the surface normal, $\hat{\boldsymbol{n}}$, always has a non-zero projection onto the vertical: $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}} \neq 0$. That is, the surfaces never become vertical nor do they overturn. It also means that there is a 1-to-1 invertible relation between σ and geopotential, so that specifying $(x, y, \sigma(x, y, z, t))$ is sufficient to yield a unique z.

63.1 Relating Cartesian and GVCs

We make use of the symbol σ for a generalalized vertical coordinate. This coordinate is *not* orthogonal to the horizontal spatial coordinates x, y. This is a central property of GVCs that influences nearly all aspects of their calculus. To help develop the mathematics for transforming between Cartesian coordinates and GVCs, it is important to distinguish the two coordinate systems. For that purpose we write the time coordinate and spatial Cartesian coordinates according to

$$\xi^\alpha = (\xi^0, \xi^a) = (\xi^0, \xi^1, \xi^2, \xi^3) = (t, x, y, z) \text{ with } \alpha = 0, 1, 2, 3, \text{ and } a = 1, 2, 3. \tag{63.1}$$

As defined, the tensor label a runs over the spatial coordinates $1, 2, 3$ whereas α also includes the time coordinate with $\alpha = 0$. The corresponding generalized vertical coordinates are denoted with an overbar

$$\xi^{\overline{\alpha}} = (\xi^{\overline{0}}, \xi^{\overline{1}}, \xi^{\overline{2}}, \xi^{\overline{3}}) = (\overline{t}, \overline{x}, \overline{y}, \sigma). \tag{63.2}$$

The 1-to-1 coordinate transformation between Cartesian and GVC coordinates is written

$$\xi^{\overline{0}} = \xi^0 \Longleftrightarrow \overline{t} = t \tag{63.3a}$$

$$\xi^{\overline{1}} = \xi^1 \Longleftrightarrow \overline{x} = x \tag{63.3b}$$

$$\xi^{\overline{2}} = \xi^2 \Longleftrightarrow \overline{y} = y \tag{63.3c}$$

$$\xi^{\overline{3}} = \sigma(x, y, z, t), \tag{63.3d}$$

with the final relation expressing the generalized vertical coordinate as a function of space and time. We ordered the appearance of independent variables in σ with time in the last position, which is the conventional ordering in this book for functions of space and time even though the zeroth coordinate is time.

The coordinate transformation is invertible so that we can write

$$\xi^0 = \xi^{\overline{0}} \tag{63.4a}$$

$$\xi^1 = \xi^{\overline{1}} \tag{63.4b}$$

$$\xi^2 = \xi^{\overline{2}} \tag{63.4c}$$

$$\xi^3 = \xi^3(\overline{x}, \overline{y}, \sigma, \overline{t}) = \xi^3(x, y, \sigma, t). \tag{63.4d}$$

The relation

$$\xi^3 = \xi^3(\xi^{\overline{a}}) = \xi^3(x, t, \sigma, t) \tag{63.5}$$

provides the vertical position of a given σ surface. Since $\xi^3 = z$ one commonly writes

$$z = z(x, y, \sigma, t). \tag{63.6}$$

However, this expression is prone to confusion since the meaning of z is overloaded.[1] Namely, one meaning ascribes z to a particular value of the vertical position; i.e., $z = -100$ m. The other meaning, as on the right hand side, is for z as the vertical coordinate function of a particular σ surface, with this value a function of space, time, and σ. Learning to distinguish when z refers to a particular vertical position or as a coordinate function takes some practice, and those who routinely work with generalized vertical coordinates typically find no problem with the overloaded meanings. Indeed, after reading this chapter we should be able to hold the two meanings in our mind without confusion. As a reminder, we commonly write the vertical coordinate function as

$$z = \eta(x, y, \sigma, t), \tag{63.7}$$

where η is used throughtout this book to represent the vertical position of a surface, such as the ocean free surface, solid-earth topography, or a generalized vertical coordinate surface. Hence, for example, the vertical position of a pressure surface of chosen value p is given by the functional relation

$$\xi^3 = z = \eta(\overline{x}, \overline{y}, p, \overline{t}) = \eta(x, y, p, t). \tag{63.8}$$

We make use of the η nomenclature where it seems useful but gradually sprinkle in more use of the $z(x, y, \sigma, t)$ notation since it is proves to be natural for many of the formulations.

63.2 Example generalized vertical coordinates

Before further diving into the mathematics, we here offer some examples of generalized vertical coordinates commonly used to study geophysical fluid flows.

63.2.1 Pressure coordinates

Hydrostatic compressible fluids, such as the large-scale atmosphere, pressure is a convenient choice as vertical since it absorbs the appearance of density in many formula such as mass

[1] We use the term *overloaded* as in computer science where a symbol has more than one meaning or usage.

continuity as discussed in Section 64.9.2 and the geostrophic balance given by equation (31.1a). Hence, a natural expression of the compressible hydrostatic equations of motion make use of pressure rather than geopotential for the vertical coordinate, in which case $\sigma = p(x, y, z, t)$.

63.2.2 Terrain following coordinates

When allowing for a time dependent ocean free surface, the terrain following coordinate in oceanography is given by

$$\sigma = \frac{z - \eta_{\text{surf}}}{-\eta_{\text{b}} + \eta_{\text{surf}}} \qquad \text{terrain following ocean coordinate,} \tag{63.9}$$

where $z = \eta_{\text{surf}}(x, y, t)$ is the vertical position of the ocean surface. The terrain following coordinate is non-dimensional and extends from $\sigma = 0$ at the ocean surface and $\sigma = -1$ at the ocean bottom (where $z = \eta_{\text{b}}(x, y)$). For rigid lid ocean models with $\eta_{\text{surf}} = 0$, the terrain following coordinate becomes time independent

$$\sigma = -\frac{z}{\eta_{\text{b}}} \qquad \text{terrain following rigid lid ocean.} \tag{63.10}$$

Finally, for a compressible ocean, it is more convenient to use pressure to define the terrain following coordinate so that

$$\sigma = \frac{p - p_{\text{a}}}{p_{\text{b}} - p_{\text{a}}} \qquad \text{terrain following atmosphere coordinate.} \tag{63.11}$$

In this equation, p_{a} is the pressure applied at the ocean surface and p_{b} is the pressure at the ocean bottom. For an atmosphere model we might set p_{a} as the top of the atmosphere pressure, which is typically assumed to be zero as in *Phillips* (1957).

63.2.3 Bottom slope oriented coordinates

Peterson and Callies (2022) consider an alternative to the traditional terrain following coordinates from Section 63.2.2, here defining a bottom slope oriented coordinate (recall $\eta_{\text{b}} = \eta_{\text{b}}(x, y)$)

$$\sigma = z - \boldsymbol{x} \cdot \nabla \eta_{\text{b}} = z - x\, \partial \eta_{\text{b}}/\partial x - y\, \partial \eta_{\text{b}}/\partial y, \tag{63.12}$$

with $\nabla \eta_{\text{b}}$ the slope of the bottom topography.

63.2.4 Isopycnal or buoyancy coordinates

Buoyancy surfaces are material when there is no mixing. Hence, for the study of perfect fluid mechanics it is quite convenient to use the Archimedian buoyancy, b, as the vertical coordinate, $\sigma = b(x, y, z, t)$. Equivalently, one may choose the potential density as the vertical coordinate. We have more to say about such vertical coordinates in Chapter 66 when developing the equations for isopycnal ocean models.

63.3 Spatial basis vectors

Making use of the tensor formalism from Chapter 4, consider the transformation of the Cartesian basis vectors into their corresponding GVC representation. This transformation takes is given by

$$\boldsymbol{e}_{\overline{a}} = \Lambda^{a}{}_{\overline{a}}\, \boldsymbol{e}_{a}, \tag{63.13}$$

where the transformation matrix is

$$\Lambda^{a}{}_{\overline{a}} = \begin{bmatrix} \partial x/\partial\overline{x} & \partial x/\partial\overline{y} & \partial x/\partial\sigma \\ \partial y/\partial\overline{x} & \partial y/\partial\overline{y} & \partial y/\partial\sigma \\ \partial z/\partial\overline{x} & \partial z/\partial\overline{y} & \partial z/\partial\sigma \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \partial\eta/\partial\overline{x} & \partial\eta/\partial\overline{y} & \partial\eta/\partial\sigma \end{bmatrix}, \tag{63.14}$$

where the second equality used our preferred notation $z = \eta(x, y, \sigma, t)$ for the vertical position of a σ surface. The diagonal unit values for the space-space components arise since a horizontal position in Cartesian and GVCs is the same and the horizontal directions are orthogonal. Likewise, the time coordinate does not change when changing $\overline{x}$, $\overline{y}$, or σ. Additionally, $\partial x/\partial\sigma = \partial y/\partial\sigma = 0$ since the horizontal position remains unchanged when moving across a GVC surface. In contrast, a non-zero value for $\partial\eta/\partial\overline{x}$ and $\partial\eta/\partial\overline{y}$ arise since we generally change vertical position when moving horizontally along a sloped σ surface. Finally, the element $\partial\eta/\partial\sigma$ is nonzero due to vertical stratification of the fluid when represented using general vertical coordinates.

63.3.1 More on the transformation matrix

To further detail how to produce elements of the transformation matrix (63.14), it is crucial to ensure that the proper variables are held fixed when performing the partial derivatives. For example, consider the top row where we compute

$$\Lambda^{1}{}_{\overline{a}} = \begin{bmatrix} [\partial x/\partial\overline{x}]_{\overline{y},\sigma} & [\partial x/\partial\overline{y}]_{\overline{x},\sigma} & [\partial x/\partial\sigma]_{\overline{x},\overline{y}} \end{bmatrix} \tag{63.15}$$

Since $x = \overline{x}$, all elements vanish except for the first. Namely, $[\partial x/\partial\overline{y}]_{\overline{x},\sigma} = 0$ since x cannot change when $\overline{x}$ is fixed. The same idea leads to the results for y derivatives.

63.3.2 Expressions for the basis vectors

Use of the transformation matrix (63.14) renders the spatial components of the GVC basis vectors

$$\boldsymbol{e}_{\overline{1}} = \hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,(\partial\eta/\partial\overline{x}) \tag{63.16a}$$
$$\boldsymbol{e}_{\overline{2}} = \hat{\boldsymbol{y}} + \hat{\boldsymbol{z}}\,(\partial\eta/\partial\overline{y}) \tag{63.16b}$$
$$\boldsymbol{e}_{\overline{3}} = \hat{\boldsymbol{z}}\,(\partial\eta/\partial\sigma). \tag{63.16c}$$

The basis vectors $\boldsymbol{e}_{\overline{1}}$ and $\boldsymbol{e}_{\overline{2}}$ have a vertical component due to sloping GVC surfaces. These basis vectors lie within the tangent plane of the GVC surface. The basis vector $\boldsymbol{e}_{\overline{3}}$ is purely vertical and has a non-unit magnitude due to the inverse vertical stratification, $\partial\eta/\partial\sigma$. The left panel of Figure 63.2 illustrates the basis vectors.

As an example, consider the rigid lid terrain following vertical coordinate (63.10), where $\sigma = -z/\eta_{\text{b}}$. In this case, the vertical position of a generalized vertical surface is given by $\eta = -\sigma\,\eta_{\text{b}}$ so that the basis vectors are

$$\boldsymbol{e}_{\overline{1}} = \hat{\boldsymbol{x}} - \hat{\boldsymbol{z}}\,\sigma\,(\partial\eta_{\text{b}}/\partial\overline{x}) \quad \text{and} \quad \boldsymbol{e}_{\overline{2}} = \hat{\boldsymbol{y}} - \hat{\boldsymbol{z}}\,\sigma\,(\partial\eta_{\text{b}}/\partial\overline{y}) \quad \text{and} \quad \boldsymbol{e}_{\overline{3}} = -\hat{\boldsymbol{z}}\,\eta_{\text{b}}. \tag{63.17}$$

Similarly, the bottom slope oriented coordinate (63.12), with $\sigma = z - \boldsymbol{x}\cdot\nabla\eta_{\text{b}}$ so that $\eta = \sigma + \boldsymbol{x}\cdot\nabla\eta_{\text{b}}$, has the corresponding basis vectors

$$\boldsymbol{e}_{\overline{1}} = \hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,(\partial\eta_{\text{b}}/\partial\overline{x}) \quad \text{and} \quad \boldsymbol{e}_{\overline{2}} = \hat{\boldsymbol{y}} + \hat{\boldsymbol{z}}\,(\partial\eta_{\text{b}}/\partial\overline{y}) \quad \text{and} \quad \boldsymbol{e}_{\overline{3}} = \hat{\boldsymbol{z}}. \tag{63.18}$$

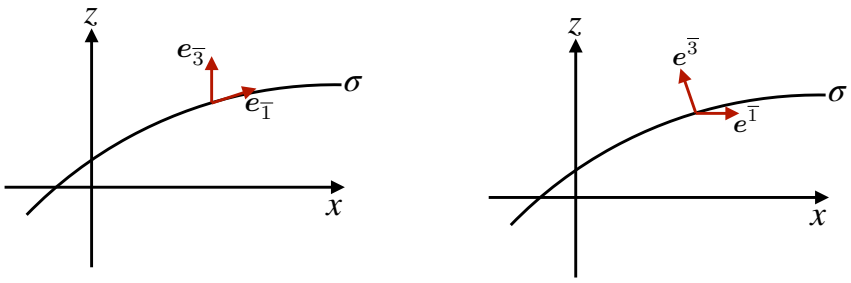

FIGURE 63.2: Illustrating the basis vectors (left panel) and basis one-forms (right panel) for generalized vertical coordinates. The $\boldsymbol{e}_{\overline{3}}$ basis vector is vertical whereas $\boldsymbol{e}_{\overline{1}}$ and $\boldsymbol{e}_{\overline{2}}$ lie within the tangent plane to the σ surface. As a complement, the basis one-form $\boldsymbol{e}^{\overline{3}}$ is normal to the σ surface whereas the basis one-forms $\boldsymbol{e}^{\overline{1}}$ and $\boldsymbol{e}^{\overline{2}}$ are horizontal.

63.4 Basis one-forms

The basis one-forms are obtained by transforming from Cartesian into GVCs through use of the inverse transformation

$$\boldsymbol{e}^{\overline{a}} = \Lambda^{\overline{a}}{}_{a}\, \boldsymbol{e}^{a}, \tag{63.19}$$

where the inverse transformation matrix takes the form

$$\Lambda^{\overline{a}}{}_{a} = \begin{bmatrix} \partial\overline{x}/\partial x & \partial\overline{x}/\partial y & \partial\overline{x}/\partial z \\ \partial\overline{y}/\partial x & \partial\overline{y}/\partial y & \partial\overline{y}/\partial z \\ \partial\sigma/\partial x & \partial\sigma/\partial y & \partial\sigma/\partial z \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \partial\sigma/\partial x & \partial\sigma/\partial y & \partial\sigma/\partial z \end{bmatrix}. \tag{63.20}$$

As for the transformation matrix (63.14), the unit diagonal values arise since a horizontal position in Cartesian and GVCs is the same and the horizontal directions are orthogonal. Likewise, $\partial\overline{x}/\partial z = \partial\overline{y}/\partial z = 0$ since the horizontal position on a GVC surface remains unchanged when moving across a depth surface. The nonzero values for $\partial\sigma/\partial x$, $\partial\sigma/\partial y$, and $\partial\sigma/\partial z$, arise in the presence of horizontal and vertical stratification of the generalized vertical coordinate.

63.4.1 More on the inverse transformation matrix

When computing elements of the inverse transformation matrix (63.20), it is crucial to ensure that the proper variables are held fixed. For example, consider the top row where we compute

$$\Lambda^{\overline{1}}{}_{a} = \begin{bmatrix} [\partial\overline{x}/\partial x]_{y,z} & [\partial\overline{x}/\partial y]_{x,z} & [\partial\overline{x}/\partial z]_{x,y} \end{bmatrix}. \tag{63.21}$$

Just as for the transformation matrix (63.15), since $x = \overline{x}$, all but the first element vanish in equation (63.21). Namely, $[\partial\overline{x}/\partial y]_{x,z} = 0$ since the $\overline{x}$ cannot change when x is fixed. The same idea holds for the $\overline{y}$ row.

63.4.2 GVC basis one-forms

Use of the inverse transformation matrix (63.20) renders the spatial components of the GVC basis one-forms

$$\boldsymbol{e}^{\overline{1}} = \hat{\boldsymbol{x}} \tag{63.22a}$$

$$\boldsymbol{e}^{\overline{2}} = \hat{\boldsymbol{y}} \tag{63.22b}$$

$$\boldsymbol{e}^{\overline{3}} = \boldsymbol{e}^{a}\, \partial_a \sigma = \hat{\boldsymbol{x}}\, (\partial\sigma/\partial x) + \hat{\boldsymbol{y}}\, (\partial\sigma/\partial y) + \hat{\boldsymbol{z}}\, (\partial\sigma/\partial z) = \nabla\sigma. \tag{63.22c}$$

The left panel of Figure 63.2 illustrates the basis one-forms.

As an example, consider again the rigid lid terrain following coordinate (63.10), $\sigma = -z/\eta_\mathrm{b}$, in which case

$$\boldsymbol{e}^{\overline{3}} = \nabla\sigma = -(1/\eta_\mathrm{b})\,[\hat{\boldsymbol{z}} - (z/\eta_\mathrm{b})\,\nabla\eta_\mathrm{b}]. \tag{63.23}$$

Similarly, the bottom slope oriented coordinate (63.12), with $\sigma = z - \boldsymbol{x}\cdot\nabla\eta_\mathrm{b}$, has

$$\boldsymbol{e}^{\overline{3}} = \hat{\boldsymbol{z}} - \nabla\eta_\mathrm{b} - \hat{\boldsymbol{x}}\,(\boldsymbol{x}\cdot\partial_x\nabla\eta_\mathrm{b}) - \hat{\boldsymbol{y}}\,(\boldsymbol{x}\cdot\partial_y\nabla\eta_\mathrm{b}) = \hat{\boldsymbol{z}} - \nabla\eta_\mathrm{b} - (\boldsymbol{x}\cdot\nabla)\,\nabla\eta_\mathrm{b}. \tag{63.24}$$

In the case where the bottom slope is constant in both directions then this result simplifies to

$$\boldsymbol{e}^{\overline{3}} = \hat{\boldsymbol{z}} - \nabla\eta_\mathrm{b}. \tag{63.25}$$

63.4.3 Verifying the bi-orthogonality relation

The basis one-forms satisfy the bi-orthogonality relation (4.25) with the basis vectors

$$\boldsymbol{e}^{\overline{a}}\cdot\boldsymbol{e}_{\overline{b}} = \delta^{\overline{a}}_{\overline{b}}. \tag{63.26}$$

This identity is trivial to verify for all $\overline{a} = 1, 2, 3$.

63.5 Triple product identities

We find various occasions to make use of a suite of triple product identities that hold for GVCs. For this purpose we write σ as a composite function as in Section 4.9.3

$$\sigma = \sigma(x, y, z, t) = \sigma[x, y, z(\overline{t}, \overline{x}, \overline{y}, \sigma), t], \tag{63.27}$$

with $\eta(\overline{x}, \overline{y}, \sigma, \overline{t})$ written as $z(\overline{x}, \overline{y}, \sigma, \overline{t})$ as it here eases the manipulations. Use of the chain rule leads to the space-time differential increment

$$\mathrm{d}\sigma = \mathrm{d}t\left[\frac{\partial\sigma}{\partial t}\right]_{x,y,z} + \mathrm{d}x\left[\frac{\partial\sigma}{\partial x}\right]_{t,y,z} + \mathrm{d}y\left[\frac{\partial\sigma}{\partial y}\right]_{t,x,z} + \mathrm{d}z\left[\frac{\partial\sigma}{\partial z}\right]_{t,x,y}. \tag{63.28}$$

Likewise, writing $z = z[\overline{t}, \overline{x}, \overline{y}, \sigma]$ leads to the space-time differential increment $\mathrm{d}z$

$$\mathrm{d}z = \mathrm{d}\overline{t}\left[\frac{\partial z}{\partial \overline{t}}\right]_{\overline{x},\overline{y},\sigma} + \mathrm{d}\overline{x}\left[\frac{\partial z}{\partial \overline{x}}\right]_{\overline{t},\overline{y},\sigma} + \mathrm{d}\overline{y}\left[\frac{\partial z}{\partial \overline{y}}\right]_{\overline{t},\overline{x},\sigma} + \mathrm{d}\sigma\left[\frac{\partial z}{\partial \sigma}\right]_{\overline{t},\overline{x},\overline{y}}. \tag{63.29}$$

We note the identities

$$\left[\frac{\partial\sigma}{\partial z}\right]_{t,x,y}\left[\frac{\partial z}{\partial\sigma}\right]_{\overline{t},\overline{x},\overline{y}} = 1 \qquad \mathrm{d}\overline{t} = \mathrm{d}t \qquad \mathrm{d}\overline{x} = \mathrm{d}x \qquad \mathrm{d}\overline{y} = \mathrm{d}y, \tag{63.30}$$

which follow since $t = \overline{t}$, $x = \overline{x}$, and $y = \overline{y}$. Substituting equation (63.29) into equation (63.28) and making use of the identities (63.30) yields

$$\begin{aligned} 0 = \mathrm{d}t &\left[\left[\frac{\partial\sigma}{\partial t}\right]_{x,y,z} + \left[\frac{\partial\sigma}{\partial z}\right]_{t,x,y}\left[\frac{\partial z}{\partial \overline{t}}\right]_{\overline{x},\overline{y},\sigma}\right] \\ + \mathrm{d}x &\left[\left[\frac{\partial\sigma}{\partial x}\right]_{t,y,z} + \left[\frac{\partial\sigma}{\partial z}\right]_{t,x,y}\left[\frac{\partial z}{\partial \overline{x}}\right]_{\overline{t},\overline{y},\sigma}\right] + \mathrm{d}y\left[\left[\frac{\partial\sigma}{\partial y}\right]_{t,x,z} + \left[\frac{\partial\sigma}{\partial z}\right]_{t,x,y}\left[\frac{\partial z}{\partial \overline{y}}\right]_{\overline{t},\overline{x},\sigma}\right]. \end{aligned} \tag{63.31}$$

For this equation to hold with general increments $\mathrm{d}t$, $\mathrm{d}x$, and $\mathrm{d}y$ requires that each bracketed term vanish, which in turn leads to the following set of triple product identities[2]

$$\left[\frac{\partial\sigma}{\partial z}\right]_{t,x,y}\left[\frac{\partial z}{\partial\overline{t}}\right]_{\overline{x},\overline{y},\sigma} = -\left[\frac{\partial\sigma}{\partial t}\right]_{x,y,z} \tag{63.32a}$$

$$\left[\frac{\partial\sigma}{\partial z}\right]_{t,x,y}\left[\frac{\partial z}{\partial\overline{x}}\right]_{\overline{t},\overline{y},\sigma} = -\left[\frac{\partial\sigma}{\partial x}\right]_{t,y,z} \tag{63.32b}$$

$$\left[\frac{\partial\sigma}{\partial z}\right]_{t,x,y}\left[\frac{\partial z}{\partial\overline{y}}\right]_{\overline{t},\overline{x},\sigma} = -\left[\frac{\partial\sigma}{\partial y}\right]_{t,x,z}. \tag{63.32c}$$

If the vertical stratification, $\partial\sigma/\partial z$, is non-zero, the triple product identities are equivalent to

$$\left[\frac{\partial z}{\partial\overline{t}}\right]_{\overline{x},\overline{y},\sigma} = -\frac{[\partial\sigma/\partial t]_{x,y,z}}{[\partial\sigma/\partial z]_{t,x,y}} = -\left[\frac{\partial\sigma}{\partial t}\right]_{x,y,z}\left[\frac{\partial z}{\partial\sigma}\right]_{t,x,y} \tag{63.33a}$$

$$\left[\frac{\partial z}{\partial\overline{x}}\right]_{\overline{t},\overline{y},\sigma} = -\frac{[\partial\sigma/\partial x]_{t,y,z}}{[\partial\sigma/\partial z]_{t,x,y}} = -\left[\frac{\partial\sigma}{\partial x}\right]_{t,y,z}\left[\frac{\partial z}{\partial\sigma}\right]_{t,x,y} \tag{63.33b}$$

$$\left[\frac{\partial z}{\partial\overline{y}}\right]_{\overline{t},\overline{x},\sigma} = -\frac{[\partial\sigma/\partial y]_{t,x,z}}{[\partial\sigma/\partial z]_{t,x,y}} = -\left[\frac{\partial\sigma}{\partial y}\right]_{t,x,z}\left[\frac{\partial z}{\partial\sigma}\right]_{t,x,y}. \tag{63.33c}$$

Since $t=\overline{t}$, $x=\overline{x}$, and $y=\overline{y}$ we can write these identities in the more succinct form

$$\left[\frac{\partial z}{\partial\overline{t}}\right]_{\sigma} = \left[\frac{\partial\eta}{\partial\overline{t}}\right]_{\sigma} = -\frac{[\partial\sigma/\partial t]_z}{[\partial\sigma/\partial z]} \tag{63.34a}$$

$$\left[\frac{\partial z}{\partial\overline{x}}\right]_{\sigma} = \left[\frac{\partial\eta}{\partial\overline{x}}\right]_{\sigma} = -\frac{[\partial\sigma/\partial x]_z}{[\partial\sigma/\partial z]} \tag{63.34b}$$

$$\left[\frac{\partial z}{\partial\overline{y}}\right]_{\sigma} = \left[\frac{\partial\eta}{\partial\overline{y}}\right]_{\sigma} = -\frac{[\partial\sigma/\partial y]_z}{[\partial\sigma/\partial z]}, \tag{63.34c}$$

where we reintroduced the notation $\eta(x,y,\sigma,t)=z(x,y,\sigma,t)$. These identities are quite useful for manipulating equations involving GVCs. In particular, equations (63.34b) and (63.34c) provide alternate expressions for the slope of σ isosurfaces relative to the horizontal plane (see Section 63.12).

63.6 Position vector

We are familiar with locating a point in space using Cartesian coordinates as in Figure 1.1. What about specifying the position using GVCs? We can do so by making use of the basis vectors (63.16a)-(63.16c) so that the position of an arbitrary point in space is given by

$$\mathscr{P} = \xi^{\overline{a}}\,\boldsymbol{e}_{\overline{a}} \tag{63.35a}$$

$$= \overline{x}\,[\hat{\boldsymbol{x}} + (\partial\eta/\partial\overline{x})\,\hat{\boldsymbol{z}}] + \overline{y}\,[\hat{\boldsymbol{y}} + (\partial\eta/\partial\overline{y})\,\hat{\boldsymbol{z}}] + \sigma\,(\partial\eta/\partial\sigma)\,\hat{\boldsymbol{z}} \tag{63.35b}$$

$$= \hat{\boldsymbol{x}}\,\overline{x} + \hat{\boldsymbol{y}}\,\overline{y} + \hat{\boldsymbol{z}}\,[\overline{x}\,(\partial\eta/\partial\overline{x}) + \overline{y}\,(\partial\eta/\partial\overline{y}) + \sigma\,(\partial\eta/\partial\sigma)] \tag{63.35c}$$

$$= \hat{\boldsymbol{x}}\,\overline{x} + \hat{\boldsymbol{y}}\,\overline{y} + \hat{\boldsymbol{z}}\,\xi^{\overline{a}}\,\partial_{\overline{a}}\eta. \tag{63.35d}$$

We identify the following properties as a means to help understand these expressions, with Figure 63.3 offering a schematic.

[2] These identities are directly analogous to the Maxwell relations from thermodynamics, with an introduction in Section 22.8 and full details in the book by *Callen* (1985).

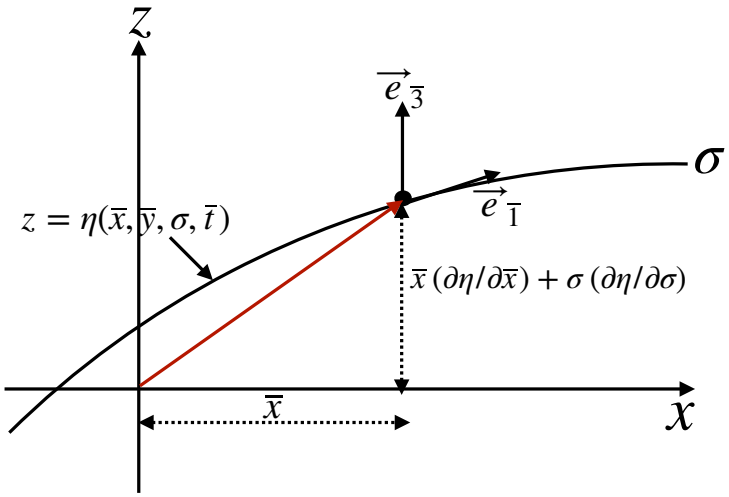

FIGURE 63.3: The position of a point in space as represented using GVCs following equation (63.36a). For this example, $\overline{y} = 0$ so that the horizontal position is determined by the coordinate $\overline{x} = x$, whereas the vertical postion is determined by $\overline{x}\,(\partial z/\partial\overline{x}) + \sigma\,(\partial z/\partial\sigma) = \overline{x}\,(\partial\eta/\partial\overline{x}) + \sigma\,(\partial\eta/\partial\sigma)$.

- The expression (63.35b) has horizontal positions $\overline{x}$ and $\overline{y}$ multiplying the basis vectors $\boldsymbol{e}_{\overline{x}}$ and $\boldsymbol{e}_{\overline{y}}$, with these vectors oriented parallel to a surface of constant GVC as in Figure 63.3. Likewise, the third term, $\sigma\,(\partial\eta/\partial\sigma)\,\hat{\boldsymbol{z}}$, positions the point vertically according to the value of the GVC and its inverse stratification.

- Consider the case of $\overline{y} = 0$ so that

$$\begin{aligned} \mathscr{P} &= \overline{x}\,\hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,[\overline{x}\,(\partial\eta/\partial\overline{x}) + \sigma\,(\partial\eta/\partial\sigma)] && \text{(63.36a)} \\ &= \overline{x}\,\hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,(\partial\eta/\partial\sigma)\,[\overline{x}\,(\partial\sigma/\partial z)_x(\partial\eta/\partial\overline{x})_\sigma + \sigma] && \text{(63.36b)} \\ &= \overline{x}\,\hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,(\partial\eta/\partial\sigma)\,[-\overline{x}\,(\partial\sigma/\partial x)_z + \sigma], && \text{(63.36c)} \end{aligned}$$

  where we used the triple product identity (63.34b) for the final equality. Consequently, a horizontal position vector is realized using GVC coordinates with $\sigma = \overline{x}\,(\partial\sigma/\partial x)$. That is, a horizontal position vector crosses surfaces of constant GVC when the GVC surface has a nonzero horizontal slope.

- The projection of the position vector onto the basis one-forms leads to

$$\mathscr{P} \cdot \boldsymbol{e}^{\overline{b}} = \xi^{\overline{a}}\,\boldsymbol{e}_{\overline{a}} \cdot \boldsymbol{e}^{\overline{b}} = \xi^{\overline{b}}. \tag{63.37}$$

  This result follows from the orthogonality relation (4.25). So the projection of the position vector onto a basis one-form picks out the corresponding coordinate value.

- Equation (63.7) provides the spatial dependence for the vertical position of the surface of constant GVC

$$z = z(\xi^{\overline{a}}) = \eta(\xi^{\overline{a}}). \tag{63.38}$$

  At any particular time instance we can perform a Taylor series about a reference geopotential $z_0 = \eta_0$, so that

$$\eta(\xi^{\overline{a}}) \approx \eta_0 + \xi^{\overline{a}}\,\partial_{\overline{a}}\eta. \tag{63.39}$$

  We can thus write the position (63.35d) in the form

$$\mathscr{P} = \hat{\boldsymbol{x}}\,\overline{x} + \hat{\boldsymbol{y}}\,\overline{y} + \hat{\boldsymbol{z}}\,[\eta - \eta_0]. \tag{63.40}$$

  Taking the reference geopotential as $\eta_0 = 0$ recovers the Cartesian expression. Since the

position vector is a geometric object, it is reassuring that the GVC representation is the same as the Cartesian representation; it is merely a reorganization of the basis vectors and corresponding coordinates.

63.7 Transforming components of a vector

Consider a vector field $\vec{F}$ with Cartesian representation

$$\vec{F} = \boldsymbol{F} = F^a \, \boldsymbol{e}_a = F^x \, \hat{\boldsymbol{x}} + F^y \, \hat{\boldsymbol{y}} + F^z \, \hat{\boldsymbol{z}}. \tag{63.41}$$

The corresponding GVC components are related through the transformation matrix

$$F^{\overline{a}} = \Lambda^{\overline{a}}{}_a \, F^a. \tag{63.42}$$

Making use of the transformation matrix (63.20) yields the relations between GVC components and Cartesian components

$$F^{\overline{1}} = F^1 \quad \text{and} \quad F^{\overline{2}} = F^2 \quad \text{and} \quad F^{\overline{3}} = \nabla\sigma \cdot \boldsymbol{F}, \tag{63.43}$$

where we wrote

$$\nabla\sigma \cdot \boldsymbol{F} = (\partial\sigma/\partial x) \, F^1 + (\partial\sigma/\partial y) \, F^2 + (\partial\sigma/\partial z) \, F^3. \tag{63.44}$$

The vector field thus can be represented in GVC coordinates as

$$\vec{F} = F^{\overline{a}} \, \boldsymbol{e}_{\overline{a}} = F^1 \, \boldsymbol{e}_{\overline{1}} + F^2 \, \boldsymbol{e}_{\overline{2}} + (\nabla\sigma \cdot \boldsymbol{F}) \, \boldsymbol{e}_{\overline{3}}. \tag{63.45}$$

Similarly, the covariant components transform as $F_{\overline{a}} = \Lambda^a{}_{\overline{a}} \, F_a$, where use of the inverse transformation matrix (63.20) renders

$$F_{\overline{1}} = F_1 + (\partial z/\partial\overline{x}) \, F_3 = F_1 + (\partial\eta/\partial\overline{x}) \, F_3 \tag{63.46a}$$
$$F_{\overline{2}} = F_2 + (\partial z/\partial\overline{y}) \, F_3 = F_2 + (\partial\eta/\partial\overline{y}) \, F_3 \tag{63.46b}$$
$$F_{\overline{3}} = (\partial z/\partial\sigma) \, F_3 = (\partial\eta/\partial\sigma) \, F_3, \tag{63.46c}$$

and the expression for the vector field

$$\vec{F} = F_{\overline{a}} \, \boldsymbol{e}^{\overline{a}} = [F_1 + (\partial\eta/\partial\overline{x}) \, F_3] \, \boldsymbol{e}^{\overline{1}} + [F_2 + (\partial\eta/\partial\overline{y}) \, F_3] \, \boldsymbol{e}^{\overline{2}} + (\partial\eta/\partial\sigma) \, F_3 \, \boldsymbol{e}^{\overline{3}}. \tag{63.47}$$

Recall also that for Cartesian coordinates the contravarient and covariant components to a vector are identical: $F^a = F_a$.

63.8 Velocity

As an example of the results from Section 63.7, we here represent the velocity vector, considering both covariant and contravariant representations. As for the position vector detailed in Section 63.6, we are assured that both representations lead to the same velocity vector since the velocity is an objective geometric object (i.e., an arrow with a magnitude). In Section 63.8.4 we verify that the transformation formalism indeed respects this equivalance, with the GVC representations equivalent to the Cartesian representation

$$\vec{v} = u \, \hat{\boldsymbol{x}} + v \, \hat{\boldsymbol{y}} + w \, \hat{\boldsymbol{z}}. \tag{63.48}$$

63.8.1 Contravariant components

Following Section 63.7, we have the contravariant velocity components

$$v^{\overline{1}} = u \qquad \text{and} \qquad v^{\overline{2}} = v \qquad \text{and} \qquad v^{\overline{3}} = \boldsymbol{v} \cdot \nabla\sigma. \tag{63.49}$$

Use of the basis vectors (63.16a)-(63.16c) then leads to

$$\begin{aligned} \vec{v} &= v^{\overline{a}}\, \boldsymbol{e}_{\overline{a}} && \text{(63.50a)} \\ &= u\, \boldsymbol{e}_{\overline{x}} + v\, \boldsymbol{e}_{\overline{y}} + (\boldsymbol{v} \cdot \nabla\sigma)\, \boldsymbol{e}_{\sigma} && \text{(63.50b)} \\ &= u\, [\hat{\boldsymbol{x}} + (\partial\eta/\partial\overline{x})\, \hat{\boldsymbol{z}}] + v\, [\hat{\boldsymbol{y}} + (\partial\eta/\partial\overline{y})\, \hat{\boldsymbol{z}}] + (\boldsymbol{v} \cdot \nabla\sigma)\, (\partial\eta/\partial\sigma)\, \hat{\boldsymbol{z}}. && \text{(63.50c)} \end{aligned}$$

63.8.2 Covariant components

The covariant velocity components are given by

$$v_{\overline{1}} = u + (\partial\eta/\partial\overline{x})\, w \qquad \text{and} \qquad v_{\overline{2}} = v + (\partial\eta/\partial\overline{y})\, w \qquad \text{and} \qquad v_{\overline{3}} = (\partial\eta/\partial\sigma)\, w. \tag{63.51}$$

The one-form basis (63.22a)–(63.22c) thus leads to the velocity vector

$$\vec{v} = v_{\overline{a}}\, \tilde{e}^{\overline{a}} = [u + (\partial\eta/\partial\overline{x})\, w]\, \hat{\boldsymbol{x}} + [v + (\partial\eta/\partial\overline{y})\, w]\, \hat{\boldsymbol{y}} + w\, (\partial\eta/\partial\sigma)\, \nabla\sigma. \tag{63.52}$$

63.8.3 Introducing the material time derivative

The material evolution for the generalized vertical coordinate can be written

$$\frac{\mathrm{D}\sigma}{\mathrm{D}t} = \frac{\partial\sigma}{\partial t} + \boldsymbol{v} \cdot \nabla\sigma = \dot{\sigma}, \tag{63.53}$$

with $\dot{\sigma}$ symbolizing any process contributing to motion across σ isosurfaces (as fully explained in Section 64.3). Using the expression (63.53) in the velocity vector expression (63.50c) leads to

$$\begin{aligned} \vec{v} &= u\, [\hat{\boldsymbol{x}} + (\partial\eta/\partial\overline{x})\, \hat{\boldsymbol{z}}] + v\, [\hat{\boldsymbol{y}} + (\partial\eta/\partial\overline{y})\, \hat{\boldsymbol{z}}] + (\boldsymbol{v} \cdot \nabla\sigma)\, (\partial\eta/\partial\sigma)\, \hat{\boldsymbol{z}}. && \text{(63.54a)} \\ &= u\, [\hat{\boldsymbol{x}} + (\partial\eta/\partial\overline{x})\, \hat{\boldsymbol{z}}] + v\, [\hat{\boldsymbol{y}} + (\partial\eta/\partial\overline{y})\, \hat{\boldsymbol{z}}] + (\dot{\sigma} - \partial\sigma/\partial t)\, (\partial\eta/\partial\sigma)\, \hat{\boldsymbol{z}} && \text{(63.54b)} \\ &= u\, \hat{\boldsymbol{x}} + v\, \hat{\boldsymbol{y}} + [\partial\eta/\partial\overline{t} + \boldsymbol{u} \cdot \nabla_{\!\varpi} z + (\partial\eta/\partial\sigma)\dot{\sigma}]\, \hat{\boldsymbol{z}}, && \text{(63.54c)} \end{aligned}$$

where the final equality made use of the triple product (63.33a): $(\partial\sigma/\partial t)\, (\partial\eta/\partial\sigma) = -\partial\eta/\partial\overline{t}$. In the steady state and in the absence of material changes to σ, the three dimensional flow lies within a surface of constant σ, whereby $\boldsymbol{v} \cdot \nabla\sigma = 0$ and

$$\vec{v} = u\, [\hat{\boldsymbol{x}} + (\partial\eta/\partial\overline{x})\, \hat{\boldsymbol{z}}] + v\, [\hat{\boldsymbol{y}} + (\partial\eta/\partial\overline{y})\, \hat{\boldsymbol{z}}] \qquad \text{if } \partial_t\sigma = 0 \text{ and } \dot{\sigma} = 0. \tag{63.55}$$

However, in general there are transient fluctuations and material changes to σ so that $\boldsymbol{v} \cdot \nabla\sigma \neq 0$.

63.8.4 Equivalence to the Cartesian velocity representation

Use of the triple product identities (63.34b)-(63.34c) allows us to manipulate both expressions (63.50c) and (63.52) to recover the Cartesian expression

$$\vec{v} = u\, \hat{\boldsymbol{x}} + v\, \hat{\boldsymbol{y}} + w\, \hat{\boldsymbol{z}}. \tag{63.56}$$

Another way to see this identity is to note that in equation (63.54c), the vertical component is an expression for the material time derivative of the vertical position

$$w = \frac{\mathrm{D}z}{\mathrm{D}t} = \frac{\partial \eta}{\partial \overline{t}} + \boldsymbol{u} \cdot \nabla_{\!\!\varpi} \eta + \frac{\partial \eta}{\partial \sigma} \, \dot{\sigma}. \tag{63.57}$$

We derive this identity in Section 64.4 where we discuss further kinematic results using GVCs.

63.9 Metric tensor

Recall from Section 4.1 that we make use of a metric tensor to measure the distance between two points in space. The GVC representation of the metric tensor is given by

$$g_{\overline{a}\overline{b}} = \boldsymbol{e}_{\overline{a}} \cdot \boldsymbol{e}_{\overline{b}} = \begin{bmatrix} 1 + (\partial z/\partial \overline{x})^2 & (\partial z/\partial \overline{x}) \, (\partial z/\partial \overline{y}) & (\partial z/\partial \overline{x}) \, (\partial z/\partial \sigma) \\ (\partial z/\partial \overline{x}) \, (\partial z/\partial \overline{y}) & 1 + (\partial z/\partial \overline{y})^2 & (\partial z/\partial \overline{y}) \, (\partial z/\partial \sigma) \\ (\partial z/\partial \overline{x}) \, (\partial z/\partial \sigma) & (\partial z/\partial \overline{y}) \, (\partial z/\partial \sigma) & (\partial z/\partial \sigma)^2 \end{bmatrix}, \tag{63.58}$$

with the triple product identities (63.34b) and (63.34c) bringing the metric into the form

$$g_{\overline{a}\overline{b}} = \begin{bmatrix} 1 + [(\partial \sigma/\partial x) \, (\partial z/\partial \sigma)]^2 & (\partial \sigma/\partial x) \, (\partial \sigma/\partial y) \, (\partial z/\partial \sigma)^2 & -(\partial \sigma/\partial x) \, (\partial z/\partial \sigma)^2 \\ (\partial \sigma/\partial x) \, (\partial \sigma/\partial y) \, (\partial z/\partial \sigma)^2 & 1 + [(\partial \sigma/\partial y) \, (\partial z/\partial \sigma)]^2 & -(\partial \sigma/\partial y) \, (\partial z/\partial \sigma)^2 \\ -(\partial \sigma/\partial x) \, (\partial z/\partial \sigma)^2 & -(\partial \sigma/\partial y) \, (\partial z/\partial \sigma)^2 & (\partial z/\partial \sigma)^2 \end{bmatrix}. \tag{63.59}$$

The representation of the inverse metric tensor is given by the somewhat simpler expression

$$g^{\overline{a}\overline{b}} = \boldsymbol{e}^{\overline{a}} \cdot \boldsymbol{e}^{\overline{b}} = \begin{bmatrix} 1 & 0 & \partial \sigma/\partial x \\ 0 & 1 & \partial \sigma/\partial y \\ \partial \sigma/\partial x & \partial \sigma/\partial y & |\nabla \sigma|^2 \end{bmatrix}. \tag{63.60}$$

Proof that $g^{\overline{a}\overline{b}} \, g_{\overline{b}\overline{c}} = \delta^{\overline{a}}_{\overline{c}}$ requires use of the triple product identities (63.34b) and (63.34c). Note that an additional means to derive the metric tensor (63.58) is given by writing the squared line element as[3]

$$\mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2 \tag{63.61a}$$

$$= \mathrm{d}x^2 + \mathrm{d}y^2 + [(\partial z/\partial \overline{x}) \, \mathrm{d}x + (\partial z/\partial \overline{y}) \, \mathrm{d}y + (\partial z/\partial \sigma) \, \mathrm{d}\sigma]^2, \tag{63.61b}$$

from which the metric tensor (63.58) is revealed upon expanding the quadratic term and then rearranging.

63.9.1 Jacobian of transformation

The determinant of the GVC representation of the metric tensor (63.58) is

$$\det(g_{\overline{a}\overline{b}}) = (\partial z/\partial \sigma)^2 = (\partial \eta/\partial \sigma)^2 \tag{63.62}$$

so that the Jacobian of transformation (Section 4.5) is the specific thickness

$$\frac{\partial(x, y, z)}{\partial(\overline{x}, \overline{y}, \sigma)} = \frac{\partial z}{\partial \sigma} = \frac{\partial \eta}{\partial \sigma}. \tag{63.63}$$

[3]The traditional notation in physics writes the squared line element as $\mathrm{d}s^2 = (\mathrm{d}s)^2$. Likewise, $\mathrm{d}x^2 = (\mathrm{d}x)^2$, etc.

The coordinate transformation from Cartesian to generalized vertical is invertible only so long as the Jabobian remains nonzero and single-signed, meaning the fluid retains a monotonic vertical stratification of GVC surfaces. The invertible relation between z and σ means that each point in the vertical can be uniquely specified by either of the two vertical coordinates, z or σ. For example, the Jacobian for pressure as the generalized vertical coordinate in a hydrostatic fluid is given by[4]

$$\frac{\partial z}{\partial \sigma} = \frac{\partial z}{\partial p} = -\frac{1}{\rho g}, \tag{63.64}$$

which is indeed single-signed since the mass density is always positive.

63.9.2 Covariant and contravariant representations

The metric tensor allows us to convert between the covariant and contravariant representations of a vector via the identity (Section 4.2.3)

$$F_{\overline{a}} = g_{\overline{a}\overline{b}} F^{\overline{b}}. \tag{63.65}$$

We use triple product identities (63.34b)-(63.34c) to verify that this relation agrees with the transformation matrix approach detailed in Section 63.7. For example,

$$\begin{aligned}
F_{\overline{1}} &= g_{\overline{1}\overline{b}} F^{\overline{b}} && \text{(63.66a)}\\
&= [1 + (\partial\eta/\partial\overline{x})^2] F^{\overline{1}} + (\partial\eta/\partial\overline{x})(\partial\eta/\partial\overline{y}) F^{\overline{2}} + (\partial\eta/\partial\overline{x})(\partial\eta/\partial\sigma) F^{\sigma} && \text{(63.66b)}\\
&= [1 + (\partial\eta/\partial\overline{x})^2] F^{1} + (\partial\eta/\partial\overline{x})(\partial\eta/\partial\overline{y}) F^{2} + (\partial\eta/\partial\overline{x})(\partial\eta/\partial\sigma) \nabla\sigma \cdot \boldsymbol{F} && \text{(63.66c)}\\
&= F^1 + (\partial\eta/\partial\overline{x}) F^3 && \text{(63.66d)}\\
&= F_1 + (\partial\eta/\partial\overline{x}) F_3, && \text{(63.66e)}
\end{aligned}$$

where the final equality holds since $F^1 = F_1$ and $F^3 = F_3$ for Cartesian tensor components.

63.10 Volume element and the Levi-Civita tensor

The square root of the determinant of the metric tensor (63.58) is

$$\sqrt{\det(g_{\overline{a}\overline{b}})} = \partial z/\partial\sigma = \partial\eta/\partial\sigma \tag{63.67}$$

so that the volume element (Section 4.5) is

$$\mathrm{d}V = (\partial z/\partial\sigma)\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}\sigma. \tag{63.68}$$

The covariant Levi-Civita tensor (Section 4.7) has the GVC representations

$$\varepsilon_{\overline{a}\overline{b}\overline{c}} = (\partial z/\partial\sigma)\,\epsilon_{\overline{a}\overline{b}\overline{c}} \qquad \varepsilon^{\overline{a}\overline{b}\overline{c}} = (\partial z/\partial\sigma)^{-1}\,\epsilon^{\overline{a}\overline{b}\overline{c}} \tag{63.69}$$

where ϵ is the permutation symbol introduced in Section 1.7.1 with its components independent of coordinate representation.

[4] We derive the hydrostatic balance in Section 27.2.

63.11 Vector cross product of basis vectors

We now verify the relation (4.87) for the cross product of two basis vectors using GVCs

$$\boldsymbol{e}_{\overline{a}} \times \boldsymbol{e}_{\overline{b}} = \varepsilon_{\overline{a}\overline{b}\overline{c}}\, \boldsymbol{e}^{\overline{c}} \implies \boldsymbol{e}_{\overline{a}} \times \boldsymbol{e}_{\overline{b}} = (\partial z/\partial\sigma)\epsilon_{\overline{a}\overline{b}\overline{c}}\, \boldsymbol{e}^{\overline{c}}. \tag{63.70}$$

Making use of the basis vectors from Section 63.3 and the basis one-forms from Section 63.4 renders

$$\boldsymbol{e}_{\overline{x}} \times \boldsymbol{e}_{\overline{y}} = \hat{\boldsymbol{z}} - \hat{\boldsymbol{x}}\,(\partial\eta/\partial\overline{x}) - \hat{\boldsymbol{y}}\,(\partial\eta/\partial\overline{y}) = (\partial z/\partial\sigma)\,\nabla\sigma = \varepsilon_{\overline{x}\overline{y}\sigma}\,\boldsymbol{e}^{\sigma} \tag{63.71a}$$

$$\boldsymbol{e}_{\overline{y}} \times \boldsymbol{e}_{\sigma} = \hat{\boldsymbol{x}}\,(\partial z/\partial\sigma) = \varepsilon_{\overline{y}\sigma\overline{x}}\,\boldsymbol{e}^{\overline{x}} \tag{63.71b}$$

$$\boldsymbol{e}_{\sigma} \times \boldsymbol{e}_{\overline{x}} = \hat{\boldsymbol{y}}\,(\partial z/\partial\sigma) = \varepsilon_{\sigma\overline{x}\overline{y}}\,\boldsymbol{e}^{\overline{y}}. \tag{63.71c}$$

63.12 Partial derivative operators

We here consider the partial derivative operators and their transformation between coordinate systems. These identities are used throughout GVC calculus. Given the importance of these expressions, we offer two derivations. Notably, the geometric derivation in Section 63.12.2 requires minimal use of the previous tensor formalism.

63.12.1 Analytical derivation

The partial derivative operators in GVCs are computed via $\partial_{\overline{a}} = \Lambda^{a}{}_{\overline{a}}\,\partial_a$. Including also the time component leads to the relations

$$\partial_{\overline{t}} = \partial_t + (\partial z/\partial\overline{t})\,\partial_z = \partial_t + (\partial\eta/\partial\overline{t})\,\partial_z \tag{63.72a}$$

$$\partial_{\overline{x}} = \partial_x + (\partial z/\partial\overline{x})\,\partial_z = \partial_x + (\partial\eta/\partial\overline{x})\,\partial_z \tag{63.72b}$$

$$\partial_{\overline{y}} = \partial_y + (\partial z/\partial\overline{y})\,\partial_z = \partial_y + (\partial\eta/\partial\overline{y})\,\partial_z \tag{63.72c}$$

$$\partial_{\sigma} = (\partial z/\partial\sigma)\,\partial_z = (\partial\eta/\partial\sigma)\,\partial_z. \tag{63.72d}$$

We can make use of the triple product identities (63.34b) and (63.34c) to express the slope of a constant GVC surface in the equivalent manners

$$\boldsymbol{S} = \nabla_{\!\!\text{h}\sigma}\eta = \nabla_{\!\!\text{h}\sigma} z = -(\partial\sigma/\partial z)^{-1}\,\nabla_{\!\!\text{h}}\sigma \tag{63.73}$$

where we introduced the standard shorthand notation

$$\nabla_{\!\!\text{h}\sigma} = \hat{\boldsymbol{x}}\,\partial/\partial\overline{x} + \hat{\boldsymbol{y}}\,\partial/\partial\overline{y} \qquad \text{and} \qquad \nabla_{\!\!\text{h}} = \hat{\boldsymbol{x}}\,\partial/\partial x + \hat{\boldsymbol{y}}\,\partial/\partial y. \tag{63.74}$$

It is common to transform between the horizontal gradient operators, in which case we write

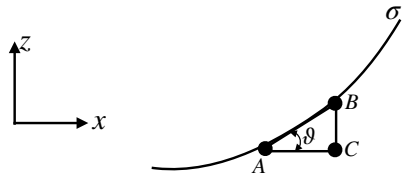
$$\nabla_{\!\!\text{h}\sigma} = \nabla_{\!\!\text{h}} + (\nabla_{\!\!\text{h}\sigma} z)\,\partial_z \equiv \nabla_{\!\!\text{h}} + \boldsymbol{S}\,\partial_z. \tag{63.75}$$

We emphasize that $\nabla_{\!\!\text{h}\sigma}$ is merely a shorthand for the two partial derivative operators and that it only has components in the horizontal directions. Furthermore, the σ subscript is not a tensor index.

63.12.2 Geometrical derivation

We provide a geometric derivation for the lateral derivative operator that complements the previous analytical derivation. This operator is computed by taking the difference of a function along surfaces of constant generalized vertical coordinate, but with the lateral distance computed

in the horizontal direction as show in Figure 63.4. This feature of the horizontal derivative operator is a key aspect of the GVCs' non-orthogonality.



$$\left[\frac{\partial \psi}{\partial x}\right]_\sigma \approx \frac{\psi(B)-\psi(A)}{x(C)-x(A)}$$

FIGURE 63.4: A surface of constant generalized vertical coordinate, σ, along with a local tangent plane with a slope $\tan\vartheta$ with respect to the horizontal plane. This figure illustrates the identities (63.77a)-(63.77d), with these identities relating a lateral derivative taken along the GVC surface to horizontal and vertical derivatives taken along orthogonal Cartesian axes.

Consider the geometry shown in Figure 63.4, which shows a generalized vertical coordinate surface (constant σ surface) along with a sample tangent plane with a slope

$$S^x = \frac{\text{rise}}{\text{run}} = \tan\vartheta = \frac{z(B)-z(C)}{x(C)-x(A)} \approx \left[\frac{\partial z}{\partial x}\right]_\sigma = -\frac{(\partial\sigma/\partial x)_z}{(\partial\sigma/\partial z)} \tag{63.76}$$

relative to the horizontal. We readily verify the following identities based on finite difference operations for an arbitrary function

$$\left[\frac{\partial \psi}{\partial x}\right]_\sigma \approx \frac{\psi(B)-\psi(A)}{x(C)-x(A)} \tag{63.77a}$$

$$= \frac{\psi(C)-\psi(A)}{x(C)-x(A)} + \frac{\psi(B)-\psi(C)}{x(C)-x(A)} \tag{63.77b}$$

$$= \frac{\psi(C)-\psi(A)}{x(C)-x(A)} + \left[\frac{z(B)-z(C)}{x(C)-x(A)}\right]\frac{\psi(B)-\psi(C)}{z(B)-z(C)} \tag{63.77c}$$

$$= \left[\frac{\partial \psi}{\partial x}\right]_z + S^x \left[\frac{\partial \psi}{\partial z}\right]_x. \tag{63.77d}$$

Taking the continuum limit then leads to the relations between horizontal derivatives computed on constant σ surfaces to those computed on constant z surfaces

$$\left[\frac{\partial}{\partial x}\right]_\sigma = \left[\frac{\partial}{\partial x}\right]_z + \left[\frac{\partial z}{\partial x}\right]_\sigma \frac{\partial}{\partial z} = \left[\frac{\partial}{\partial x}\right]_z + \left[\frac{\partial \eta}{\partial x}\right]_\sigma \frac{\partial}{\partial z} \tag{63.78a}$$

$$\left[\frac{\partial}{\partial y}\right]_\sigma = \left[\frac{\partial}{\partial y}\right]_z + \left[\frac{\partial z}{\partial y}\right]_\sigma \frac{\partial}{\partial z} = \left[\frac{\partial}{\partial y}\right]_z + \left[\frac{\partial \eta}{\partial y}\right]_\sigma \frac{\partial}{\partial z}, \tag{63.78b}$$

which can be written in the shorthand vector notation

$$\nabla_{\!\sigma} = \hat{\boldsymbol{x}}\left[\frac{\partial}{\partial x}\right]_\sigma + \hat{\boldsymbol{y}}\left[\frac{\partial}{\partial y}\right]_\sigma = \nabla_{\!\mathrm{h}} + (\nabla_{\!\sigma} z)\,\partial_z = \nabla_{\!\mathrm{h}} + (\nabla_{\!\sigma}\eta)\,\partial_z. \tag{63.79}$$

63.12.3 The gradient as a tensor operator

The gradient is given by the equivalent expressions

$$\nabla = \boldsymbol{e}^a\,\partial_a = \boldsymbol{e}^{\overline{a}}\,\partial_{\overline{a}}. \tag{63.80}$$

The gradient has the following Cartesian coordinate expression

$$\nabla = \hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y + \hat{\boldsymbol{z}}\,\partial_z, \tag{63.81}$$

and the equivalent generalized vertical coordinate expression

$$\nabla = \hat{\boldsymbol{x}}\,\partial_{\overline{x}} + \hat{\boldsymbol{y}}\,\partial_{\overline{y}} + (\nabla\sigma)\,\partial_\sigma. \tag{63.82}$$

As a check on the equality between equations (63.81) and (63.82), make use of equations (63.72b)-(63.72d) for the partial derivatives and equations (63.22a)-(63.22c) for the one-form basis so that

$$\hat{\boldsymbol{x}}\,\partial_{\overline{x}} + \hat{\boldsymbol{y}}\,\partial_{\overline{y}} + (\nabla\sigma)\,\partial_\sigma = \hat{\boldsymbol{x}}\,[\partial_x + (\partial_{\overline{x}} z)\,\partial_z] + \hat{\boldsymbol{y}}\,[\partial_y + (\partial_{\overline{y}} z)\,\partial_z] + (\nabla\sigma)\,(\partial z/\partial\sigma)\,\partial_z. \tag{63.83}$$

Next use the triple product identities (63.34b) and (63.34c) to have

$$\partial_{\overline{x}} z + (\partial\sigma/\partial x)\,(\partial z/\partial\sigma) = 0 \tag{63.84a}$$
$$\partial_{\overline{y}} z + (\partial\sigma/\partial y)\,(\partial z/\partial\sigma) = 0, \tag{63.84b}$$

in which case

$$\hat{\boldsymbol{x}}\,[\partial_x + (\partial_{\overline{x}} z)\,\partial_z] + \hat{\boldsymbol{y}}\,[\partial_y + (\partial_{\overline{y}} z)\,\partial_z] + (\nabla\sigma)\,(\partial z/\partial\sigma)\,\partial_z = \hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y + \hat{\boldsymbol{z}}\,\partial_z. \tag{63.85}$$

63.13 Material time derivative

Making use of the relations for the partial derivative operators in Section 63.12 allows us to write the material time derivative in the following equivalent forms

$$\frac{\mathrm{D}}{\mathrm{D}t} = \left[\frac{\partial}{\partial t}\right]_z + \boldsymbol{u}\cdot\nabla_{\!\mathrm{h}} + w\,\frac{\partial}{\partial z} \tag{63.86a}$$
$$= \left[\frac{\partial}{\partial t}\right]_\sigma - (\partial\eta/\partial\overline{t})\,\partial_z + \boldsymbol{u}\cdot[\nabla_{\!\mathrm{h}\sigma} - (\nabla_{\!\mathrm{h}\sigma}\eta)\,\partial_z] + w\,\partial/\partial z \tag{63.86b}$$
$$= \left[\frac{\partial}{\partial t}\right]_\sigma + \boldsymbol{u}\cdot\nabla_{\!\mathrm{h}\sigma} + \left[w - \boldsymbol{u}\cdot\nabla_{\!\mathrm{h}\sigma}\eta - \partial\eta/\partial\overline{t}\right](\partial\sigma/\partial z)\,\partial/\partial\sigma \tag{63.86c}$$
$$= \left[\frac{\partial}{\partial t}\right]_\sigma + \boldsymbol{u}\cdot\nabla_{\!\mathrm{h}\sigma} + \frac{\mathrm{D}\sigma}{\mathrm{D}t}\,\frac{\partial}{\partial\sigma} \tag{63.86d}$$
$$= \left[\frac{\partial}{\partial t}\right]_\sigma + \boldsymbol{u}\cdot\nabla_{\!\mathrm{h}\sigma} + \frac{\partial z}{\partial\sigma}\,\frac{\mathrm{D}\sigma}{\mathrm{D}t}\,\frac{\partial}{\partial z}. \tag{63.86e}$$

The equality (63.86d) made use of the identity (63.57), which is itself derived in Section 64.4 where we discuss further kinematic results using GVCs. Besides differences in the spatial operators, it is important to note that the time derivative operators are computed on constant geopotential and constant GVC surfaces, respectively. However, the horizontal velocity component is the *same* for both forms of the material time derivative

$$(u, v) = \frac{\mathrm{D}(x, y)}{\mathrm{D}t}. \tag{63.87}$$

63.14 Divergence of a vector and the divergence theorem

Making use of the general expression (4.15) for the covariant divergence of a vector renders the GVC expression

$$\nabla_{\overline{a}}\, F^{\overline{a}} = [\det(g_{\overline{a}\overline{b}})]^{-1/2}\,\partial_{\overline{a}}\left[[\det(g_{\overline{a}\overline{b}})]^{1/2}\, F^{\overline{a}}\right] = (\partial z/\partial\sigma)^{-1}\partial_{\overline{a}}\,[(\partial z/\partial\sigma)\, F^{\overline{a}}]. \tag{63.88}$$

Recall that the GVC vector components, $F^{\overline{a}}$, are related to the Cartesian components in equation (63.43), and the GVC components of the partial derivative operator, $\partial_{\overline{a}}$, are related to the Cartesian operator in equation (63.74).

When making use of the divergence theorem (Section 4.19), we require the product of the volume element and the covariant divergence. For GVCs this product takes on the form

$$(\nabla_{\overline{a}} F^{\overline{a}}) \, \mathrm{d}V = \partial_{\overline{a}} \left[(\partial z / \partial \sigma) \, F^{\overline{a}} \right] \mathrm{d}\overline{x} \, \mathrm{d}\overline{y} \, \mathrm{d}\sigma, \tag{63.89}$$

which reduces to a boundary integral when integrating over a volume.

63.15 The diffusion operator

As an explicit example of the covariant divergence operator (63.88), we here consider the diffusion operator discussed in Chapter 69. The derivation here recovers much of what we just discussed in Section 63.14, yet we make use of a bit less tensor formalism though at the cost of more algebra.

63.15.1 Continuous expression

The diffusion operator is the convergence of the diffusive flux

$$\mathcal{R} = -\nabla \cdot \mathbf{J}, \tag{63.90}$$

where $\mathbf{J}$ is the tracer flux vector. Let us convert the pieces of this operator from Cartesian coordinates into generalized vertical coordinate, making use of the transformation of partial derivative operators given in Section 63.12. Also, we make use of the shorthand $z(x, y, \sigma, t)$ rather than $\eta(x, y, \sigma, t)$

$$\begin{aligned}
-\mathcal{R} &= \nabla \cdot \boldsymbol{J} && \text{(63.91a)} \\
&= \nabla_{\!\mathrm{h}} \cdot \boldsymbol{J}^{\mathrm{h}} + \partial_z J^z && \text{(63.91b)} \\
&= (\nabla_{\!\mathrm{h}\sigma} - \nabla_{\!\mathrm{h}\sigma} z \, \partial_z) \cdot \boldsymbol{J}^{\mathrm{h}} + (\sigma_z) \, \partial_\sigma J^z && \text{(63.91c)} \\
&= \sigma_z \left[z_\sigma \, \nabla_{\!\mathrm{h}\sigma} \cdot \boldsymbol{J}^{\mathrm{h}} + (\hat{\boldsymbol{z}} \, \partial_\sigma - \nabla_{\!\mathrm{h}\sigma} z \, \partial_\sigma) \cdot \boldsymbol{J} \right] && \text{(63.91d)} \\
&= \sigma_z \left[\nabla_{\!\mathrm{h}\sigma} \cdot (z_\sigma \, \boldsymbol{J}^{\mathrm{h}}) - \boldsymbol{J}^{\mathrm{h}} \cdot \nabla_{\!\mathrm{h}\sigma} (z_\sigma) + \partial_\sigma J^z - \partial_\sigma \left(\nabla_{\!\mathrm{h}\sigma} z \cdot \boldsymbol{J} \right) + \boldsymbol{J} \cdot \partial_\sigma \left(\nabla_{\!\mathrm{h}\sigma} z \right) \right] && \text{(63.91e)} \\
&= \sigma_z \left[\nabla_{\!\mathrm{h}\sigma} \cdot (z_\sigma \, \boldsymbol{J}^{\mathrm{h}}) + \partial_\sigma J^z - \partial_\sigma \left(\nabla_{\!\mathrm{h}\sigma} z \cdot \boldsymbol{J}^{\mathrm{h}} \right) \right] && \text{(63.91f)} \\
&= \sigma_z \left(\nabla_{\!\mathrm{h}\sigma} \cdot (\partial_\sigma z \, \boldsymbol{J}^{\mathrm{h}}) + \partial_\sigma \left[(\hat{\boldsymbol{z}} - \nabla_{\!\mathrm{h}\sigma} z) \cdot \boldsymbol{J} \right] \right) && \text{(63.91g)} \\
&= \sigma_z \left[\nabla_{\!\mathrm{h}\sigma} \cdot (z_\sigma \, \boldsymbol{J}^{\mathrm{h}}) + \partial_\sigma \left(z_\sigma \, \nabla\sigma \cdot \boldsymbol{J} \right) \right], && \text{(63.91h)}
\end{aligned}$$

where we used

$$z_\sigma \nabla \sigma = \hat{\boldsymbol{z}} - \nabla_{\!\mathrm{h}\sigma} z \tag{63.92}$$

to reach the final equality, and made use of the shorthand

$$z_\sigma = \partial z / \partial \sigma \qquad \text{and} \qquad \sigma_z = \partial \sigma / \partial z = (z_\sigma)^{-1}. \tag{63.93}$$

The coordinate transformations in Section 63.7 for vector components reveal that the expression (63.91h) is identical to equation (63.88) derived using formal tensor methods. Likewise, multiplying by the volume element

$$\mathrm{d}V = \mathrm{d}x \, \mathrm{d}y \, \mathrm{d}z = \mathrm{d}x \, \mathrm{d}y \, z_\sigma \, \mathrm{d}\sigma, \tag{63.94}$$

leads to

$$-\mathcal{R}\,\mathrm{d}V = [\nabla_{h\sigma}\cdot(z_\sigma\,\boldsymbol{J}^{h}) + \partial_\sigma\,(z_\sigma\,\nabla\sigma\cdot\boldsymbol{J})]\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}\sigma, \tag{63.95}$$

which is identical to the expression (63.89).

63.15.2 Layer thickness weighted diffusion operator

Consider a prescribed increment, $\delta\sigma$, separating two σ isosurfaces. This increment commutes with the horizontal operator $\nabla_{h\sigma}$, acting within the layer. We can thus formally consider the following layer-integrated or thickness weighted form of the diffusion operator

$$-\mathcal{R}\,\delta V = [\nabla_{h\sigma}\cdot(\delta\sigma\,z_\sigma\,\boldsymbol{J}^{h}) + \delta\sigma\,\partial_\sigma\,(z_\sigma\,\nabla\sigma\cdot\boldsymbol{J})]\,\delta x\,\delta y \tag{63.96a}$$

$$= \frac{1}{\delta z}\,[\nabla_{h\sigma}\cdot(\delta\sigma\,z_\sigma\,\boldsymbol{J}^{h}) + \delta\sigma\,\partial_\sigma\,(z_\sigma\,\nabla\sigma\cdot\boldsymbol{J})]\,\delta x\,\delta y\,\delta z \tag{63.96b}$$

$$= \frac{1}{h}\,[\nabla_{h\sigma}\cdot(h\,\boldsymbol{J}^{h}) + \Delta_\sigma(z_\sigma\,\nabla\sigma\cdot\boldsymbol{J})]\,\delta x\,\delta y\,h, \tag{63.96c}$$

where we introduced the infinitesimal layer thickness

$$h = z_\sigma\,\delta\sigma \tag{63.97}$$

and the non-dimensional differential operator

$$\Delta_\sigma \equiv \delta\sigma\,\frac{\partial}{\partial\sigma}. \tag{63.98}$$

Cancelling the volume element on both sides leads to the diffusion operator

$$\mathcal{R} = -\frac{1}{h}\,[\nabla_{h\sigma}\cdot(h\,\boldsymbol{J}^{h}) + \Delta_\sigma(z_\sigma\,\nabla\sigma\cdot\boldsymbol{J})]\,. \tag{63.99}$$

This form is commonly found in the numerical modeling literature when considering generalized vertical coordinate models.

We make the following comments concerning the diffusion operator in equation (63.99).

- Our introduction of the layer thickness $h = z_\sigma\,\delta\sigma$ is treated a bit more formally in Sections 64.9 and 64.10 by considering a vertical integral over a coordinate layer. Even so, the resulting diffusion operator is the same as that derived here.

- The thickness weighted flux, $h\,\boldsymbol{J}^{h}$, is oriented within the horizontal plane. However, its contribution to the diffusion operator is computed by taking its convergence using the operator $\nabla_{h\sigma}$ rather than the horizontal operator ∇_{h}. This distinction is fundamental to how operators, such as advection and diffusion, appear using generalized vertical coordinates.

- The flux $z_\sigma\nabla\sigma\cdot\boldsymbol{J}$ is commonly referred to as the dia-surface subgrid scale flux.

- For the special case of a diffusive flux with zero component parallel to $\nabla\sigma$, the diffusion operator reduces to

$$\mathcal{R} = -\frac{1}{h}\,[\nabla_{h\sigma}\cdot(h\,\boldsymbol{J}^{h})] \qquad \text{if } \nabla\sigma\cdot\boldsymbol{J} = 0. \tag{63.100}$$

  The neutral diffusion operator of Section 71.4.4 is an example of such an operator, with σ in that case given by the locally referenced potential density.

63.16 Vorticity

As detailed in Chapter 40, vorticity is the curl of the velocity

$$\vec{\omega} = \text{curl}(\vec{v}), \tag{63.101}$$

where the curl has components (Section 4.18)

$$\text{curl}(\vec{v}) = \boldsymbol{e}_{\overline{a}}\, \varepsilon^{\overline{a}\overline{b}\overline{c}} \partial_{\overline{b}} v_{\overline{c}}. \tag{63.102}$$

63.16.1 The components

We identify the contravariant components of the vorticity via

$$\omega^{\overline{a}} = \varepsilon^{\overline{a}\overline{b}\overline{c}} \partial_{\overline{b}} v_{\overline{c}} = (\partial z/\partial\sigma)^{-1}\, \epsilon^{\overline{a}\overline{b}\overline{c}}\, \partial_{\overline{b}} v_{\overline{c}} \tag{63.103}$$

where we made use of equation (63.69) to introduce the permutation symbol. Expanding the components leads to

$$\omega^{\overline{1}} = (\partial\sigma/\partial z)\, (\partial_{\overline{2}}\, v_{\overline{3}} - \partial_{\overline{3}}\, v_{\overline{2}}) \tag{63.104a}$$

$$\omega^{\overline{2}} = (\partial\sigma/\partial z)\, (\partial_{\overline{3}}\, v_{\overline{1}} - \partial_{\overline{1}}\, v_{\overline{3}}) \tag{63.104b}$$

$$\omega^{\overline{3}} = \omega^{\sigma} = (\partial\sigma/\partial z)\, (\partial_{\overline{1}}\, v_{\overline{2}} - \partial_{\overline{2}}\, v_{\overline{1}}). \tag{63.104c}$$

63.16.2 Transforming from Cartesian coordinates

The above approach works solely with the GVC coordinates. An alternative approach connects the GVC vorticity components and the Cartesian vorticity components. For that purpose we use the transformation matrix via

$$\omega^{\overline{a}} = \Lambda^{\overline{a}}{}_{a}\, \omega^{a}, \tag{63.105}$$

where ω^a are the Cartesian components

$$\boldsymbol{\omega} = \hat{\boldsymbol{x}} \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \right) + \hat{\boldsymbol{y}} \left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \right) + \hat{\boldsymbol{z}} \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right). \tag{63.106}$$

Making use of the transformation matrix $\Lambda^{\overline{a}}{}_{a}$ from equation (63.20) yields (as in Section 63.7)

$$\omega^{\overline{x}} = \omega^{x} = \frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \qquad \text{and} \qquad \omega^{\overline{y}} = \omega^{y} = \frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \qquad \text{and} \qquad \omega^{\sigma} = \boldsymbol{\omega} \cdot \nabla\sigma. \tag{63.107}$$

Note that for isopycnal coordinates in a Boussinesq fluid, ω^σ equals to the potential vorticity when the vorticity is the absolute vorticity (Section 66.3). That is, the potential vorticity is the isopycnal component of the absolute vorticity.

63.17 Velocity circulation

The velocity circulation (Section 37.4) is given by the closed oriented path integral of the velocity projected into the direction of the path

$$\mathcal{C} \equiv \oint_{\partial S} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} \tag{63.108}$$

where $\mathrm{d}\boldsymbol{x}$ is the vector line element along the path and $\partial\mathcal{S}$ is the closed path defining the boundary to a two-dimensional surface $\mathcal{S}$. Stokes' Theorem from Section 2.6 leads to the identity

$$\mathcal{C} = \oint_{\partial\mathcal{S}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} (\nabla \times \boldsymbol{v}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \int_{\mathcal{S}} \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{63.109}$$

where $\hat{\boldsymbol{n}}$ is the outward normal vector orienting the area element $\mathrm{d}\mathcal{S}$ according to the right-hand rule applied to the bounding circuit. These results are all written in a generally covariant manner (Section 3.1) so that they hold for an arbitrary coordinate representation.

As a particular case, consider the circulation around a closed path on a constant σ surface, in which

$$\hat{\boldsymbol{n}} = \frac{\nabla\sigma}{|\nabla\sigma|} \tag{63.110}$$

is the outward normal and

$$\boldsymbol{\omega} \cdot \hat{\boldsymbol{n}} = \frac{\omega^\sigma}{|\nabla\sigma|} \tag{63.111}$$

where $\omega^\sigma = \boldsymbol{\omega} \cdot \nabla\sigma$ (equation (63.107)). So long as the vertical stratification remains non-zero ($\partial\sigma/\partial z \neq 0$) we can write the area factor in the form

$$\frac{\mathrm{d}\mathcal{S}}{|\nabla\sigma|} = \frac{\mathrm{d}\mathcal{S}}{\sqrt{(\partial\sigma/\partial x)^2 + (\partial\sigma/\partial y)^2 + (\partial\sigma/\partial z)^2}} \tag{63.112a}$$

$$= \frac{\mathrm{d}\mathcal{S}}{|\partial\sigma/\partial z| \, \sqrt{[(\partial\sigma/\partial x)/(\partial\sigma/\partial z)]^2 + [(\partial\sigma/\partial y)/(\partial\sigma/\partial z)]^2 + 1}} \tag{63.112b}$$

$$= \frac{\mathrm{d}\mathcal{S}}{|\partial\sigma/\partial z| \sqrt{1 + \tan^2\vartheta}} \tag{63.112c}$$

$$= \left| \frac{\partial z}{\partial \sigma} \right| |\cos\vartheta| \, \mathrm{d}\mathcal{S} \tag{63.112d}$$

$$= \left| \frac{\partial z}{\partial \sigma} \right| \mathrm{d}A. \tag{63.112e}$$

The equality (63.112c) introduces the angle, ϑ, between the boundary surface and the horizontal plane as in Figure 63.4. The squared slope of this surface given by

$$\tan^2\vartheta = \frac{\nabla_{\!\mathrm{h}}\sigma \cdot \nabla_{\!\mathrm{h}}\sigma}{(\partial\sigma/\partial z)^2} = \nabla_{\!\mathrm{h}\sigma} z \cdot \nabla_{\!\mathrm{h}\sigma} z. \tag{63.113}$$

The equality (63.112d) made use of a trigonometric identity, and the equality (63.112e) introduced the horizontal projection of the area,

$$\mathrm{d}A = |\cos\vartheta| \, \mathrm{d}\mathcal{S}. \tag{63.114}$$

Bringing these results together leads to the expression for circulation around a closed loop on a constant σ surface

$$\mathcal{C}_{\sigma-\text{surface}} = \int_{\mathcal{S}} (\boldsymbol{\omega} \cdot \nabla\sigma) \, |\partial z/\partial\sigma| \, \mathrm{d}A. \tag{63.115}$$

Chapter 64

KINEMATIC EQUATIONS

In providing a mechanistic description of budgets within the ocean or atmosphere, it is often useful to measure the material or momentum transfer through a surface. This transport is termed the *dia-surface transport*. Our discussion in this chapter unifies ideas developed for kinematic boundary conditions in Section 19.6 with transport across an arbitrary surface in the fluid interior. We do so by making use of the generalized vertical coordinates (GVCs) from Chapter 63. We make use of the dia-surface transport formulation to express the material time derivative operator using GVCs. This form for the material time derivative allows us to decompose the vertical velocity into motion relative to a moving GVC surface. In turn, we are afforded a means to reinterpret the velocity vector and corresponding particle trajectories. GVC kinematics also provides a means to express the subduction of fluid into the ocean interior beneath the mixed layer base. We close the chapter with derivations of the GVC version of mass continuity and the tracer equation. We also introduce the layer integrated version of the continuity and tracer equations, with the layer integrated equations appropriate for discrete numerical fluid models.

CHAPTER GUIDE

We introduced mathematical properties of generalized vertical coordinates in Chapter 63, including the calculus using these non-orthogonal coordinates. It is essential to have a working knowledge of that material to understand the present chapter. Later in Chapter 65 we detail the dynamical equations using GVCs, with material in that chapter relying on the kinematics presented here. Following the treatment in Chapter 63, we here use the symbol σ to denote a generalized vertical coordinate, where σ has functional dependence $\sigma(x, y, z, t)$.

64.1 Example generalized vertical coordinates

We here consider some generalized vertical coordinates that will prove of use for our discussion in this chapter, with Figure 64.1 illustrating the examples.

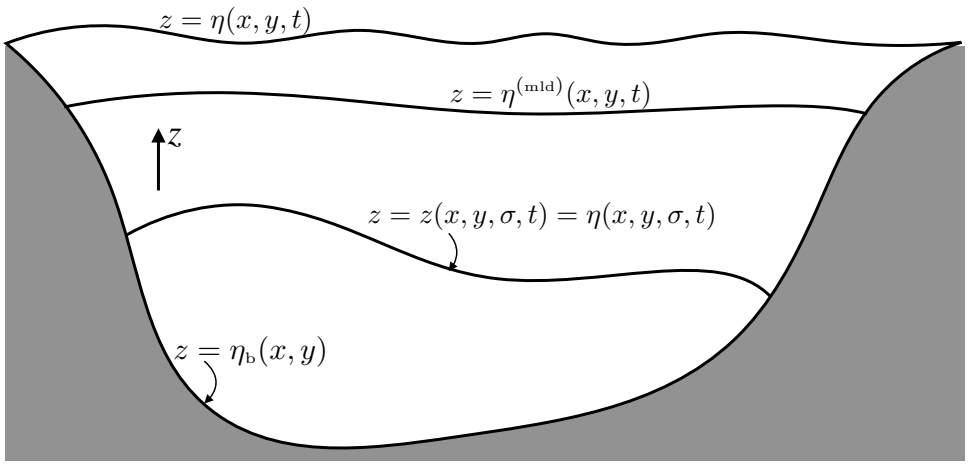


FIGURE 64.1: Example surface upon which a generalized vertical coordinate, $\sigma(x, y, z, t)$, is constant. The ocean free surface can be represented mathematically by $\sigma(x, y, z, t) = z - \eta(x, y, t) = 0$; the ocean mixed layer base by $\sigma(x, y, z, t) = z - \eta^{\mathrm{mld}}(x, y, t) = 0$; and the solid earth bottom $\sigma(x, y, z) = z - \eta_{\mathrm{b}}(x, y) = 0$. Likewise, the vertical position of an interior generalized vertical coordinate surface can be written $z - \eta(x, y, \sigma, t) = \text{constant}$, where $\eta(x, y, \sigma, t)$ is a function of horizontal position and time for the surface defined by a particular σ value.

64.1.1 Ocean free surface

The first surface is the ocean free surface, whose kinematic boundary conditions were derived in Section 19.6.3. Here, water and tracer penetrate this surface through precipitation, evaporation, river runoff (when applied as an upper ocean boundary condition), and sea ice melt. Momentum exchange arises from stresses between the ocean and atmosphere or ice. The ocean free surface

can be represented mathematically by the identity

$$\sigma(x, y, z, t) = z - \eta(x, y, t) = 0 \qquad \text{ocean free surface.} \tag{64.1}$$

This identity holds so long as we assume the surface height η is smooth and contains no overturns at the scales of interest. That is, we assume breaking surface waves are filtered from the description.

64.1.2 Solid earth boundary

We may describe the solid Earth lower boundary mathematically by using the time independent expression

$$\sigma(x, y, z) = z + H(x, y) = z - \eta_{\mathsf{b}}(x, y) = 0 \qquad \text{ocean bottom,} \tag{64.2}$$

where we introduce the two common symbols used for the bottom, $\eta_{\mathsf{b}} = -H$. We generally prefer η_{b} since H is used elsewhere in this book for vertical scale. As detailed in Section 19.6.1, we typically assume that there is no fluid mass transport through the solid Earth. However, in the case of geothermal heating, we may consider an exchange of heat between the ocean and the solid Earth. Momentum exchange through the action of stresses occur between the solid Earth and ocean fluid.

64.1.3 Ocean mixed layer base

Let

$$\sigma = z - \eta^{\mathsf{mld}}(x, y, t) = 0 \tag{64.3}$$

represent the vertical position of the ocean mixed layer base. The corresponding normal vector is given by

$$\hat{\boldsymbol{n}}^{(\mathrm{mld})} = \frac{\nabla\,(z - \eta^{\mathsf{mld}})}{|\nabla\,(z - \eta^{\mathsf{mld}})|} = \frac{\nabla\,(\hat{\boldsymbol{z}} - \nabla\eta^{\mathsf{mld}})}{\sqrt{1 + |\nabla\eta^{\mathsf{mld}}|^2}}. \tag{64.4}$$

This example is relevant for the study of ocean ventilation, whereby we are interested in measuring the transport of fluid that enters the ocean interior across the mixed layer base (see Section 64.7).

64.1.4 Interior generalized vertical coordinate surfaces

Within the ocean interior, transport across surfaces of constant generalized vertical coordinate $\sigma = \sigma(x, y, z, t)$ constitutes the dia-surface transport affecting budgets of mass, tracer, and momentum within layers bounded by two generalized vertical coordinate surfaces. A canonical example is provided by isopycnal layers formed by surfaces of constant potential density (or equivalently constant buoyancy surfaces) as used in isopycnal ocean models as well as theoretical descriptions of adiabatic ocean dynamics. The vertical position of this surface is written in one of two equivalent manners

$$z = z(x, y, \sigma, t) = \eta(x, y, \sigma, t). \tag{64.5}$$

The first expression exposes the functional dependence of the vertical position of the σ surface at a horizontal position and time. In Section 63.1 we discussed the potential for confusion between writing z as a particular vertical position versus a function, thus motivating $z = \eta(x, y, \sigma, t)$. However, by now we should have sufficient experience with generalized vertical coordinates so that we can well distinguish when z refers to a particular vertical position versus $z(x, y, \sigma, t)$ as a coordinate function. For this reason we only infrequently use the nomenclature $z = \eta(x, y, \sigma, t)$ in this chapter.

64.2 Specific thickness

As mentioned in Section 63.9.1, a surface of constant generalized vertical coordinate can be successfully used to partition the vertical so long as the transformation between the generalized vertical coordinate and the geopotential coordinate is invertible. The Jacobian of transformation is given by

$$\frac{\partial z}{\partial \sigma} = z_\sigma, \tag{64.6}$$

which must be single signed for suitable generalized vertical coordinates. This constraint means that we do not allow the surfaces to overturn, which is the same assumption made about the ocean surface, $z = \eta(x, y, t)$, and solid earth bottom, $z = \eta_{\mathrm{b}}(x, y)$. This restriction places a limitation on the ability of certain GVC models (e.g., isopycnal models) to describe non-hydrostatic processes, such as the overturning common in Kelvin-Helmholtz billows and gravitational convection. Note that for both the solid earth bottom and ocean free surface

$$\frac{\partial z}{\partial \sigma} = 1 \qquad \text{ocean free surface and fluid/solid interface.} \tag{64.7}$$

Furthermore, this relation also holds, trivially, for geopotential coordinates in which $\sigma = z$.

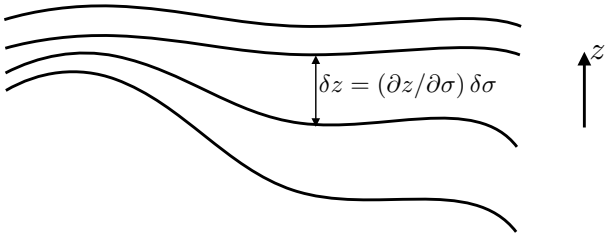

FIGURE 64.2: Illustrating the thickness between surfaces of constant generalized vertical coordinates, $\delta z = (\partial z/\partial \sigma)\, \delta \sigma$. In regions with larger magnitude for the specific thickness, $\partial z/\partial \sigma$, or equivalently smaller vertical stratification of the σ surfaces, $\partial \sigma/\partial z$, the layer thicknesses are further apart. The converse holds where $\partial z/\partial \sigma$ is small (equivalently $\partial \sigma/\partial z$ is large).

We refer to the Jacobian z_σ as the *specific thickness* and sometimes find it useful to write it as

$$\hbar = z_\sigma = \frac{\partial z}{\partial \sigma}. \tag{64.8}$$

This name is motivated by noting that the vertical thickness of an infinitesimal layer of coordinate thickness $\delta\sigma$ is given by

$$\delta z = \frac{\partial z}{\partial \sigma}\, \delta \sigma = \hbar\, \delta \sigma, \tag{64.9}$$

with Figure 64.2 providing an example with finitely thick layers. For example, if $\sigma = b(x, y, z, t)$ (buoyancy or potential density as in isopycnal models), then the thickness of a buoyancy layer is given by

$$\delta z = \frac{\partial z}{\partial \sigma}\, \delta b = N^{-2}\, \delta b, \tag{64.10}$$

with

$$N^2 = \frac{\partial b}{\partial z} \tag{64.11}$$

the squared buoyancy frequency (Section 30.6) in a Boussinesq fluid (Chapter 29). For a hydrostatic fluid using pressure as the vertical coordinate, the thickness of a pressure layer is

$$\delta z = \frac{\partial z}{\partial p}\, \delta p = -\frac{1}{\rho\, g}\, \delta p \tag{64.12}$$

where we used the hydrostatic relation (Section 27.2)

$$\frac{\partial p}{\partial z} = -\rho\, g \tag{64.13}$$

with g the constant acceleration due to effective gravity. Note that we assume the layer thickness is positive, $\delta z > 0$. For this purpose, with hydrostatic pressure we might choose to consider negative pressure increments, $\delta p < 0$, as this corresponds to vertically upward movement in a fluid column.

64.3 The dia-surface transport

In this section we develop the concept of dia-surface transport and derive its expression in terms of the material time derivative of the GVC surface.

64.3.1 Flow normal to the GVC surface

At an arbitrary point on a surface of constant generalized vertical coordinate (see Figure 64.3), the rate at which fluid moves in the direction normal to the surface is given by

$$\text{RATE OF FLUID FLOW IN DIRECTION } \hat{\boldsymbol{n}} = \boldsymbol{v} \cdot \hat{\boldsymbol{n}}, \tag{64.14}$$

where

$$\hat{\boldsymbol{n}} = \frac{\nabla \sigma}{|\nabla \sigma|}, \tag{64.15}$$

is the surface unit normal. Two examples are useful to ground this expression in common experience. For the ocean free surface, $\sigma = z - \eta(x, y, t) = 0$, the unit normal takes the form

$$\hat{\boldsymbol{n}} = \frac{\nabla\,(z - \eta)}{|\nabla\,(z - \eta)|} = \frac{\hat{\boldsymbol{z}} - \nabla \eta}{\sqrt{1 + |\nabla \eta|^2}}, \tag{64.16}$$

whereas at the solid Earth bottom, $\sigma = z - \eta_{\mathrm{b}}(x, y) = 0$,

$$\hat{\boldsymbol{n}} = -\frac{\nabla\,(z - \eta_{\mathrm{b}})}{|\nabla\,(z - \eta_{\mathrm{b}})|} = -\frac{\hat{\boldsymbol{z}} - \nabla \eta_{\mathrm{b}}}{\sqrt{1 + |\nabla \eta_{\mathrm{b}}|^2}}. \tag{64.17}$$

Introducing the material time derivative

$$\frac{\mathrm{D}\sigma}{\mathrm{D}t} = \frac{\partial \sigma}{\partial t} + \boldsymbol{v} \cdot \nabla \sigma \tag{64.18}$$

to equation (64.14) leads to the identity

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = \frac{1}{|\nabla \sigma|} \left[\frac{\mathrm{D}\sigma}{\mathrm{D}t} - \frac{\partial \sigma}{\partial t} \right]. \tag{64.19}$$

Hence, the component to the velocity of a fluid particle that is normal to a GVC surface is proportional to the difference between the material time derivative of the surface coordinate and its partial time derivative.

64.3.2 Accounting for movement of the surface

A generalized vertical coordinate surface is generally moving. So to diagnose the net transport of fluid penetrating the surface requires us to subtract the velocity of the surface, $\boldsymbol{v}^{(\sigma)}$, from the

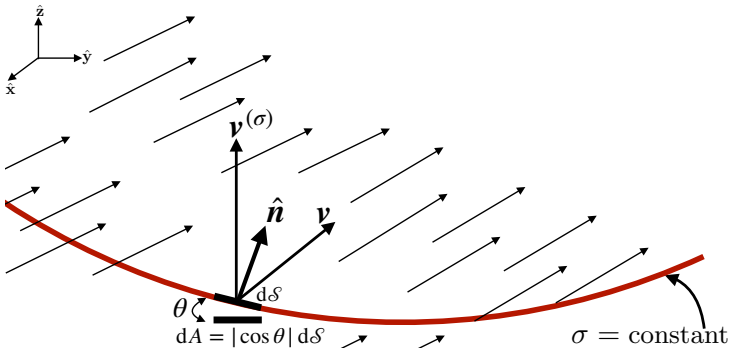

FIGURE 64.3: A surface of constant generalized vertical coordinate, $\sigma = \text{constant}$, within a fluid. The normal direction, $\hat{\boldsymbol{n}} = \nabla\sigma/|\nabla\sigma|$, points in the direction of increasing σ. We show an example velocity vector for a fluid particle, $\boldsymbol{v}$, at a point on the surface as well as the velocity, $\boldsymbol{v}^{(\sigma)}$, of a point that lives on the surface. Note that kinematics is only concerned with the normal component to the surface velocity, $\boldsymbol{v}^{(\sigma)} \cdot \hat{\boldsymbol{n}}$, as per equation (64.25). We require dynamical information to obtain information about the tangential component of $\boldsymbol{v}^{(\sigma)}$, but such information is not required for this chapter. Following equation (64.30), the horizontal projection of the surface area element is given by $\mathrm{d}A = |\cos\vartheta|\,\mathrm{d}\mathcal{S}$, where ϑ is the angle between the surface and the horizontal and $\mathrm{d}A = \mathrm{d}x\,\mathrm{d}y$.

velocity of a fluid particle. We are thus led to

$$\text{RATE THAT FLUID CROSSES A MOVING GVC SURFACE} = \hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}). \tag{64.20}$$

We next develop a kinematic property of the surface velocity, or more precisely the normal component to that velocity. For that purpose, consider an infinitesimal increment in both space and time under which σ undergoes an infinitesimal change

$$\delta\sigma = \delta\boldsymbol{x} \cdot \nabla\sigma + \delta t\, \partial_t \sigma. \tag{64.21}$$

Now restrict attention to a point fixed on a constant σ surface, in which

$$\delta\sigma = \delta\boldsymbol{x}^{(\sigma)} \cdot \nabla\sigma + \delta t\, \partial_t \sigma = 0, \tag{64.22}$$

where $\delta\boldsymbol{x}^{(\sigma)}$ is a differential increment following the moving surface. We define the velocity of that point as

$$\boldsymbol{v}^{(\sigma)} = \frac{\delta\boldsymbol{x}^{(\sigma)}}{\delta t}, \tag{64.23}$$

in which case equation (64.22) implies that at each point within the fluid,

$$\frac{\partial\sigma}{\partial t} + \boldsymbol{v}^{(\sigma)} \cdot \nabla\sigma = 0. \tag{64.24}$$

We can likewise write this equation as one for the normal component of the surface velocity

$$\boldsymbol{v}^{(\sigma)} \cdot \hat{\boldsymbol{n}} = -\frac{1}{|\nabla\sigma|}\,\frac{\partial\sigma}{\partial t}. \tag{64.25}$$

Hence, we reach the sensible result that the normal component to the velocity of the surface vanishes when the surface is static.

64.3.3 We only care about divergent surface motion

For the kinematics of fluid motion relative to a surface of constant generalized vertical coordinates, we are only concerned with the normal component to the surface velocity, $\boldsymbol{v}^{(\sigma)} \cdot \hat{\boldsymbol{n}}$. That is, we are only concerned with divergent motion of the surface, defined as motion parallel to the surface normal direction, $\hat{\boldsymbol{n}}$. We have no concern for rotational or tangential motion, which is motion perpendicular to $\hat{\boldsymbol{n}}$. Even so, some authors, by fiat, choose to set to zero the tangential component of the surface motion. In fact, specification of the tangential surface velocity component is generally not available without extra information about the surface motion, nor is its specification necessary for developing kinematic properties of fluid motion relative to arbitrary generalized vertical coordinate surfaces. Hence, we make no statement about tangential motion of the surface.

64.3.4 Cross GVC transport in terms of GVC material evolution

Using expression (64.25) in equation (64.20) leads to the net flux of fluid crossing the GVC surface

$$\hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}) = \frac{1}{|\nabla\sigma|} \frac{\mathrm{D}\sigma}{\mathrm{D}t}. \tag{64.26}$$

The material time derivative of the GVC surface thus vanishes if no fluid crosses the surface. Notably, this result holds for motion of the fluid as defined by the barycentric velocity, $\boldsymbol{v}$, of Section 20.1.2. For multi-component fluids, $\dot{\sigma} = 0$ can still, in principle, be associed with trace matter exchange across the surface via diffusion so long as the net matter crossing the surface is zero. But this situation is rather fine tuned and thus unlikely. Additionally, matter diffusion also occurs with heat diffusion, in which case $\dot{\sigma} = 0$ only occurs in the absence of both matter and heat diffusion, which then means that σ is a material surface.

64.3.5 Defining the dia-surface transport

The area normalizing the volume flux in equation (64.26) is the area $\mathrm{d}\mathcal{S}$ of an infinitesimal patch on the surface of constant generalized vertical coordinate with outward unit normal $\hat{\boldsymbol{n}}$. We now follow the trigonometry discussed in Section 63.17 to introduce the horizontal projection of this area, $\mathrm{d}A$, which is more convenient to work with for many purposes. So long as the vertical stratification remains non-zero ($\partial\sigma/\partial z \neq 0$) we can write the area factor in the form

$$\begin{aligned}
\frac{\mathrm{d}\mathcal{S}}{|\nabla\sigma|} &= \frac{\mathrm{d}\mathcal{S}}{\sqrt{(\partial\sigma/\partial x)^2 + (\partial\sigma/\partial y)^2 + (\partial\sigma/\partial z)^2}} && \text{(64.27a)} \\
&= \frac{\mathrm{d}\mathcal{S}}{|\partial\sigma/\partial z| \sqrt{[(\partial\sigma/\partial x)/(\partial\sigma/\partial z)]^2 + [(\partial\sigma/\partial y)/(\partial\sigma/\partial z)]^2 + 1}} && \text{(64.27b)} \\
&= \frac{\mathrm{d}\mathcal{S}}{|\partial\sigma/\partial z| \sqrt{1 + \tan^2\vartheta}} && \text{(64.27c)} \\
&= \left|\frac{\partial z}{\partial\sigma}\right| |\cos\vartheta| \, \mathrm{d}\mathcal{S} && \text{(64.27d)} \\
&= \left|\frac{\partial z}{\partial\sigma}\right| \mathrm{d}A. && \text{(64.27e)}
\end{aligned}$$

The equality (64.27c) introduced the angle, ϑ, between the boundary surface and the horizontal plane. The squared slope of this surface given by (see Section 63.12)

$$\tan^2\vartheta = \frac{\nabla_{\!\mathrm{h}}\sigma \cdot \nabla_{\!\mathrm{h}}\sigma}{(\partial\sigma/\partial z)^2} = \nabla_{\!\mathrm{h}\sigma} z \cdot \nabla_{\!\mathrm{h}\sigma} z. \tag{64.28}$$

The equality (64.27d) made use of a trigonometric identity so that

$$|\cos\vartheta|^{-1} = |z_\sigma \, \nabla\sigma|. \tag{64.29}$$

Furthermore, the equality (64.27e) introduced the horizontal projection of the area,

$$\mathrm{d}A = |\cos\vartheta| \, \mathrm{d}\mathcal{S}. \tag{64.30}$$

We now introduce the *dia-surface velocity component* for the GVC coordinate

$$w^{(\dot\sigma)} = \frac{\partial z}{\partial \sigma} \frac{\mathrm{D}\sigma}{\mathrm{D}t} = z_\sigma \, \dot\sigma, \tag{64.31}$$

which measures the volume of fluid passing through the surface, per unit horizontal area, per unit time

$$w^{(\dot\sigma)} \equiv \hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}) \, \frac{\mathrm{d}\mathcal{S}}{\mathrm{d}A} \tag{64.32}$$

$$= \frac{\text{(VOLUME/TIME) FLUID THROUGH SURFACE}}{\text{HORIZONTAL AREA OF SURFACE}}, \tag{64.33}$$

so that

$$w^{(\dot\sigma)} \, \mathrm{d}A \equiv \hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}) \, \mathrm{d}\mathcal{S}. \tag{64.34}$$

The velocity component $w^{(\dot\sigma)}$ is referred to as the dia-surface velocity component since it measures flow rate of fluid through the surface. We can think of $w^{(\dot\sigma)}$ as the "vertical" velocity which, when multiplied by the horizontal area element, measures the transport of fluid that crosses the surface in the normal direction.

64.3.6 Expressions for the dia-surface velocity component

Making use of various identities derived above, as well as the transformation of partial derivative operators in Section 63.12, allows us to write the dia-surface velocity component in the following equivalent forms

$$w^{(\dot\sigma)} = \frac{\partial z}{\partial \sigma} \frac{\mathrm{D}\sigma}{\mathrm{D}t} \tag{64.35a}$$

$$= \frac{\partial z}{\partial \sigma} |\nabla\sigma| \, \hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}) \tag{64.35b}$$

$$= \frac{\partial z}{\partial \sigma} \nabla\sigma \cdot \boldsymbol{v} - \frac{\partial z}{\partial \sigma} |\nabla\sigma| \, \hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}) \tag{64.35c}$$

$$= (\hat{\boldsymbol{z}} - \nabla_{\!\mathrm{h}\sigma} z) \cdot \boldsymbol{v} + \frac{\partial z}{\partial \sigma} \frac{\partial \sigma}{\partial t} \tag{64.35d}$$

$$= (\hat{\boldsymbol{z}} - \nabla_{\!\mathrm{h}\sigma} z) \cdot \boldsymbol{v} - \frac{\partial z}{\partial t} \tag{64.35e}$$

$$= w - (\partial_t + \boldsymbol{u} \cdot \nabla_{\!\mathrm{h}\sigma}) z, \tag{64.35f}$$

where $\partial z/\partial t = (\partial z/\partial t)_\sigma$ is the time derivative for the depth of the σ surface. We also made use of the identity (see equations (63.34b) and (63.34c))

$$\nabla_{\!\mathrm{h}\sigma} z = -z_\sigma \, \nabla_{\!\mathrm{h}}\sigma \tag{64.36}$$

to express the slope of the σ surface as projected onto the horizontal direction plane, as well as the corresponding identity (63.34a) for the time derivative

$$\left[\frac{\partial z}{\partial t}\right]_{\sigma} = -\frac{[\partial\sigma/\partial t]_z}{[\partial\sigma/\partial z]}. \tag{64.37}$$

The form given by equation (64.35f) directly relates the vertical component to the fluid particle velocity to the dia-surface velocity component

$$w = \frac{\mathrm{D}z}{\mathrm{D}t} \longleftrightarrow w^{(\dot\sigma)} = \frac{\partial z}{\partial\sigma}\frac{\mathrm{D}\sigma}{\mathrm{D}t} = w - (\partial_t + \boldsymbol{u}\cdot\nabla_{h\sigma})z. \tag{64.38}$$

When the GVC surface is static, so that it occupies a constant vertical position $\partial z/\partial t = 0$, then the dia-surface velocity component reduces to

$$w^{(\dot\sigma)} = w - \boldsymbol{u}\cdot\nabla_{h\sigma} z \qquad \text{static surface,} \tag{64.39}$$

whereas if the GVC surface is flat, then the dia-surface velocity component measures the flux of fluid moving vertically relative to the motion of the GVC surface. Finally, if the surface is flat and static, the dia-surface velocity component becomes the vertical velocity component

$$w^{(\dot\sigma)} = w = \frac{\mathrm{D}z}{\mathrm{D}t} \qquad \text{GVC surface static and flat,} \tag{64.40}$$

which is the case for the geopotential vertical coordinate. This relation reveals the kinematic distinction between w and $w^{(\dot\sigma)}$, with the two differing in the presence of GVC transients and horizontal velocities that project onto a non-horizontal GVC surface. Equation (64.35f) thus offers a useful means to distinguish w from $w^{(\dot\sigma)}$.

64.3.7 An alternative definition of dia-surface velocity component

In some literature presentations, the dia-surface velocity component is taken to be

$$w^{\text{dia}} = \hat{\boldsymbol{n}}\cdot(\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}) = \frac{1}{|\nabla\sigma|}\frac{\mathrm{D}\sigma}{\mathrm{D}t}. \tag{64.41}$$

For example, *Groeskamp et al.* (2019) prefer this definition for watermass analysis. As seen in Chapter 73, the reason to prefer expression (64.41) for watermass analysis is that we do not wish to assume vertically stable stratification for surfaces of constant σ. Dropping that assumption allows us to consider transformation between arbitrarily oriented elements of seawater, even those that are gravitationally unstable.

64.3.8 Area integrated dia-surface transport for non-divergent flows

We close this section by further emphasizing the distinction in time dependent flows between dia-surface transport and flow normal to a surface. For this purpose consider a non-divergent flow whereby $\nabla\cdot\boldsymbol{v} = 0$. Non-divergence means that for any closed surface within the fluid interior, the following identity holds via the divergence theorem

$$0 = \int_{\mathscr{R}} \nabla\cdot\boldsymbol{v}\,\mathrm{d}V = \oint_{\partial\mathscr{R}} \hat{\boldsymbol{n}}\cdot\boldsymbol{v}\,\mathrm{d}\mathcal{S}. \tag{64.42}$$

Notably, only in the case of a static surface do we conclude there is no net flow across the surface (see Exercise 21.6). For surfaces that move, there is generally a nonzero net dia-surface transport. We clarify this rather puzzling statement in the following.

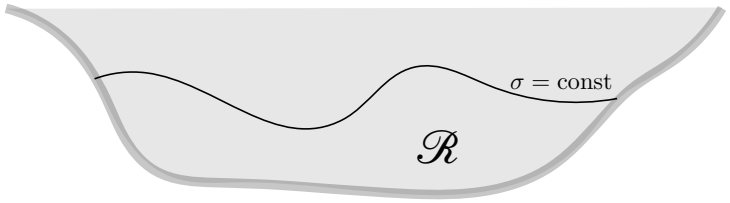

FIGURE 64.4: A constant GVC surface, $\sigma =$ constant, within an ocean basin that intersects the bottom. The region $\mathscr{R}$ is bounded above by the σ surface and below by the solid-earth. Along the constant σ surface a non-divergent flow satisfies $\int_{\sigma=\text{const}} \hat{\boldsymbol{n}} \cdot \boldsymbol{v} \, \mathrm{d}\mathcal{S} = 0$.

As a specific example, consider a fluid region such as shown in Figure 64.4, which is bounded by the solid-earth bottom and a constant GVC surface. Since the solid-earth bottom is static and there is no-normal flow through the bottom, the identity (64.42) means that the area integrated flow normal to the GVC vanishes

$$\int_{\sigma=\text{const}} \hat{\boldsymbol{n}} \cdot \boldsymbol{v} \, \mathrm{d}\mathcal{S} = 0. \tag{64.43}$$

But what does this identity imply about the area integrated dia-surface velocity? For the case of a geopotential vertical coordinate, $\sigma = z$, it means that the area integrated vertical velocity vanishes across any geopotential surface below the ocean free surface, $\int_{z=\text{const}} w \, \mathrm{d}A = 0$ (see Exercise 21.6). What about other GVCs?

To address this question consider the general result

$$\int_{\sigma=\text{const}} \hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}) \, \mathrm{d}\mathcal{S} = \int_{\sigma=\text{const}} w^{\text{dia}} \, \mathrm{d}\mathcal{S} = \int_{\sigma=\text{const}} w^{(\dot\sigma)} \, \mathrm{d}A, \tag{64.44}$$

where again $\mathrm{d}A = \mathrm{d}x \, \mathrm{d}y$. Now make use of the property (64.43) for non-divergent flows as well as the identity (64.25) to render

$$\begin{aligned}
\int_{\sigma=\text{const}} w^{(\dot\sigma)} \, \mathrm{d}A &= 0 - \int_{\sigma=\text{const}} \hat{\boldsymbol{n}} \cdot \boldsymbol{v}^{(\sigma)} \, \mathrm{d}\mathcal{S} && \text{(64.45a)} \\
&= \int_{\sigma=\text{const}} \frac{\partial\sigma/\partial t}{|\nabla\sigma|} \, \mathrm{d}\mathcal{S} && \text{(64.45b)} \\
&= \int_{\sigma=\text{const}} \frac{\partial\sigma}{\partial t} \left| \frac{\partial z}{\partial\sigma} \right| \mathrm{d}A && \text{(64.45c)} \\
&= -\int_{\sigma=\text{const}} \left[\frac{\partial z}{\partial t} \right]_\sigma \mathrm{d}A. && \text{(64.45d)}
\end{aligned}$$

The final equality holds if $\partial z/\partial\sigma > 0$, whereas we swap signs when the vertical stratification is $\partial z/\partial\sigma < 0$. We can go one further step by noting that the time derivative is computed with σ constant, as is the horizontal area integral. Hence, we can pull the time derivative outside the integral to render

$$\int_{\sigma=\text{const}} w^{(\dot\sigma)} \, \mathrm{d}A = -\left[\frac{\partial}{\partial t} \right]_\sigma \int_{\sigma=\text{const}} z \, \mathrm{d}A. \tag{64.46}$$

This identity means that for a non-divergent flow, the integrated dia-surface transport across the GVC surface equals to minus the time tendency for the area integrated vertical position of that surface. Hence, there is an area integrated dia-surface transport across the GVC surface so long as there is a volume change for the region beneath the surface.

For the case of an isopycnal surface in an adiabatic fluid, there is no change in the volume beneath any interior isopycnal since no flow crosses the isopycnal, in which case we recover the

expected result $\int_{\sigma=\text{const}} w^{(\dot{\sigma})}\,\mathrm{d}A = 0$. However, this result does not hold for other coordinates, such as the rescaled vertical coordinate, $\sigma = z^*$ defined by equation (64.112). In this case

$$z^* = H\,\frac{z-\eta}{H+\eta} \tag{64.47a}$$

$$\frac{\partial z}{\partial z^*} = 1 + H/\eta > 0 \tag{64.47b}$$

$$\left[\frac{\partial z}{\partial t}\right]_{z^*} = \frac{\partial \eta}{\partial t}\,(1 + z^*/H), \tag{64.47c}$$

so that

$$\int_{z^*=\text{const}} w^{(\dot{z^*})}\,\mathrm{d}A = \int_{z^*=\text{const}} (\partial\eta/\partial t)\,(1 + z^*/H)\,\mathrm{d}A, \tag{64.48}$$

which is generally nonzero. For example, consider a flat bottom so that

$$\int_{z^*=\text{const}} w^{(\dot{z^*})}\,\mathrm{d}A = (1 + z^*/H)\int_{z^*=\text{const}} (\partial\eta/\partial t)\,\mathrm{d}A = (1 + z^*/H)\int_{z^*=\text{const}} (Q_\text{m}/\rho_\text{o})\,\mathrm{d}A, \tag{64.49}$$

where Q_m is the surface mass flux and we made use of the free surface equation (21.81) holding for a non-divergent flow. In this case the area integrated dia-surface transport across a z^* surface is proportional to the area integrated surface mass flux.

64.4 Material time derivative

The expression (64.31) for $w^{(\dot{\sigma})}$ brings the material time derivative operator into the following equivalent forms

$$\frac{\mathrm{D}}{\mathrm{D}t} = \left[\frac{\partial}{\partial t}\right]_z + \boldsymbol{u}\cdot\nabla_\text{h} + w\,\frac{\partial}{\partial z} \tag{64.50a}$$

$$= \left[\frac{\partial}{\partial t}\right]_\sigma + \boldsymbol{u}\cdot\nabla_{\text{h}\sigma} + \frac{\mathrm{D}\sigma}{\mathrm{D}t}\,\frac{\partial}{\partial \sigma} \tag{64.50b}$$

$$= \left[\frac{\partial}{\partial t}\right]_\sigma + \boldsymbol{u}\cdot\nabla_{\text{h}\sigma} + w^{(\dot{\sigma})}\,\frac{\partial}{\partial z}. \tag{64.50c}$$

Note that the chain-rule means that

$$\frac{\partial}{\partial \sigma} = \frac{\partial z}{\partial \sigma}\,\frac{\partial}{\partial z}, \tag{64.51}$$

thus providing a relationship between the two vertical coordinate partial derivatives. Furthermore, recall that subscripts in the above derivative operators denote variables held fixed when taking the partial derivatives.

We highlight the special case of no fluid particles crossing the generalized coordinate surface. This sitution occurs in the case of adiabatic flows with σ equal to the buoyancy or isopycnal coordinate. For adiabatic flow, the material time derivative in equation (64.50c) only has a horizontal two-dimensional advective component, $\boldsymbol{u}\cdot\nabla_{\text{h}\sigma}$. This result should not be interpreted to mean that the fluid particle velocity in an adiabatic flow is strictly horizontal. Indeed, it generally is not, as the form given by equation (64.50a) makes clear. Rather, it means that the advective transport of fluid properties occurs along surfaces of constant buoyancy, and such transport is measured by the convergence of horizontal advective fluxes as measured along these constant buoyancy surfaces.

64.5 Vertical velocity and dia-surface velocity

Making use of the material time derivative operator (64.50c) affords us an opportunity to emphasize both the differences and similarities between the vertical velocity component and the dia-surface velocity component. Namely, the vertical velocity component takes on the equivalent forms

$$w = \frac{\mathrm{D}z}{\mathrm{D}t} = \left[\frac{\partial z}{\partial t}\right]_\sigma + \boldsymbol{u} \cdot \nabla_{\!\!\mathrm{h}\sigma} z + w^{(\dot\sigma)} = \frac{\partial z}{\partial \sigma}\left[-\frac{\partial \sigma}{\partial t} - \boldsymbol{u} \cdot \nabla_{\!\!\mathrm{h}} \sigma + \frac{\mathrm{D}\sigma}{\mathrm{D}t}\right], \tag{64.52}$$

and the corresponding expressions for the dia-surface velocity component are given by

$$w^{(\dot\sigma)} = \frac{\partial z}{\partial \sigma}\frac{\mathrm{D}\sigma}{\mathrm{D}t} = \frac{\partial z}{\partial \sigma}\left[\frac{\partial \sigma}{\partial t} + \boldsymbol{u} \cdot \nabla_{\!\!\mathrm{h}} \sigma + w \frac{\partial \sigma}{\partial z}\right] = -\left[\frac{\partial z}{\partial t}\right]_\sigma - \boldsymbol{u} \cdot \nabla_{\!\!\mathrm{h}\sigma} z + w. \tag{64.53}$$

Whereas the vertical velocity component, w, measures the transport crossing z surfaces, which are static and horizontal, the dia-surface velocity component, $w^{(\dot\sigma)}$, measures the transport crossing σ surfaces, which are generally moving and sloped. It is notable that the area normalization used in equation (64.33) for the dia-surface velocity component means that it appears only in the expression for the vertical velocity. However, as we will see in the following, the appearance of $w^{(\dot\sigma)}$ in the w equation does not necessarily mean that $w^{(\dot\sigma)}$ corresponds to vertical particle motion. Instead, when it arises from mixing, $w^{(\dot\sigma)}$ can lead to vertical motion of the σ surface while maintaining a fixed position for the fluid particle.

64.5.1 Decomposing the vertical velocity

The expression

$$w = \left[\frac{\partial z}{\partial t}\right]_\sigma + \boldsymbol{u} \cdot \nabla_{\!\!\mathrm{h}\sigma} z + w^{(\dot\sigma)} \tag{64.54}$$

decomposes the vertical velocity of a fluid particle into (i) changes to the vertical position of the σ-surface at a particular horizontal point, (ii) lateral particle motion projected onto a sloped σ-surface, (iii) motion that crosses a σ-surface. Importantly, the three terms are coupled. For example, consider the case of σ defined by isopycnals, in which case irreversible mixing ($w^{(\dot\sigma)} \neq 0$) changes the configuration of σ surfaces by changing both their height, $(\partial z/\partial t)_\sigma$, and slope $\nabla_{\!\!\mathrm{h}\sigma} z$.

64.5.2 Another form of the vertical velocity decomposition

Consider the velocity for a point on the surface, $\boldsymbol{v}^{(\sigma)}$, which satisfies (Section 64.3.2)

$$\frac{\partial \sigma}{\partial t} + \boldsymbol{v}^{(\sigma)} \cdot \nabla \sigma = 0. \tag{64.55}$$

Making use of the triple product identities from Section 63.5

$$\frac{\partial z}{\partial \sigma}\nabla\sigma = -\nabla_{\!\!\mathrm{h}\sigma} z + \hat{\boldsymbol{z}} \qquad \text{and} \qquad \frac{\partial z}{\partial \sigma}\left[\frac{\partial \sigma}{\partial t}\right]_z = -\left[\frac{\partial z}{\partial t}\right]_\sigma \tag{64.56}$$

brings equation (64.55) into the form

$$\left[\frac{\partial z}{\partial t}\right]_\sigma = (\hat{\boldsymbol{z}} - \nabla_{\!\!\mathrm{h}\sigma} z) \cdot \boldsymbol{v}^{(\sigma)} \Longrightarrow \hat{\boldsymbol{z}} \cdot \boldsymbol{v}^{(\sigma)} = \left[\frac{\partial z}{\partial t}\right]_\sigma + \boldsymbol{u}^{(\sigma)} \cdot \nabla_{\!\!\mathrm{h}\sigma} z, \tag{64.57}$$

where $\boldsymbol{u}^{(\sigma)}$ is the horizontal component to the surface velocity $\boldsymbol{v}^{(\sigma)}$. This equation shows that the vertical component to the σ-surface velocity is given by the sum of the changes to the vertical position of the surface plus the projection of the horizontal motion of the surface onto the slope

of the surface. Additionally, even if the σ-surface has no component of velocity in the vertical, the depth of the σ-surface measured at a horizontal point generally changes if the surface is sloped and moves horizontally pass that point

$$\left[\frac{\partial z}{\partial t}\right]_\sigma = -\boldsymbol{u}^{(\sigma)} \cdot \nabla_{\!\!\text{h}\sigma} z \qquad \text{if } \hat{\boldsymbol{z}} \cdot \boldsymbol{v}^{(\sigma)} = 0. \tag{64.58}$$

Returning to the general result (64.57) allows us to write

$$\left[\frac{\partial z}{\partial t}\right]_\sigma + \boldsymbol{u} \cdot \nabla_{\!\!\text{h}\sigma} z = \hat{\boldsymbol{z}} \cdot \boldsymbol{v}^{(\sigma)} + (\boldsymbol{u} - \boldsymbol{u}^{(\sigma)}) \cdot \nabla_{\!\!\text{h}\sigma} z. \tag{64.59}$$

Furthermore, return to the fundamental definition of the dia-surface velocity component detailed in Section 64.3, in which we showed that

$$w^{(\dot\sigma)} = \frac{\partial z}{\partial \sigma} \frac{\mathrm{D}\sigma}{\mathrm{D}t} = \frac{\partial z}{\partial \sigma} \nabla\sigma \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}) = (-\nabla_{\!\!\text{h}\sigma} z + \hat{\boldsymbol{z}}) \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)}). \tag{64.60}$$

This expression, along with equation (64.59), leads to the rather elaborate decomposition of the vertical velocity component according to motion of a generalized vertical coordinate surface

$$w = \underbrace{\left[\hat{\boldsymbol{z}} \cdot \boldsymbol{v}^{(\sigma)} + (\boldsymbol{u} - \boldsymbol{u}^{(\sigma)}) \cdot \nabla_{\!\!\text{h}\sigma} z\right]}_{(\partial_t + \boldsymbol{u} \cdot \nabla_{\!\!\text{h}\sigma}) z} + \underbrace{\left[\hat{\boldsymbol{z}} \cdot \boldsymbol{v} - \hat{\boldsymbol{z}} \cdot \boldsymbol{v}^{(\sigma)} - (\boldsymbol{u} - \boldsymbol{u}^{(\sigma)}) \cdot \nabla_{\!\!\text{h}\sigma} z\right]}_{w^{(\dot\sigma)}}. \tag{64.61}$$

Terms in the first bracket compute vertical particle motion relative to the σ-surface. The dia-surface contribution from the second bracket removes the contribution from σ-surface motion to leave just the vertical motion of the particle. All terms on the right hand side cancel, except for $\hat{\boldsymbol{z}} \cdot \boldsymbol{v} = w$, thus trivially revealing $w = w$. The decomposition of w is rather pedantic when viewed in the unpacked form of equation (64.61). Even so, let us consider some special cases to offer further interpretation.

- NO HORIZONTAL CONTRIBUTION: Consider the case where the horizontal velocity of a fluid particle matches that of the σ-surface: $\boldsymbol{u} = \boldsymbol{u}^{(\sigma)}$. Alternatively, consider the case with flat σ-surfaces so that $\nabla_{\!\!\text{h}\sigma} z = 0$. In either case the vertical velocity is given by

$$w = \underbrace{\left[\hat{\boldsymbol{z}} \cdot \boldsymbol{v}^{(\sigma)}\right]}_{(\partial_t + \boldsymbol{u} \cdot \nabla_{\!\!\text{h}\sigma}) z} + \underbrace{\left[\hat{\boldsymbol{z}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\sigma)})\right]}_{w^{(\dot\sigma)}}. \tag{64.62}$$

  The first contribution is from vertical motion of the σ-surface. The second contribution adjusts for the vertical motion of the particle relative to the σ-surface, leaving behind just the vertical motion of the particle. This rather trivial case exemplifies the contributions from the two pieces of the vertical velocity.

- ZERO VERTICAL PARTICLE MOTION: Consider the case where $w = 0$ so that

$$\begin{aligned} w &= 0 && \text{(64.63a)} \\ &= \left[\frac{\partial z}{\partial t}\right]_\sigma + \boldsymbol{u} \cdot \nabla_{\!\!\text{h}\sigma} z + w^{(\dot\sigma)} && \text{(64.63b)} \\ &= \underbrace{\left[\hat{\boldsymbol{z}} \cdot \boldsymbol{v}^{(\sigma)} + (\boldsymbol{u} - \boldsymbol{u}^{(\sigma)}) \cdot \nabla_{\!\!\text{h}\sigma} z\right]}_{(\partial_t + \boldsymbol{u} \cdot \nabla_{\!\!\text{h}\sigma}) z} + \underbrace{\left[-\hat{\boldsymbol{z}} \cdot \boldsymbol{v}^{(\sigma)} - (\boldsymbol{u} - \boldsymbol{u}^{(\sigma)}) \cdot \nabla_{\!\!\text{h}\sigma} z\right]}_{w^{(\dot\sigma)}}. && \text{(64.63c)} \end{aligned}$$

  The final expression is trivial since each term in one bracket identically cancels terms in

the other bracket. The penultimate expression reveals the balance between dia-surface transport and motion relative to the σ surface

$$-w^{(\dot\sigma)} = \left[\frac{\partial z}{\partial t}\right]_\sigma + \boldsymbol{u}\cdot\nabla_\sigma z \qquad \text{if } \; w = 0. \tag{64.64}$$

A particularly simple realization of this balance holds for σ given by isopycnals and where the isosurfaces are horizontal. In the presence of uniform mixing, the flat isopycnals stay flat and there is correspondingly no vertical motion of fluid particles even as the vertical stratification is modified. In contrast, the vertical position of an isopycnal surface changes according to the dia-surface velocity component $(\partial z/\partial t)_\sigma = -w^{(\dot\sigma)} \neq 0$. This case illustrates that $w^{(\dot\sigma)} \neq 0$ can still occur even when there is zero fluid particle motion since $w^{(\dot\sigma)} \neq 0$ can arise from motion of a σ-surface alone.

64.6 The velocity vector and fluid particle trajectories

Recall from Section 64.5 the alternative forms for the vertical velocity component given by equation (64.52). We focus on the form

$$w = \left[\frac{\partial z}{\partial t}\right]_\sigma + \boldsymbol{u}\cdot\nabla_\sigma z + w^{(\dot\sigma)} \tag{64.65}$$

so that the velocity vector is written[1]

$$\boldsymbol{v} = u\,\hat{\boldsymbol{x}} + v\,\hat{\boldsymbol{y}} + w\,\hat{\boldsymbol{z}} \tag{64.66a}$$

$$= u\,\hat{\boldsymbol{x}} + v\,\hat{\boldsymbol{y}} + \left[(\partial z/\partial t)_\sigma + \boldsymbol{u}\cdot\nabla_\sigma z + w^{(\dot\sigma)}\right]\hat{\boldsymbol{z}} \tag{64.66b}$$

$$= u\,[\hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,(\partial z/\partial x)_\sigma] + v\,[\hat{\boldsymbol{y}} + \hat{\boldsymbol{z}}\,(\partial z/\partial y)_\sigma] + \left[(\partial z/\partial t)_\sigma + w^{(\dot\sigma)}\right]\hat{\boldsymbol{z}}. \tag{64.66c}$$

To help further understand these velocity expressions we consider the following three cases, each of which are illustrated in Figure 64.5.

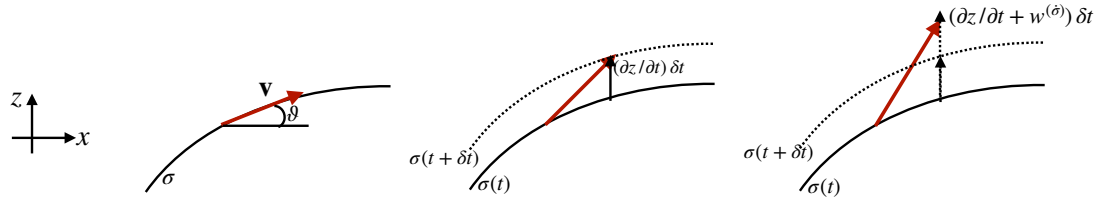

FIGURE 64.5: This schematic shows the various contributions to the fluid particle velocity (red vector) when written relative to motion of a particular generalized vertical coordinate surface. The fluid particle sits at the tail of the velocity vector at time t and at the head at time $t+\delta t$. The left panel is for the case of a static and material σ-surface so that the particle remains on the σ-surface and has a velocity vector given by equation (64.68). The slope of the σ-surface in the $\hat{\boldsymbol{x}}$-direction is given by $\tan\vartheta = (\partial z/\partial x)_\sigma$. The middle panel is for a non-steady material σ-surface whereby the velocity of a particle takes on the form (64.69), with the particle remaining on the moving σ-surface. The right panel shows the case of a non-steady and non-material σ-surface with velocity (64.70). In this final case the particle position departs from the original σ-surface due to the nonzero dia-surface velocity component, $w^{(\dot\sigma)} \neq 0$. However, it is not known *a priori* whether this departure is due to particle motion or motion of the surface. Notably, the horizontal position of the particle remains identical for each of the three cases. It is only the vertical position that is modified according to the slope of the σ-surface (left panel), motion of the σ-surface (middle panel), and motion crossing the σ-surface (right panel).

[1] As discussed in Section 63.7, we can connect these expressions to the contravariant representation of the velocity vector using GVCs.

- STEADY AND MATERIAL σ-SURFACE: The velocity vector is aligned with the instantaneous σ-surface ($\boldsymbol{v} \cdot \nabla\sigma = 0$) when the σ-surface is steady ($\partial\sigma/\partial t = 0$) and material ($\mathrm{D}\sigma/\mathrm{D}t = 0$). Hence, we can diagnose the vertical velocity component in terms of the horizontal via

$$w\,\partial\sigma/\partial z = -\boldsymbol{u} \cdot \nabla_{\mathsf{h}}\sigma \Longrightarrow w = \boldsymbol{u} \cdot \nabla_{\mathsf{h}\sigma} z, \tag{64.67}$$

  where we used the triple product identities (63.34b) and (63.34c) for the final equality. The velocity vector thus takes on the form

$$\boldsymbol{v} = u\,[\hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,(\partial z/\partial x)_\sigma] + v\,[\hat{\boldsymbol{y}} + \hat{\boldsymbol{z}}\,(\partial z/\partial y)_\sigma] \qquad \partial\sigma/\partial t = 0 \text{ and } \mathrm{D}\sigma/\mathrm{D}t = 0. \tag{64.68}$$

  In this case, the velocity vector is determined only by the horizontal velocity plus the slope of the σ surface.

- NON-STEADY AND MATERIAL σ-SURFACE: Next consider material σ surfaces ($\mathrm{D}\sigma/\mathrm{D}t = 0$) that move ($\partial_t\sigma \neq 0$), in which case the velocity vector is

$$\boldsymbol{v} = u\,[\hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,(\partial z/\partial x)_\sigma] + v\,[\hat{\boldsymbol{y}} + \hat{\boldsymbol{z}}\,(\partial z/\partial y)_\sigma] + (\partial z/\partial t)_\sigma\,\hat{\boldsymbol{z}} \qquad \mathrm{D}\sigma/\mathrm{D}t = 0. \tag{64.69}$$

  To remain on the moving surface, the fluid particle must move vertically by the extra amount $(\partial z/\partial t)_\sigma\,\delta t\,\hat{\boldsymbol{z}}$ relative to the case of a static σ-surface.

- NON-STEADY AND NON-MATERIAL σ-SURFACE: The general case with a non-material and non-steady σ also requires the dia-surface velocity component, $w^{(\dot\sigma)}$, which is diagnosed based on the material time derivative of σ and the inverse stratification, $w^{(\dot\sigma)} = (\partial z/\partial\sigma)\,\mathrm{D}\sigma/\mathrm{D}t$:

$$\boldsymbol{v} = u\,[\hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,(\partial z/\partial x)_\sigma] + v\,[\hat{\boldsymbol{y}} + \hat{\boldsymbol{z}}\,(\partial z/\partial y)_\sigma] + \left[(\partial z/\partial t)_\sigma + w^{(\dot\sigma)}\right]\hat{\boldsymbol{z}}. \tag{64.70}$$

  The contribution $w^{(\dot\sigma)}$ measures the vertical motion of the particle relative to the moving σ-surface. Hence, the sum, $(\partial z/\partial t)_\sigma + w^{(\dot\sigma)}$, measures the vertical motion of the particle relative to a fixed origin. As emphasized in Section 64.5, a non-zero $w^{(\dot\sigma)}$ arises from motion of the fluid particle relative to the σ-surface, and this relative motion does not necessarily mean that the particle moves; e.g., recall the example discussed in Section 64.5.2 with a static particle and moving σ-surface.

64.7 Subduction across the mixed layer base

Consider the generalized vertical coordinate defined according to the mixed layer base as in equation (64.3). The dia-surface mass transport across this surface leads us to define the subduction

$$-\mathcal{S}^{(\text{subduction})} \equiv \rho\,\mathrm{d}A\left[\frac{\mathrm{D}(z - \eta^{\mathsf{mld}})}{\mathrm{D}t}\right] \qquad \text{at } z = \eta^{\mathsf{mld}}(x, y, t), \tag{64.71}$$

where the mass transport $\mathcal{S}^{(\text{subduction})}$ (dimensions of mass per time) is positive for fluid moving downward beneath the mixed layer base into the pycnocline (subduction) and negative for water moving into the mixed layer (obduction). The area element $\mathrm{d}A$ is the horizontal projection of the area on the mixed layer base. Expanding the material time derivative leads to

$$-\left[\frac{\mathcal{S}^{(\text{subduction})}}{\rho\,\mathrm{d}A}\right] = w - [\partial_t + \boldsymbol{u} \cdot \nabla]\,\eta^{\mathsf{mld}} \qquad \text{at } z = \eta^{\mathsf{mld}}(x, y, t), \tag{64.72}$$

where again we define

$$\mathcal{S}^{(\text{subduction})} > 0 \qquad \text{subduction} \tag{64.73}$$

$$\mathcal{S}^{(\text{subduction})} < 0 \qquad \text{obduction.} \tag{64.74}$$

We illustrate this definition in Figure 64.6, and note that this definition is consistent with that introduced by *Cushman-Roisin* (1987).

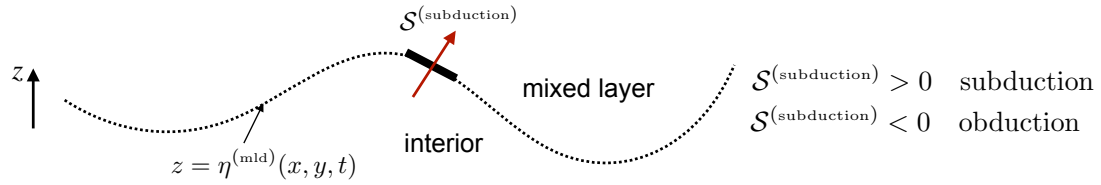

FIGURE 64.6: Illustrating the subduction rate as defined by equation (64.72), which measures the mass transport acrros the base of the ocean mixed layer. When water enters the ocean interior, $\mathcal{S}^{(\text{subduction})} > 0$, and we say that water subducts from the mixed layer to the ocean interior. Conversely, when water enters the mixed layer from below, $\mathcal{S}^{(\text{subduction})} < 0$ and we say that water is obducted from the interior to the mixed layer.

64.8 Mass continuity

We here derive the Eulerian expression for mass continuity (19.6) using generalized vertical coordinates. We then specialize to non-divergent flows, in which mass conservation is converted to volume conservation. To start, recall that mass conservation for a fluid element states that

$$\rho \, \delta V = \rho \, \delta x \, \delta y \, \delta z = \rho \, \delta x \, \delta y \, z_\sigma \, \delta\sigma \tag{64.75}$$

is constant following a fluid element.[2] To develop the Eulerian expressions we first consider the case of Cartesian coordinates.

64.8.1 Cartesian coordinates

Consider the expression

$$\frac{1}{\rho \, \delta V} \frac{\mathrm{D}(\rho \, \delta V)}{\mathrm{D}t} = \frac{1}{\rho} \frac{\mathrm{D}\rho}{\mathrm{D}t} + \frac{1}{\delta V} \frac{\mathrm{D}(\delta V)}{\mathrm{D}t}. \tag{64.76}$$

Now make use of Cartesian coordinates to write the volume

$$\frac{1}{\delta V} \frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = \frac{1}{\delta x \, \delta y \, \delta z} \frac{\mathrm{D}(\delta x \, \delta y \, \delta z)}{\mathrm{D}t} \tag{64.77a}$$

$$= \frac{1}{\delta x} \frac{\mathrm{D}(\delta x)}{\mathrm{D}t} + \frac{1}{\delta y} \frac{\mathrm{D}(\delta y)}{\mathrm{D}t} + \frac{1}{\delta z} \frac{\mathrm{D}(\delta z)}{\mathrm{D}t} \tag{64.77b}$$

$$= \frac{\delta u}{\delta x} + \frac{\delta v}{\delta y} + \frac{\delta w}{\delta z} \tag{64.77c}$$

$$= \nabla \cdot \boldsymbol{v}. \tag{64.77d}$$

Setting $\mathrm{D}(\rho \, \delta V)/\mathrm{D}t = 0$ leads to the familiar expression for the continuity equation

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\rho \, \nabla \cdot \boldsymbol{v}. \tag{64.78}$$

[2] Recall that we write δ as an infinitesimal increment following a fluid element.

64.8.2 Generalized vertical coordinates

We follow the above procedure but now with generalized vertical coordinates so that

$$\frac{1}{\delta V}\frac{\mathrm{D}\,(\delta V)}{\mathrm{D}t} = \frac{1}{\delta x\,\delta y\,z_\sigma\,\delta\sigma}\frac{\mathrm{D}(\delta x\,\delta y\,z_\sigma\,\delta\sigma)}{\mathrm{D}t} \tag{64.79a}$$

$$= \frac{1}{\delta x}\frac{\mathrm{D}(\delta x)}{\mathrm{D}t} + \frac{1}{\delta y}\frac{\mathrm{D}(\delta y)}{\mathrm{D}t} + \frac{1}{z_\sigma}\frac{\mathrm{D}(z_\sigma)}{\mathrm{D}t} + \frac{1}{\delta\sigma}\frac{\mathrm{D}(\delta\sigma)}{\mathrm{D}t} \tag{64.79b}$$

$$= \frac{\delta u}{\delta x} + \frac{\delta v}{\delta y} + \frac{1}{z_\sigma}\frac{\mathrm{D}(z_\sigma)}{\mathrm{D}t} + \frac{\delta(\dot\sigma)}{\delta\sigma} \tag{64.79c}$$

$$= \nabla_{\!\mathrm{h}\sigma}\cdot\boldsymbol{u} + \frac{1}{z_\sigma}\frac{\mathrm{D}(z_\sigma)}{\mathrm{D}t} + \frac{\partial\dot\sigma}{\partial\sigma} \tag{64.79d}$$

where we introduced the shorthand $\dot\sigma = \mathrm{D}\sigma/\mathrm{D}t$. Note that we set

$$\frac{\delta u}{\delta x} + \frac{\delta v}{\delta y} = \nabla_{\!\mathrm{h}\sigma}\cdot\boldsymbol{u} \tag{64.80}$$

since we are working with generalized vertical coordinates so that we consider infinitesimal displacements occurring on constant σ surfaces. We are thus led to

$$\frac{1}{\rho\,\delta V}\frac{\mathrm{D}(\rho\,\delta V)}{\mathrm{D}t} = \nabla_{\!\mathrm{h}\sigma}\cdot\boldsymbol{u} + \frac{1}{z_\sigma}\frac{\mathrm{D}z_\sigma}{\mathrm{D}t} + \frac{\partial\dot\sigma}{\partial\sigma} + \frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} = 0. \tag{64.81}$$

Now use the material time derivative in the form (64.50b) to derive the Eulerian expression of mass conservation

$$\frac{\partial(\rho\,z_\sigma)}{\partial t} + \nabla_{\!\mathrm{h}\sigma}\cdot(\rho\,z_\sigma\boldsymbol{u}) + \frac{\partial(\rho\,z_\sigma\,\dot\sigma)}{\partial\sigma} = 0, \tag{64.82}$$

where the time derivative is computed holding σ fixed. We can furthermore introduce the dia-surface velocity component

$$w^{(\dot\sigma)} = z_\sigma\,\dot\sigma \tag{64.83}$$

so that mass continuity takes the form

$$\frac{\partial(\rho\,z_\sigma)}{\partial t} + \nabla_{\!\mathrm{h}\sigma}\cdot(\rho\,z_\sigma\boldsymbol{u}) + \frac{\partial(\rho\,w^{(\dot\sigma)})}{\partial\sigma} = 0. \tag{64.84}$$

Alternatively, we can reintroduce the material time derivative operator to write the mass continuity equation (64.82) in the form

$$\frac{1}{\rho\,z_\sigma}\frac{\mathrm{D}(\rho\,z_\sigma)}{\mathrm{D}t} = -(\nabla_{\!\mathrm{h}\sigma}\cdot\boldsymbol{u} + \partial\dot\sigma/\partial\sigma), \tag{64.85}$$

where we used equation (64.50b) to write

$$\frac{\mathrm{D}}{\mathrm{D}t} = \left[\frac{\partial}{\partial t}\right]_\sigma + \boldsymbol{u}\cdot\nabla_{\!\mathrm{h}\sigma} + \dot\sigma\,\frac{\partial}{\partial\sigma}. \tag{64.86}$$

64.9 Layer integrated mass continuity

The formulation thus far has been continuous, with the only assumption made that the specific thickness, $\hbar = \partial z/\partial\sigma$, is single signed. We here consider a discrete increment in the generalized vertical coordinate,

$$\sigma - \delta\sigma/2 \le \sigma' \le \sigma + \delta\sigma/2, \tag{64.87}$$

and formulate the mass budget over this layer whose thickness is given by

$$h \equiv \int_{z(\sigma-\delta\sigma/2)}^{z(\sigma+\delta\sigma/2)} \mathrm{d}z = \int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \frac{\partial z}{\partial \sigma}\, \mathrm{d}\sigma, \tag{64.88}$$

and whose mass per horizontal area is

$$\delta m = \int_{z(\sigma-\delta\sigma/2)}^{z(\sigma+\delta\sigma/2)} \rho\, \mathrm{d}z = \int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \rho\, z_\sigma\, \mathrm{d}\sigma = \overline{\rho}\, h, \tag{64.89}$$

where $\overline{\rho}$ is the layer averaged density. Note that for Boussinesq fluids the mass per area equals to the layer thickness times the reference density

$$\delta m = \rho_o\, h \qquad \text{Boussinesq.} \tag{64.90}$$

As defined by equation (64.88) and illustrated in Figure 64.2, the thickness of a layer is relatively large in regions where $\partial\sigma/\partial z$ is small; i.e., in regions where σ is weakly stratified in the vertical. Conversely, the layer thickness is relatively small where the vertical stratification is large. Furthermore, if the specific thickness is negative, then the layer thickness remains positive by choosing $\delta\sigma < 0$. For example, in a stably stratified fluid with σ given by potential density, $\partial\sigma/\partial z = -(g/\rho_o)\, N^2 < 0$ so that we take $\delta\sigma < 0$ to move vertically upward in the water column to regions of lower potential density. The same situation holds when σ is the hydrostatic pressure in which $\partial p/\partial z = -\rho\, g$ (Section 64.9.2).

The formulation in this section, and its companion for tracers in Section 64.10, holds across all generalized vertical coordinates, even incorporating the trivial case of geopotential coordinates ($\sigma = z$) whereby the specific thickness is unity. Application of the resulting layer integrated kinematics include the development of discrete equations for numerical layered models (see *Griffies et al.* (2020) for a review), as well as the shallow water models discussed in Part VI of this book.

64.9.1 Compressible fluids

Performing a layer integral of the specific thickness equation (64.84) renders

$$\int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \left[\frac{\partial(\rho\, z_\sigma)}{\partial t} + \nabla_{h\sigma} \cdot (\rho\, z_\sigma \boldsymbol{u}) + \frac{\partial(\rho\, w^{(\dot\sigma)})}{\partial \sigma} \right] \mathrm{d}\sigma = 0. \tag{64.91}$$

The dia-surface term integrates to a finite difference across the layer

$$\int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \left[\frac{\partial(\rho\, z_\sigma)}{\partial t} + \nabla_{h\sigma} \cdot (\rho\, z_\sigma \boldsymbol{u}) \right] = -\Delta_\sigma(\rho\, w^{(\dot\sigma)}), \tag{64.92}$$

where we introduced the dimensionless finite difference operator for properties defined at the layer interface

$$\Delta_\sigma(A) = A(\sigma + \delta\sigma/2) - A(\sigma - \delta\sigma/2). \tag{64.93}$$

The time derivative and horizontal space derivative commute with the layer integral, since the limits are specified fixed values for the layer increment, $\delta\sigma$, and the derivatives are computed with σ fixed. Hence, layer mass continuity takes the form

$$\left[\frac{\partial}{\partial t}\right]_\sigma \int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \rho\, z_\sigma\, \mathrm{d}\sigma + \nabla_{h\sigma} \cdot \int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \rho\, \boldsymbol{u}\, z_\sigma\, \mathrm{d}\sigma = -\Delta_\sigma(\rho\, w^{(\dot\sigma)}). \tag{64.94}$$

The first term involves the layer averaged density times the layer thickness as per equation (64.89). The second term involves the layer averaged density-weighted velocity, which is the layer averaged horizontal mass flux

$$\int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \rho\, \boldsymbol{u}\, z_\sigma \,\mathrm{d}\sigma = h\, \overline{\rho\, \boldsymbol{u}}. \tag{64.95}$$

We are thus led to the layer integrated continuity equation

$$\left[\frac{\partial (h\, \overline{\rho})}{\partial t}\right]_\sigma + \nabla_{h\sigma} \cdot (h\, \overline{\rho\, \boldsymbol{u}}) + \Delta_\sigma(\rho\, w^{(\dot{\sigma})}) = 0. \tag{64.96}$$

When evolving the fields in a discrete numerical model, we have information only about layer averaged fields. So how do we estimate the depth average of the horizontal advective flux, $\overline{\rho\, \boldsymbol{u}}$, appearing in equation (64.96)? One method interprets all fields as their layer averaged values so that $\overline{\rho\, \boldsymbol{u}} = \overline{\rho}\, \overline{\boldsymbol{u}}$, thus considering uncomputed sub-layer correlations $\overline{\rho'\, \boldsymbol{u}'}$ as part of the truncation error. Alternately, we note that compressible hydrostatic flows can be described by a pressure-based vertical coordinate in which case the layer mass per horizontal area is proportional to a prescribed increment in pressure

$$\delta m = \int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \rho\, z_\sigma \,\mathrm{d}\sigma = \overline{\rho}\, h = -g^{-1}\, \delta p. \tag{64.97}$$

Correspondingly, the layer integrated horizontal mass flux equals to the mass increment times the pressure-layer averaged velocity

$$\int_{\sigma-\delta\sigma/2}^{\sigma+\delta\sigma/2} \rho\, \boldsymbol{u}\, z_\sigma \,\mathrm{d}\sigma = -g^{-1} \int_{p-\delta p/2}^{p+\delta p/2} \boldsymbol{u} \,\mathrm{d}p = -g^{-1}\, \overline{\boldsymbol{u}}\, \delta p = h\, \overline{\rho}\, \overline{\boldsymbol{u}}. \tag{64.98}$$

With either of the above two methods, we are led to the same layer integrated continuity equation, which we write in the generic form that drops overbars

$$\left[\frac{\partial (h\, \rho)}{\partial t}\right]_\sigma + \nabla_{h\sigma} \cdot (h\, \rho\, \boldsymbol{u}) + \Delta_\sigma\, (\rho\, w^{(\dot{\sigma})}) = 0. \tag{64.99}$$

We illustrate contributions to this layer mass budget in Figure 64.7.

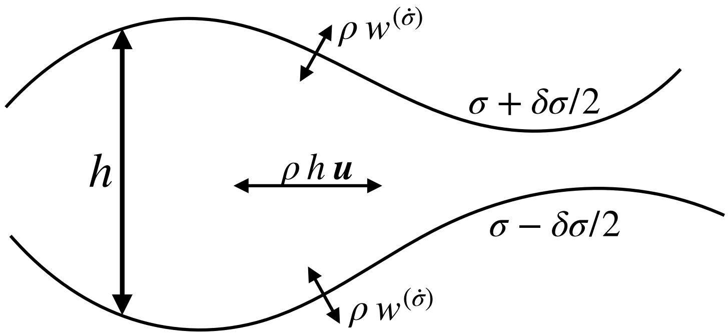

FIGURE 64.7: Illustrating the terms contributing to changes in layer mass according to the layer integrated continuity equation (64.99). The discrete layer is shown here with bounding interfaces at $\sigma - \delta\sigma/2$ and $\sigma + \delta\sigma/2$. Within a layer there is a horizontal redistribution due to horizontal advective transport. Additionally, matter can cross the layer due to dia-surface transport via $w^{(\dot{\sigma})}$.

64.9.2 Mass continuity using pressure coordinates

Let us here consider in some detail the special case of pressure coordinates in a hydrostatic fluid, and thus derive mass continuity using these coordinates.

Method I

The thickness of a hydrostatic pressure layer (equation (64.88)) takes on the following form

$$h = \int_{p-\delta p/2}^{p+\delta p/2} \frac{\partial z}{\partial p}\, \mathrm{d}p = -\int_{p-\delta p/2}^{p+\delta p/2} \frac{\mathrm{d}p}{\rho\, g}, \tag{64.100}$$

so that its mass per unit area is

$$\int_{p-\delta p/2}^{p+\delta p/2} \rho\, \frac{\partial z}{\partial p}\, \mathrm{d}p = -\delta p/g. \tag{64.101}$$

The mass continuity equation (64.99) thus becomes

$$\frac{\partial(\delta p)}{\partial t} + \nabla_{\mathsf{hp}} \cdot (\boldsymbol{u}\, \delta p) + \Delta_p\, (\dot{p}) = 0. \tag{64.102}$$

The partial time derivative vanishes since it is computed by holding pressure fixed so that the pressure increment has a zero time tendency

$$\left[\frac{\partial(\delta p)}{\partial t}\right]_p = 0. \tag{64.103}$$

Likewise, $\nabla_{\mathsf{hp}}\, (\delta p) = 0$. Thus, we can divide by δp to render the continuity equation

$$\nabla_{\mathsf{hp}} \cdot \boldsymbol{u} + \frac{\partial \dot{p}}{\partial p} = 0 \qquad \text{compressible hydrostatic.} \tag{64.104}$$

This equation is isomorphic to the continuity equation for non-divergent flows written using geopotential coordinates

$$\nabla_{\mathsf{h}} \cdot \boldsymbol{u} + \frac{\partial \dot{z}}{\partial z} = \nabla_{\mathsf{h}} \cdot \boldsymbol{u} + \frac{\partial w}{\partial z} 0 \qquad \text{non-divergent flow,} \tag{64.105}$$

where $w = \dot{z}$ is the vertical component to the velocity vector. For both pressure coordinates, describing non-Boussinesq fluids, and depth coordinates, describing Boussinesq fluids, the continuity equation is a diagnostic relation (i.e., no time derivatives) rather than prognostic (i.e., containing time derivatives).

Method II

For the second method we make use of the approach detailed in Section 64.8.2, which starts from

$$\frac{\mathrm{D}(\rho\, \delta V)}{\mathrm{D}t} = 0. \tag{64.106}$$

In pressure coordinates the volume of the fluid element takes the form

$$\delta V = \delta x\, \delta y\, \delta z = \delta x\, \delta y \left[\frac{\partial z}{\partial p}\right] \delta p = -(\rho\, g)^{-1}\, \delta x\, \delta y\, \delta p. \tag{64.107}$$

Consequently,

$$0 = \frac{\mathrm{D}(\rho\,\delta V)}{\mathrm{D}t} = g^{-1}\left(\frac{\mathrm{D}\left(\delta x\,\delta y\,\delta p\right)}{\mathrm{D}t}\right), \tag{64.108}$$

so that

$$0 = \frac{1}{\delta x\,\delta y\,\delta p}\left(\frac{\mathrm{D}\left(\delta x\,\delta y\,\delta p\right)}{\mathrm{D}t}\right) = \nabla_{\mathsf{hp}}\cdot\boldsymbol{u} + \frac{\partial\dot{p}}{\partial p}. \tag{64.109}$$

The second step made use of the isomorphism between this result and that for equation (18.140) that holds for a geopotential vertical coordinate.

64.9.3 Non-divergent flow

Specializing to a non-divergent flow where fluid elements conserve their volume (see Chapters 21 and 29) yields the layer thickness equation

$$\frac{\partial h}{\partial t} + \nabla_{\mathsf{h}\sigma}\cdot(h\,\boldsymbol{u}) + \Delta_\sigma w^{(\dot{\sigma})} = 0. \tag{64.110}$$

Further specializing to the case of zero dia-surface transport leads to

$$\frac{\partial h}{\partial t} + \nabla_{\mathsf{h}\sigma}\cdot(h\,\boldsymbol{u}) = 0 \qquad \text{no dia-surface transport.} \tag{64.111}$$

This case is commonly studied for adiabatic fluids using isopycnal coordinates, in which isopycnal surfaces are material (Section 66.2).

64.9.4 Rescaled geopotential coordinates

The rescaled geopotential coordinate

$$z^* = \frac{H\,(z-\eta)}{H+\eta} = \frac{\eta_{\mathsf{b}}\,(z-\eta)}{\eta_{\mathsf{b}}-\eta} \quad \text{and} \quad \eta_{\mathsf{b}}(x,y) \le z^* \le 0, \tag{64.112}$$

is commonly used in Boussinesq ocean models, where $z=\eta(x,y,t)$ is the ocean free surface and $z=\eta_{\mathsf{b}}(x,y)=-H(x,y)$ is the ocean bottom. The thickness of a coordinate layer is given by

$$h = \mathrm{d}z = \frac{\partial z}{\partial z^*}\,\mathrm{d}z^* = (1+\eta/H)\,\mathrm{d}z^* = (1-\eta/\eta_{\mathsf{b}})\,\mathrm{d}z^*. \tag{64.113}$$

The depth integrated column thickness and depth integrated coordinate thickness are given by

$$\int_{\eta_{\mathsf{b}}}^{\eta}\mathrm{d}z = \eta-\eta_{\mathsf{b}} = \eta+H \qquad \text{and} \qquad \int_{z^*(\eta_{\mathsf{b}})}^{z^*(\eta)}\mathrm{d}z^* = -\eta_{\mathsf{b}} = H. \tag{64.114}$$

Correspondingly, the depth integrated thickness equation is given by the depth integrated volume budget derived in Section 21.8

$$\frac{\partial\eta}{\partial t} + \nabla\cdot\boldsymbol{U} + [w^{(\dot{\sigma})}_{z^*=0} - w^{(\dot{\sigma})}_{z^*=\eta_{\mathsf{b}}}] = 0. \tag{64.115}$$

We assume no volume flow through the ocean bottom so that $w^{(\dot{\sigma})}_{z^*=\eta_{\mathsf{b}}}=0$, whereas

$$-\rho_{\mathsf{o}}\,w^{(\dot{\sigma})}_{z^*=0} = Q_{\mathrm{m}} \tag{64.116}$$

is the mass flux crossing the ocean free surface (Section 19.6.3).

64.10 Layer integrated tracer equation

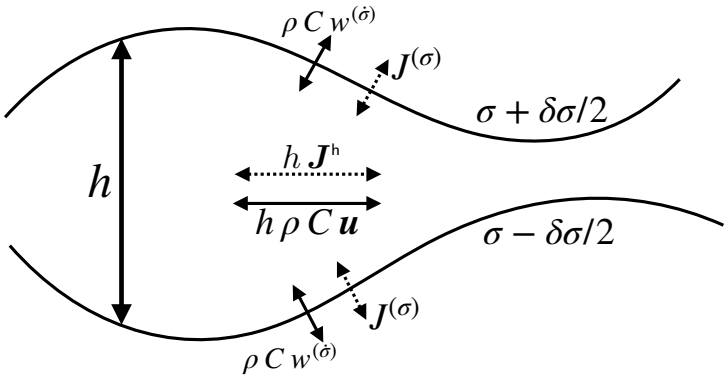

FIGURE 64.8: Illustrating the terms contributing to changes in layer tracer content according to the layer integrated tracer equation (64.121). The layer is shown here with bounding interfaces at $\sigma - \delta\sigma/2$ and $\sigma + \delta\sigma/2$. Within a layer there is a redistribution of tracer due to horizontal advective and subgrid scale tracer fluxes. Additionally, matter can cross the layer due to dia-surface transport via $\rho\, C\, w^{(\dot\sigma)}$ and subgrid tracer transport $J^{(\sigma)}$.

The tracer equation from Section 20.1.3 is given by

$$\rho\, \frac{\mathrm{D}C}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}, \tag{64.117}$$

where $\boldsymbol{J}$ is a subgrid scale flux. Now introduce the material time derivative operator in the form (64.50b) to have

$$\rho \left[\frac{\partial C}{\partial t} + \boldsymbol{u} \cdot \nabla_{\!\mathrm{h}\sigma} C + \dot\sigma\, \partial_\sigma C \right] = -\nabla \cdot \boldsymbol{J}, \tag{64.118}$$

Multiplying by the specific thickness and making use of the mass conservation equation (64.84) renders the flux-form Eulerian equation

$$\frac{\partial(z_\sigma\, \rho\, C)}{\partial t} + \nabla_{\!\mathrm{h}\sigma} \cdot (z_\sigma\, \rho\, C\, \boldsymbol{u}) + \frac{\partial(\rho\, C\, w^{(\dot\sigma)})}{\partial \sigma} = -\left[\nabla_{\!\mathrm{h}\sigma} \cdot (z_\sigma\, \boldsymbol{J}^{\mathrm{h}}) + \frac{\partial(z_\sigma\, \nabla\sigma \cdot \boldsymbol{J})}{\partial \sigma} \right], \tag{64.119}$$

where we made use of expression (63.99) for the subgrid scale operator. Now perform a layer integral as detailed in Section 64.9 and use the layer mass continuity equation (64.99) to yield the layer integrated tracer equation

$$\frac{\partial(h\, \rho\, C)}{\partial t} + \nabla_{\!\mathrm{h}\sigma} \cdot (h\, \rho\, C\, \boldsymbol{u}) + \Delta_\sigma(\rho\, C\, w^{(\dot\sigma)}) = -\left[\nabla_{\!\mathrm{h}\sigma} \cdot (h\, \boldsymbol{J}^{\mathrm{h}}) + \Delta_\sigma(z_\sigma\, \nabla\sigma \cdot \boldsymbol{J}) \right]. \tag{64.120}$$

Alternatively, we can bring all terms to the left hand side to yield

$$\frac{\partial(h\, \rho\, C)}{\partial t} + \nabla_{\!\mathrm{h}\sigma} \cdot (h\, \rho\, C\, \boldsymbol{u} + h\, \boldsymbol{J}^{\mathrm{h}}) + \Delta_\sigma(\rho\, C\, w^{(\dot\sigma)} + J^{(\sigma)}) = 0 \tag{64.121}$$

where we wrote

$$J^{(\sigma)} = z_\sigma\, \nabla\sigma \cdot \boldsymbol{J}. \tag{64.122}$$

We illustrate contributions to the layer tracer budget (64.121) in Figure 64.8. Note that we interpret these layer integrated fields and fluxes as per the discussion in Section 64.9.1.

64.11 Overturning circulation in the meridional-σ plane

In Section 21.7 we studied the meridional-depth streamfunction, where we showed that equation (21.73), or the equivalent form (21.78), are streamfunctions for the meridional-depth circulation. Here we introduce a streamfunction defined according to generalized vertical coordinate, $\sigma(x, y, z, t)$. This generalization is useful for studying the zonally integrated circulation partitioned according to σ surfaces rather than z surfaces, in particular when σ is potential density or entropy surface. We make use of Figure 64.9 for the derivation.

As noted in Section 21.7, we can make use of the Boussinesq fluid, where the flow field is non-divergent. Alternatively, we make use of a non-Boussinesq fluid when the flow is steady. As shown in this section, we are afforded a meridional-σ streamfunction only when σ is time independent.

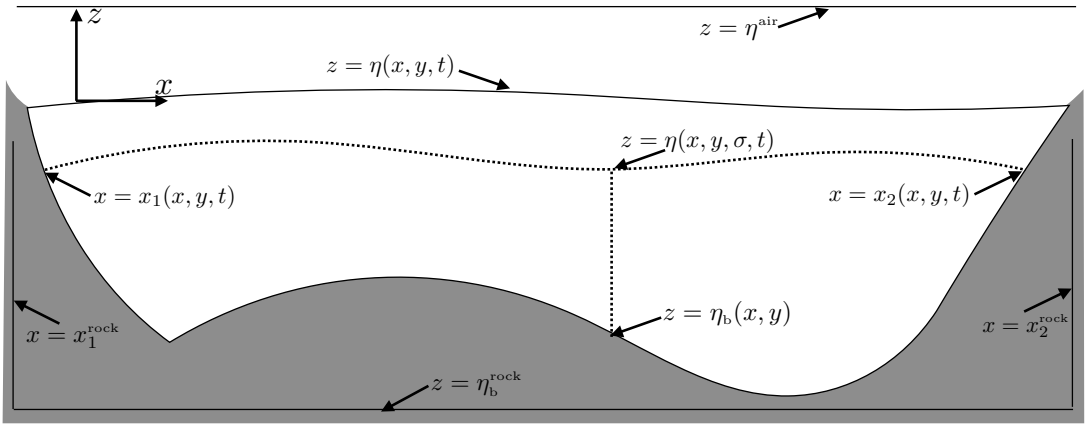

FIGURE 64.9: Geometry for computing the meridional streamfunction, here generalizing the meridional-depth streamfunction geometry in Figure 21.5 to meridional-σ. The zonal boundaries are written $x = x_1(y, z, t)$ and $x = x_2(y, z, t)$, which are generally functions of latitude and vertical position as well as time. The bottom is written as $z = \eta_{\text{b}}(x, y)$ and the vertical position of an arbitrary surface is written $z = \eta(x, y, \sigma, t)$, where we assume this surface is monotonic in the vertical. Note that for shorthand, we often find it convenient to write $z = \eta_\sigma(x, y, t)$, particularly when suppressing the dependencies on horizontal position and time. We also display the constant zonal positions, $x_{1,2}^{\text{rock}}$, which are fully within the rock, as well as the bottom position, $\eta_{\text{b}}^{\text{rock}}$, which is also within the rock.

64.11.1 Overturning streamfunction

Start from equation (21.78) for the meridional-depth streamfunction, here generalized to

$$\Psi(y, \sigma, t) = -\int_{x_1^{\text{rock}}}^{x_2^{\text{rock}}} \left[\int_{\eta_{\text{b}}(x', y)}^{z=\eta(x', y, \sigma, t)} v(x', y, z', t)\, \mathrm{d}z' \right] \mathrm{d}x'. \tag{64.123}$$

As defined, $\Psi(y, \sigma, t)$ makes use of $z = \eta(x', y, \sigma, t)$ for the upper bound on the vertical integral, where $\eta(x', y, \sigma, t)$ is the vertical position of a generalized vertical coordinate surface with value σ, such as depicted in Figure 64.9. In this manner, $\Psi(y, \sigma, t)$, is a function of latitude, σ, and time. Our job in the next subsection is to prove that $\Psi(y, \sigma, t)$ indeed serves as a streamfunction for the zonally integrated flow, with the zonal integral along constant σ surfaces rather than constant z surfaces.

64.11.2 Proving that $\Psi(y, \sigma, t)$ is a streamfunction

To prove that $\Psi(y, \sigma, t)$ is indeed a streamfunction, we proceed much like in Section 21.7.3 for the meridional-depth streamfunction, $\Psi(y, z, t)$, with the key new piece in the derivation

concerning the space-time dependence of the $z = \eta(x, y, \sigma, t)$ surface. The vertical derivative of the streamfunction is given by

$$\frac{\partial \Psi}{\partial z} = -\frac{\partial}{\partial z} \int_{x_1^{\text{rock}}}^{x_2^{\text{rock}}} \left[\int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma,t)} v(x', y, z', t)\, \mathrm{d}z' \right] \mathrm{d}x' \tag{64.124a}$$

$$= -\int_{x_1^{\text{rock}}}^{x_2^{\text{rock}}} \left[\frac{\partial}{\partial z} \int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma,t)} v(x', y, z', t)\, \mathrm{d}z' \right] \mathrm{d}x' \tag{64.124b}$$

$$= -\int_{x_1^{\text{rock}}}^{x_2^{\text{rock}}} v(x', y, z = \eta(x', y, \sigma, t))\, \mathrm{d}x' \tag{64.124c}$$

$$= -V(y, \sigma, t). \tag{64.124d}$$

In these steps we used used Leibniz's rule and noted that only the upper integration limit is a function of z. Furthermore, the upper limit on the vertical integral is evaluated at the vertical position of the σ surface. Hence, the zonal integral is defined while keeping the vertical position on the σ surface rather than on a constant geopotential surface.

For the meridional derivative we have

$$\frac{\partial \Psi}{\partial y} = -\int_{x_1^{\text{rock}}}^{x_2^{\text{rock}}} \left[\frac{\partial}{\partial y} \int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma,t)} v(x', y, z', t)\, \mathrm{d}z' \right] \mathrm{d}x'. \tag{64.125}$$

Focusing on the vertical integral yields (dropping various coordinate dependencies when not essential)

$$\frac{\partial}{\partial y} \int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma)} v(x', y, z')\, \mathrm{d}z' = v(\eta_\sigma)\, \partial_y \eta_\sigma - v(\eta_{\mathsf{b}})\, \partial_y \eta_{\mathsf{b}} + \int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma)} \partial_y v(x', y, z')\, \mathrm{d}z'. \tag{64.126}$$

Focus again on the vertical integral and make use of the non-divergence condition to yield

$$\int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma)} \partial_y v(x', y, z')\, \mathrm{d}z' = -\int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma)} [\partial_{x'} u(x', y, z') + \partial_{z'} w(x', y, z')]\, \mathrm{d}z'. \tag{64.127}$$

Leibniz's rule on the $\partial_{x'} u(x', y, z')$ term then brings us to

$$\frac{\partial}{\partial y} \int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma)} v(x', y, z')\, \mathrm{d}z' = -[w(\eta_\sigma) - \boldsymbol{u}(\eta_\sigma) \cdot \nabla \eta_\sigma] + [w(\eta_{\mathsf{b}}) - \boldsymbol{u}(\eta_{\mathsf{b}}) \cdot \nabla \eta_{\mathsf{b}}] - \frac{\partial}{\partial x} \int_{\eta_{\mathsf{b}}(x',y)}^{z=\eta(x',y,\sigma)} u(x', y, z')\, \mathrm{d}z'. \tag{64.128}$$

Recall that $w(\eta_{\mathsf{b}}) - \boldsymbol{u}(\eta_{\mathsf{b}}) \cdot \nabla \eta_{\mathsf{b}} = 0$ from the bottom kinematic boundary condition (19.56). Furthermore, from equation (64.35f) for the dia-surface velocity, we have

$$w(\eta_\sigma) - \boldsymbol{u}(\eta_\sigma) \cdot \nabla \eta_\sigma = w^{(\dot\sigma)} + \partial_t \eta_\sigma. \tag{64.129}$$

Bringing these results together then renders

$$\frac{\partial \Psi}{\partial y} = \int_{x_1^{\text{rock}}}^{x_2^{\text{rock}}} [w^{(\dot\sigma)}(x', y, z = \eta_\sigma) + \partial_t \eta_\sigma]\, \mathrm{d}x', \tag{64.130}$$

where we set

$$u(x_1^{\text{rock}}) = u(x_2^{\text{rock}}) = 0. \tag{64.131}$$

We conclude that $\Psi(y, \sigma, t)$ is a streamfunction for the special case where σ is time independent, in which case

$$\frac{\partial \Psi}{\partial y} = \int_{x_1^{\text{rock}}}^{x_2^{\text{rock}}} w^{(\dot{\sigma})}(x', y, z = \eta_\sigma) \, \mathrm{d}x' = W^{(\dot{\sigma})}(y, \sigma, t). \tag{64.132}$$

We can understand the need for time independence since that ensures that the flow underneath the σ surface is non-divergent, much like the case for a shallow water model in steady state (see Chapter 35). In the literature, one can find $\Psi(y, \sigma, t)$ referred to as a streamfunction even when the flow has time dependence, in which case extra caution is needed if inferring the associated flow patterns.

Chapter 65

Dynamical equations

In this chapter we derive the dynamical equations for momentum, vorticity, and potential vorticity using generalized vertical coordinates. These equations provide the foundations for many numerical models of the atmosphere and ocean. Besides being essential for developing methods for numerical simulations, understanding the physical and mathematical basis of these equations supports the analysis of simulations.

READER'S GUIDE TO THIS CHAPTER

We assume a working knowledge of the mathematics of generalized vertical coordinates as detailed in Chapter 63 and the corresponding kinematics in Chapter 64. We make particular use of the layer integrated notions introduced for mass continuity and the tracer equations in Sections 64.9 and 64.10. We also make use of the dynamical equations derived in Chapter 24. For most purposes in this chapter we find Cartesian horizontal coordinates sufficient. However, we note some places where spherical coordinates warrant special consideration.

65.1 Equations of motion

We here derive the equations of motion based on generalized vertical coordinates. The scalar equations were already discussed in Sections 64.8, 64.9, and 64.10, so our main focus concerns the momentum equation.

65.1.1 Notation

For much of this chapter we focus on the continuous formulation of the generalized vertical coordinates. Following the discussion in Section 64.2, we encounter the specific thickness throughout the equations

$$\hbar = \frac{\partial z}{\partial \sigma} = z_\sigma. \tag{65.1}$$

Using this notation we write the dia-surface transport velocity as

$$w^{(\dot\sigma)} = \frac{\partial z}{\partial \sigma}\,\dot\sigma = \hbar\,\dot\sigma, \tag{65.2}$$

and the dia-surface advection operator is

$$w^{(\dot\sigma)}\,\partial_z = \dot\sigma\,\partial_\sigma. \tag{65.3}$$

65.1.2 Mass and tracer equations

The mass and tracer equations were derived in Sections 64.8, 64.9, and 64.10, with their continuous vertical coordinate formulation given by

$$\frac{\partial(\rho\,\hbar)}{\partial t} + \nabla_{h\sigma}\cdot(\rho\,\hbar\,\boldsymbol{u}) + \partial_\sigma(\rho\,\hbar\,\dot\sigma) = 0 \tag{65.4a}$$

$$\frac{\partial(\hbar\,\rho\,C)}{\partial t} + \nabla_{h\sigma}\cdot(\hbar\,\rho\,C\,\boldsymbol{u} + \hbar\,\boldsymbol{J}^{\mathrm{h}}) + \partial_\sigma(\rho\,\hbar\,\dot\sigma\,C + \hbar\,\nabla\sigma\cdot\boldsymbol{J}) = 0. \tag{65.4b}$$

Compatibility is maintained between the mass continuity equation (65.4a) and the tracer equation (65.4b) so long as the tracer equation reduces to the mass equation upon setting the tracer concentration to a spatial constant. Hence, for compatibility we must have the subgrid fluxes, $\boldsymbol{J}$, vanish when the tracer is a spatial constant. For example, diffusive fluxes, which are proportional to the tracer gradient, respect this constraint. These properties originate from our discussion of mass budgets and the barycentric velocity in Section 20.1.

65.1.3 Momentum equation

From Section 26.13, the horizontal and vertical components to the momentum equation are

$$\rho\,\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + 2\,\rho\,\boldsymbol{\Omega}\times\boldsymbol{u} = -\rho\,\nabla_{\!h}\Phi - \nabla_{\!h}p + \rho\boldsymbol{F}^{\mathrm{h}} \tag{65.5a}$$

$$\rho\,\frac{\mathrm{D}w}{\mathrm{D}t} = -\rho\,\frac{\partial\Phi}{\partial z} - \frac{\partial p}{\partial z} + \rho F^z. \tag{65.5b}$$

The simple form of the geopotential sets $\Phi = g\,z$ (Section 13.10), so that the horizontal gradient of the geopotential vanishes

$$\Phi = g\,z \implies \nabla_{\!h}\Phi = 0. \tag{65.6}$$

However, this gradient is nonzero in the presence of astronomical tide forcing, such as discussed in Chapter 34.

Horizontal momentum equation

We transform the horizontal derivatives from geopotential coordinates to generalized vertical coordinates according to (see equation (63.75))

$$\nabla_{\!h} = \nabla_{h\sigma} - (\nabla_{h\sigma} z)\,\partial_z \tag{65.7}$$

thus leading to the horizontal momentum equation

$$\rho \frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + 2\,\rho\,\boldsymbol{\Omega} \times \boldsymbol{u} = -\rho\,[\nabla_{\!\mathrm{h}\sigma} - (\nabla_{\!\mathrm{h}\sigma} z)\,\partial_z]\,\Phi - [\nabla_{\!\mathrm{h}\sigma} - (\nabla_{\!\mathrm{h}\sigma} z)\,\partial_z]\,p + \rho \boldsymbol{F}^{\mathrm{h}}. \tag{65.8}$$

In Section 65.1.6 we present some special cases for this equation that simplify the pressure and geopotential terms.

Vertical momentum equation

The vertical momentum equation is transformed into

$$\rho \frac{\mathrm{D}w}{\mathrm{D}t} = -\frac{\partial \sigma}{\partial z}\left[\rho \frac{\partial \Phi}{\partial \sigma} + \frac{\partial p}{\partial \sigma}\right] + \rho\, F^z, \tag{65.9}$$

with the hydrostatic form given by

$$\frac{\partial p}{\partial \sigma} = -\rho \frac{\partial \Phi}{\partial \sigma}. \tag{65.10}$$

65.1.4 Flux-form horizontal momentum equation

Using Cartesian horizontal coordinates and generalized vertical coordinates, the horizontal momentum equation includes a contribution from the acceleration that has a form similar to that for a tracer (Section 64.10)

$$\hbar\,\rho \frac{\mathrm{D}u}{\mathrm{D}t} = \left[\frac{\partial(\hbar\,\rho\,u)}{\partial t}\right]_\sigma + \nabla_{\!\mathrm{h}\sigma} \cdot (\hbar\,\rho\,u\,\boldsymbol{u}) + \partial_\sigma(\hbar\,\rho\,u\,\dot{\sigma}) \tag{65.11a}$$

$$\hbar\,\rho \frac{\mathrm{D}v}{\mathrm{D}t} = \left[\frac{\partial(\hbar\,\rho\,v)}{\partial t}\right]_\sigma + \nabla_{\!\mathrm{h}\sigma} \cdot (\hbar\,\rho\,v\,\boldsymbol{u}) + \partial_\sigma(\hbar\,\rho\,v\,\dot{\sigma}). \tag{65.11b}$$

We provide a σ subscript on the time derivative operator to signal that this derivative is taken with σ held fixed. With spherical coordinates there are additional metric terms appearing on the right hand side, as detailed in Section 24.3. In particular, there is a metric term that contains the vertical velocity component, $w = \mathrm{D}z/\mathrm{D}t$. The appearance of w is awkward since the vertical velocity is not naturally computed using generalized vertical coordinates. This limitation is overcome through use of the vector-invariant velocity equation derived in Section 65.1.5.

65.1.5 Vector-invariant horizontal momentum equation

As noted in Section 24.4, the *vector-invariant* form of the velocity equation eliminates the metric terms that appear in the non-Cartesian flux-form equations. The vector-invariant form is also suited for deriving the vorticity equation (see Section 65.3). Here, we start with the material time derivative in the form (64.50c) appropriate for generalized vertical coordinates, in which case the horizontal acceleration is given by

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = \left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_\sigma + (\boldsymbol{u} \cdot \nabla_{\!\mathrm{h}\sigma})\,\boldsymbol{u} + (\dot{\sigma}\,\partial_\sigma)\,\boldsymbol{u}. \tag{65.12}$$

Now make use of the vector identity (see Section 2.3.4)

$$(\boldsymbol{u} \cdot \nabla_{\!\mathrm{h}\sigma})\,\boldsymbol{u} = \nabla_{\!\mathrm{h}\sigma} K + (\nabla_{\!\mathrm{h}\sigma} \times \boldsymbol{u}) \times \boldsymbol{u}, \tag{65.13}$$

where

$$K = \boldsymbol{u} \cdot \boldsymbol{u}/2 \tag{65.14}$$

is the kinetic energy per mass of the horizontal flow. Introducing the generalized vertical coordinate version of the relative vorticity (see Section 66.3.1)

$$\widetilde{\zeta} \equiv \hat{\boldsymbol{z}} \cdot (\nabla_{\!\mathrm{h}\sigma} \times \boldsymbol{u}) = \left[\frac{\partial v}{\partial x}\right]_{\sigma} - \left[\frac{\partial u}{\partial y}\right]_{\sigma} \tag{65.15}$$

renders

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = \left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_{\sigma} + \nabla_{\!\mathrm{h}\sigma}\, K + \widetilde{\zeta}\, \hat{\boldsymbol{z}} \times \boldsymbol{u} + \dot{\sigma}\, \partial_{\sigma}\, \boldsymbol{u}, \tag{65.16}$$

so that the horizontal momentum equation takes the form

$$\left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_{\sigma} + \dot{\sigma}\, \frac{\partial \boldsymbol{u}}{\partial \sigma} + (2\,\boldsymbol{\Omega} + \hat{\boldsymbol{z}}\, \widetilde{\zeta}) \times \boldsymbol{u} = -\nabla_{\!\mathrm{h}\sigma} K - \nabla_{\!\mathrm{h}} \Phi - (1/\rho)\, \nabla_{\!\mathrm{h}} p + \boldsymbol{F}^{\mathrm{h}}, \tag{65.17}$$

where again $\nabla_{\!\mathrm{h}} = \nabla_{\!\mathrm{h}\sigma} - (\nabla_{\!\mathrm{h}\sigma} z)\, \partial_z$ as per equation (65.7). This equation is form-invariant regardless the horizontal coordinates, thus motivating the name *vector-invariant*.[1]

65.1.6 Hydrostatic balance with constant gravitational acceleration

There are many special cases that simplify various terms in the momentum equation. For example, when considering a geopotential in the form $\Phi = g\, z$ (Section 13.10) with g assumed to be a constant effective gravitational acceleration, then the horizontal momentum equation (65.8) becomes

$$\rho\, \frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + 2\, \rho\, \boldsymbol{\Omega} \times \boldsymbol{u} = -[\nabla_{\!\mathrm{h}\sigma} - (\nabla_{\!\mathrm{h}\sigma} z)\, \partial_z]\, p + \rho \boldsymbol{F}^{\mathrm{h}}. \tag{65.18}$$

Furthermore, assuming an approximate hydrostatic balance (and corresponding simplification of the Coriolis acceleration as per Section 27.1.3) allows us to write $\partial p/\partial z = -g\, \rho$ so that

$$\rho\, \frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + \rho\, f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -[\nabla_{\!\mathrm{h}\sigma} p + \rho\, \nabla_{\!\mathrm{h}\sigma} \Phi] + \rho \boldsymbol{F}^{\mathrm{h}}, \tag{65.19}$$

which also takes on the vector-invariant form

$$\left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_{\sigma} + \dot{\sigma}\, \frac{\partial \boldsymbol{u}}{\partial \sigma} + (f + \widetilde{\zeta})\, \hat{\boldsymbol{z}}\, \times \boldsymbol{u} = -\nabla_{\!\mathrm{h}\sigma}(K + \Phi) - (1/\rho)\, \nabla_{\!\mathrm{h}\sigma} p + \boldsymbol{F}^{\mathrm{h}}. \tag{65.20}$$

This form is commonly used for hydrostatic models of the ocean and atmosphere, such as discussed in *Griffies et al.* (2020).

65.2 Concerning the pressure force

As seen in Section 25.2.3, the pressure force acting on a fluid region is given by the integral

$$\boldsymbol{F}^{\mathrm{press}} = -\oint_{\partial \mathcal{R}} p\, \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = -\int_{\mathcal{R}} \nabla p\, \mathrm{d}V, \tag{65.21}$$

where the second equality follows from Gauss's divergence theorem applied to a scalar field (Section 2.7.2). We refer to the right-most expression as the pressure gradient body force, and this expression is the basis for the discussion in Sections 65.1.6 and 65.2.1. In this formulation, the pressure force at a point is oriented down the pressure gradient, so that the net pressure force acting on a region is the volume integral of pressure gradient.

[1] See Section 4.4.4 of *Griffies* (2004) for a detailed derivation using arbitrary horizontal coordinates.

The middle expression in equation (65.21) formulates the pressure force as the area integrated pressure contact force acting on the region boundaries. In this form, the pressure acting on a region is computed as the integral of pressure over the area bounding the region, with the orientation determined by the inward normal at each point on the boundary. Much of this section is concerned with the contact force expression as a basis for computing the pressure force acting on a finite region as shown in Figure 65.2. The contact force perspective was taken by *Lin* (1997) and *Adcroft et al.* (2008) in their finite volume approach to computing the pressure force acting on a numerical model grid cell.

65.2.1 Computing the horizontal pressure gradient

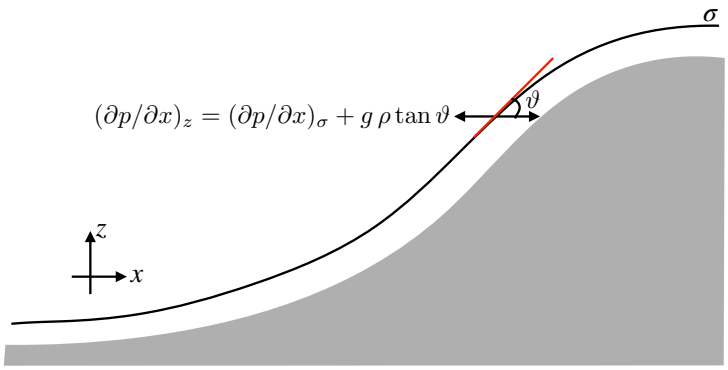

FIGURE 65.1: Illustrating how the horizontal pressure gradient is decomposed into two terms, one aligned with the surface of constant σ, and another associated with the slope of the σ-surface relative to the horizontal, $\tan\vartheta = (\partial z/\partial x)_\sigma$. We here consider the decomposition using terrain following vertical coordinates, where the vertical coordinate is aligned according to the solid-earth bottom (shaded region). Specifically, for terrain following Boussinesq ocean models we set $\sigma = (z-\eta)/(-\eta_b+\eta)$, where $z = \eta(x,y,t)$ is the ocean free surface and $z = \eta_b(x,y)$ is the ocean bottom topography. Terrain-following atmospheric models have a similar definition, often using pressure rather than geopotential so that $\sigma = (p - p_a)/(p_b - p_a)$, where p is the pressure, $p_a = p_a(x,y,t)$ is the pressure applied at the top of the atmosphere (typically assumed to be zero), and $p_b = p_b(x,y,t)$ is the pressure at the bottom of the atmosphere.

The horizontal pressure gradient is aligned perpendicular to the local gravitational direction. It is generally among the dominant horizontal forces acting on a fluid element. Hence, its accurate representation in numerical models is crucial for the physical integrity of a simulation. Unfortunately, decomposition of the horizontal pressure gradient into two terms according to the transformation (65.7) can lead to numerical difficulties. For example, with a simple geopotential and a hydrostatic fluid, equation (65.19) shows that the horizontal pressure gradient takes the form

$$\nabla_h p = \nabla_{h\sigma} p + \rho\, \nabla_{h\sigma} \Phi = \nabla_{h\sigma} p + g\, \rho\, \nabla_{h\sigma} z, \tag{65.22}$$

with this decomposition illustrated in Figure 65.1 for the case of terrain following vertical coordinates. Numerical difficulties occur when the two terms on the right hand side have comparable magnitude but distinct signs. We are thus confronted with computing the small difference between two large numbers, and that situation generally exposes a numerical simulation to nontrivial truncation errors. Unfortunately, these errors can corrupt the integrity of the computed pressure forces and in turn contribute to spurious flow. An overview of this issue for ocean models is given by *Haney* (1991), *Mellor et al.* (1998), *Griffies et al.* (2000), with advances offered by *Lin* (1997), *Shchepetkin and McWilliams* (2002), and *Adcroft et al.* (2008). In the remainder of this section, we outline a finite volume method for computing the pressure force as proposed by *Lin* (1997) for atmosphere models and *Adcroft et al.* (2008) for ocean models. This approach starts from the middle expression in equation (65.21) for the pressure force; i.e., it

formulates the pressure force as the area integral of the pressure contact force rather than the volume integral of the pressure gradient force.

65.2.2 Integrated pressure force on the cell faces

The inward normal on the grid cell vertical side boundaries points in the horizontal direction. For example, on the left side of Figure 65.2 the pressure force acts in the positive $\hat{\boldsymbol{y}}$ direction

$$\boldsymbol{F}^{\text{press}}_{\text{left}} = \hat{\boldsymbol{y}} \int_{\text{left}} p \, \mathrm{d}x \, \mathrm{d}z \tag{65.23}$$

whereas pressure on the right wall acts in the opposite direction

$$\boldsymbol{F}^{\text{press}}_{\text{right}} = -\hat{\boldsymbol{y}} \int_{\text{right}} p \, \mathrm{d}x \, \mathrm{d}z. \tag{65.24}$$

Similar expressions appear for the front and back vertical boundaries acting in the $\hat{\boldsymbol{x}}$ direction.

Since the top and bottom boundaries of the grid cell are sloped, there is a pressure force acting on this surface directed in both the horizontal and vertical directions. To unpack the form of this force, write the vertical position of a point on the top interface as $z = \eta(x, y, t)$ so that the outward normal is given by

$$\hat{\boldsymbol{n}} = \frac{\nabla(z - \eta)}{|\nabla(z - \eta)|} = \frac{\hat{\boldsymbol{z}} - \nabla\eta}{\sqrt{1 + |\nabla\eta|^2}}. \tag{65.25}$$

Following our discussion of dia-surface transport in Section 64.3.5, we know that the product of the normal direction and the area element can be written

$$\hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = (\hat{\boldsymbol{z}} - \nabla\eta) \, \mathrm{d}A, \tag{65.26}$$

where $\mathrm{d}A = \mathrm{d}x \, \mathrm{d}y$ is the horizontal projection of the area element (see Figure 64.3). Hence, the net pressure force acting on the top face is given by

$$\boldsymbol{F}^{\text{press}}_{\text{top}} = -\hat{\boldsymbol{z}} \int_{\text{top}} p \, \mathrm{d}x \, \mathrm{d}y + \hat{\boldsymbol{x}} \int_{\text{top}} p \, (\partial z/\partial x)_\sigma \, \mathrm{d}x \, \mathrm{d}y + \hat{\boldsymbol{y}} \int_{\text{top}} p \, (\partial z/\partial y)_\sigma \, \mathrm{d}x \, \mathrm{d}y, \tag{65.27}$$

where we set $z = \eta$ in the second and third terms and placed a σ subscript to emphasize that the horizontal derivative is taken with σ held constant. Notice that the pressure acts in the positive horizontal direction if the top surface slopes upward (surface shoaling) when moving in either of the two horizontal directions. Pressure acting on the bottom face has the same appearance yet with opposite signs

$$\boldsymbol{F}^{\text{press}}_{\text{bott}} = \hat{\boldsymbol{z}} \int_{\text{bott}} p \, \mathrm{d}x \, \mathrm{d}y - \hat{\boldsymbol{x}} \int_{\text{bott}} p \, (\partial z/\partial x)_\sigma \, \mathrm{d}x \, \mathrm{d}y - \hat{\boldsymbol{y}} \int_{\text{bott}} p \, (\partial z/\partial y)_\sigma \, \mathrm{d}x \, \mathrm{d}y. \tag{65.28}$$

The pressure acts in the positive horizontal direction if the bottom surface slopes downward (surface deepens) when moving in either of the two horizontal directions. As discussed in Section 25.2.3, the horizontal pressure acting on a sloped surface is known as *form stress*. Here the sloped surface is defined by a constant generalized vertical coordinate.

65.2.3 Net vertical pressure force

Bringing the pieces together leads to the net vertical pressure force acting on the grid cell

$$\boldsymbol{F}^{\text{press}}_{\text{vertical}} = -\hat{\boldsymbol{z}} \left[\int_{\text{top}} p \, \mathrm{d}x \, \mathrm{d}y - \int_{\text{bott}} p \, \mathrm{d}x \, \mathrm{d}y \right]. \tag{65.29}$$

If the fluid is in hydrostatic balance, then this vertical force is given by the weight of fluid within the cell

$$\boldsymbol{F}^{\text{press}}_{\text{vertical}} = \hat{\boldsymbol{z}} \, M g, \tag{65.30}$$

where M is the mass of fluid in the grid cell. The net vertical hydrostatic pressure force acts vertically upward since hydrostatic pressure at the cell bottom is greater than at the cell top.

65.2.4 Net horizontal pressure force

The net meridional pressure force is given by the forces acting on the sides as well as those acting on the sloped top and bottom boundaries

$$\boldsymbol{F}^{\text{press}}_{\text{merid}} = \left[\int_{\text{left}} p \, \mathrm{d}x \, \mathrm{d}z - \int_{\text{right}} p \, \mathrm{d}x \, \mathrm{d}z \right] + \left[\int_{\text{top}} p \, (\partial z / \partial y)_\sigma \, \mathrm{d}x \, \mathrm{d}y - \int_{\text{bott}} p \, (\partial z / \partial y)_\sigma \, \mathrm{d}x \, \mathrm{d}y \right]. \tag{65.31}$$

We can write this expression in a more compact form by orienting our integration in a counter-clockwise manner around the cell boundaries, and making use of the identity $(\partial z / \partial y)_\sigma \, \mathrm{d}y = \mathrm{d}z$ on the top and bottom faces, so that

$$\boldsymbol{F}^{\text{press}}_{\text{merid}} = -\oint p \, \mathrm{d}x \, \mathrm{d}z. \tag{65.32}$$

For some purposes it is more convenient to work with the geopotential, $\Phi = g \, z$, than the pressure. In this case we can write the meridional pressure force as

$$\boldsymbol{F}^{\text{press}}_{\text{merid}} = -\oint p \, \mathrm{d}x \, \mathrm{d}z = -\oint \mathrm{d}x \, [\mathrm{d}(p \, z) - z \, \mathrm{d}p] = g^{-1} \oint \Phi \, \mathrm{d}x \, \mathrm{d}p, \tag{65.33}$$

where $\oint \mathrm{d}x \, \mathrm{d}(p \, z) = 0$. This form is useful with compressible / non-Boussinesq models, in which pressure is a natural vertical coordinate (e.g., see the caption to Figure 65.1).

65.2.5 Comments

A numerical realization of the integrated contact pressure force requires a representation of pressure along the boundaries of the grid cell. A variety of methods are available with differing accuracies. *Adcroft et al.* (2008) are notable in proposing an analytic form that allows for an exact integration along the cell faces in special cases, and a highly accurate numerical integration in other cases. In general, this method for computing pressure forces is highly suited to generalized vertical coordinate grid cells, which was the motivation offered by *Lin* (1997) in the context of terrain following atmospheric models.

65.3 Hydrostatic vorticity and potential vorticity

Generalized vertical coordinates are most commonly used to study hydrostatic fluids. We are thus motivated to develop the evolution equation for the vertical component of vorticity, $\widetilde{\zeta}$, in a hydrostatic fluid as written using generalized vertical coordinates. By extension, we derive the budget equation for the corresponding potential vorticity.

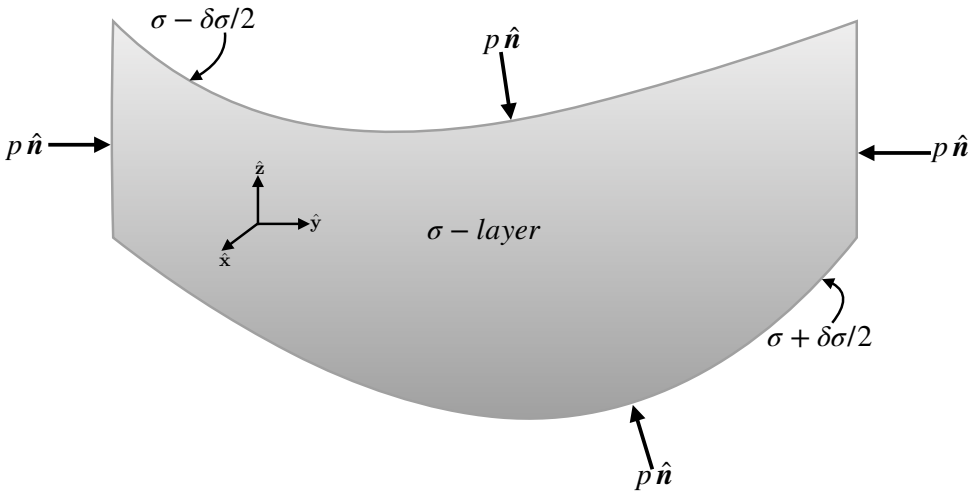

FIGURE 65.2: Schematic of pressure forces acting on the boundaries of a finite region such as a discrete model grid cell. In generalized vertical coordinate models, the side faces are vertical, so that pressure acts only in the horizontal directions. The top and bottom faces are defined by surfaces of constant generalized vertical coordinates with depth $\sigma(x, y, z, t) =$ constant. We assume that these surfaces have an outward normal that has a nonzero projection into the vertical so that we can write the depth of a point on these surfaces as $z = \eta(x, y, t)$. Because of the slope of the top and bottom surfaces, pressure has both a horizontal and vertical component when acting on these surfaces. The net pressure acting on the grid cell is given by the area integral of the pressures around the grid cell boundary.

65.3.1 Basic manipulations

Recall the the vector-invariant velocity equation given by equation (65.20)

$$\left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_\sigma + \dot\sigma\,\frac{\partial \boldsymbol{u}}{\partial \sigma} + \widetilde{\zeta}_\mathsf{a}\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -\nabla_{h\sigma}(K+\Phi) - (1/\rho)\,\nabla_{h\sigma} p + \boldsymbol{F}^\mathrm{h}, \tag{65.34}$$

where $\widetilde{\zeta}_\mathsf{a} = \widetilde{\zeta} + f$ is the absolute vorticity. Taking the curl of this equation and projecting onto the vertical direction leads to

$$\frac{\mathrm{D}\widetilde{\zeta}_\mathsf{a}}{\mathrm{D}t} = -\widetilde{\zeta}_\mathsf{a}\,\nabla_{h\sigma}\cdot\boldsymbol{u} + \frac{\hat{\boldsymbol{z}}\cdot(\nabla_{h\sigma}\rho\times\nabla_{h\sigma}p)}{\rho^2} + \hat{\boldsymbol{z}}\cdot\left[\frac{\partial \boldsymbol{u}}{\partial\sigma}\times\nabla_{h\sigma}\dot\sigma + \nabla_{h\sigma}\times\boldsymbol{F}^\mathrm{h}\right] \tag{65.35}$$

where we noted that the planetary vorticity, f, is independent of time and vertical position.

Making use of the mass conservation equation

Mass conservation in the form of equation (64.85)

$$\frac{1}{\rho\hbar}\,\frac{\mathrm{D}(\rho\hbar)}{\mathrm{D}t} = -(\nabla_{h\sigma}\cdot\boldsymbol{u} + \partial\dot\sigma/\partial\sigma), \tag{65.36}$$

renders

$$\rho\hbar\,\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{\widetilde{\zeta}_\mathsf{a}}{\rho\hbar}\right] = \frac{\hat{\boldsymbol{z}}\cdot(\nabla_{h\sigma}\rho\times\nabla_{h\sigma}p)}{\rho^2} + \widetilde{\zeta}_\mathsf{a}\,\frac{\partial\dot\sigma}{\partial\sigma} + \hat{\boldsymbol{z}}\cdot\left[\frac{\partial \boldsymbol{u}}{\partial\sigma}\times\nabla_{h\sigma}\dot\sigma + \nabla_{h\sigma}\times\boldsymbol{F}^\mathrm{h}\right]. \tag{65.37}$$

Massaging the $\dot{\sigma}$ terms

The terms containing $\dot{\sigma}$ can be written in the form

$$\widetilde{\zeta}_{\mathrm{a}}\,\partial_\sigma\dot{\sigma} + \hat{\boldsymbol{z}}\cdot(\partial_\sigma\boldsymbol{u}\times\nabla_{\!\mathrm{h}\sigma}\dot{\sigma}) = \widetilde{\zeta}_{\mathrm{a}}\,\partial_\sigma\dot{\sigma} + \hat{\boldsymbol{z}}\cdot[-\nabla_{\!\mathrm{h}\sigma}\times(\dot{\sigma}\,\partial_\sigma\boldsymbol{u}) + \dot{\sigma}\,\nabla_{\!\mathrm{h}\sigma}\times\partial_\sigma\boldsymbol{u}] \tag{65.38a}$$

$$= \widetilde{\zeta}_{\mathrm{a}}\,\partial_\sigma\dot{\sigma} + \dot{\sigma}\,\partial_\sigma\widetilde{\zeta}_{\mathrm{a}} - \hat{\boldsymbol{z}}\cdot[\nabla_{\!\mathrm{h}\sigma}\times(\dot{\sigma}\,\partial_\sigma\boldsymbol{u})] \tag{65.38b}$$

$$= \partial_\sigma(\dot{\sigma}\,\widetilde{\zeta}_{\mathrm{a}}) - \hat{\boldsymbol{z}}\cdot[\nabla_{\!\mathrm{h}\sigma}\times(\dot{\sigma}\,\partial_\sigma\boldsymbol{u})]\,. \tag{65.38c}$$

65.3.2 Vorticity and potential vorticity equation

The above results allow us to write equation (65.37) in the form

$$\rho\,\hbar\,\frac{\mathrm{D}Q}{\mathrm{D}t} = \frac{\hat{\boldsymbol{z}}\cdot(\nabla_{\!\mathrm{h}\sigma}\rho\times\nabla_{\!\mathrm{h}\sigma}p)}{\rho^2} + \partial_\sigma(\dot{\sigma}\,\widetilde{\zeta}_{\mathrm{a}}) + \nabla_{\!\mathrm{h}\sigma}\cdot[\hat{\boldsymbol{z}}\times\dot{\sigma}\,\partial_\sigma\boldsymbol{u} - \hat{\boldsymbol{z}}\times\boldsymbol{F}^{\mathrm{h}}]\,, \tag{65.39}$$

where we introduced the potential vorticity defined according to the generalized vertical coordinates

$$Q = \frac{\widetilde{\zeta}_{\mathrm{a}}}{\rho\,\hbar}. \tag{65.40}$$

The potential vorticity equation (65.39) has a generally nonzero baroclinicity contribution (see Section 40.4 for more on baroclinicity)

$$\frac{\hat{\boldsymbol{z}}\cdot(\nabla_{\!\mathrm{h}\sigma}\rho\times\nabla_{\!\mathrm{h}\sigma}p)}{\rho^2}, \tag{65.41}$$

so that the potential vorticity (65.40) is generally not materially invariant even if $\dot{\sigma}=0$. Finally, note that it is sometimes convenient to make use of the potential vorticity (65.40) in the horizontal velocity equation (65.34) so that

$$\left[\frac{\partial\boldsymbol{u}}{\partial t}\right]_\sigma + \dot{\sigma}\,\frac{\partial\boldsymbol{u}}{\partial\sigma} + (\hbar\,\rho\,Q)\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -\nabla_{\!\mathrm{h}\sigma}(K+\Phi) - (1/\rho)\,\nabla_{\!\mathrm{h}\sigma}p + \boldsymbol{F}^{\mathrm{h}}. \tag{65.42}$$

Pressure coordinates

The baroclinicity (65.41) vanishes when choosing $\sigma = p$. We already noted this property in the discussion of baroclinicity in Section 40.4. As noted there, pressure does not render a useful potential vorticity since $\dot{\sigma} = \dot{p}$ does not generally vanish for a perfect fluid. Namely, a nonzero $\dot{p}$ merely signals vertical motion, so that $\dot{p}\neq 0$ for both real and perfect fluids. Hence, even though the baroclinicity vanishes by choosing $\sigma = p$, the $\partial_\sigma(\dot{\sigma}\,\widetilde{\zeta}_{\mathrm{a}})$ term does not.

Flux-form potential vorticity budget

Just like we did in Section 65.1.4 for the velocity equation, we can make use of the thickness equation (65.4a) to bring the material time derivative in equation (65.39) into the form

$$\rho\,\hbar\,\frac{\mathrm{D}Q}{\mathrm{D}t} = \rho\,\hbar\,(\partial_t + \boldsymbol{u}\cdot\nabla_{\!\mathrm{h}\sigma} + \dot{\sigma}\partial_\sigma)\,Q + Q\,[\partial_t(\rho\,\hbar) + \nabla_{\!\mathrm{h}\sigma}\cdot(\rho\,\hbar\,\boldsymbol{u}) + \partial_\sigma(\rho\,\hbar\,\dot{\sigma})] \tag{65.43a}$$

$$= \partial_t(\rho\,\hbar\,Q) + \nabla_{\!\mathrm{h}\sigma}\cdot(\rho\,\hbar\,\boldsymbol{u}\,Q) + \partial_\sigma(\rho\,\hbar\,\dot{\sigma}\,Q). \tag{65.43b}$$

Since $\widetilde{\zeta}_{\mathrm{a}} = \hbar\,\rho\,Q$, we see that the term

$$\partial_\sigma(\rho\,\hbar\,\dot{\sigma}\,Q) = \partial_\sigma(\dot{\sigma}\,\widetilde{\zeta}_{\mathrm{a}}), \tag{65.44}$$

also appears on the right hand side of equation (65.39). Hence, it cancels from the flux form potential vorticity equation

$$\left[\frac{\partial(\rho\,\hbar\,Q)}{\partial t}\right]_\sigma = \frac{\hat{\boldsymbol{z}}\cdot(\nabla_\sigma\rho\times\nabla_\sigma p)}{\rho^2} - \nabla_\sigma\cdot\left[\rho\,\hbar\,\boldsymbol{u}\,Q + \hat{\boldsymbol{z}}\times\dot\sigma\,\partial_\sigma\boldsymbol{u} + \hat{\boldsymbol{z}}\times\boldsymbol{F}^{\text{h}}\right], \tag{65.45}$$

which is equivalent to the absolute vorticity equation

$$\left[\frac{\partial\widetilde{\zeta}_{\text{a}}}{\partial t}\right]_\sigma = \frac{\hat{\boldsymbol{z}}\cdot(\nabla_\sigma\rho\times\nabla_\sigma p)}{\rho^2} - \nabla_\sigma\cdot\left[\boldsymbol{u}\,\widetilde{\zeta}_{\text{a}} + \hat{\boldsymbol{z}}\times\dot\sigma\,\partial_\sigma\boldsymbol{u} + \hat{\boldsymbol{z}}\times\boldsymbol{F}^{\text{h}}\right]. \tag{65.46}$$

As a check, note that setting $\sigma = z$ so that $\hbar = 1$ reduces the vorticity equation (65.46) to the vertical component of the vorticity equation (40.42).

65.3.3 Boussinesq ocean

Recall the discussion of the Boussinesq ocean vorticity budget in Section 40.7, where we noted that the vertical component to the absolute vorticity is unaffected by baroclinicity. This property holds in the present context, as seen by returning to the vector-invariant velocity equation (65.34) and setting the factor $1/\rho$ multiplying the pressure gradient to $1/\rho_{\text{o}}$ as part of the Boussinesq ocean

$$(1/\rho)\,\nabla_\sigma p \longrightarrow (1/\rho_{\text{o}})\,\nabla_\sigma p, \tag{65.47}$$

in which ρ_{o} is a constant. In this case the $\nabla_\sigma\times$ operation annihilates pressure and we are left with no vertical component to the baroclinicity. We are thus led to define the Boussinesq potential vorticity

$$Q = \frac{\widetilde{\zeta}_{\text{a}}}{\hbar} \tag{65.48}$$

which satisfies the material and flux-form evolution equations

$$\hbar\,\frac{\mathrm{D}Q}{\mathrm{D}t} = \partial_\sigma(\dot\sigma\,\hbar\,Q) + \nabla_\sigma\cdot[\hat{\boldsymbol{z}}\times\dot\sigma\,\partial_\sigma\boldsymbol{u} - \hat{\boldsymbol{z}}\times\boldsymbol{F}^{\text{h}}] \tag{65.49}$$

$$\left[\frac{\partial(\hbar\,Q)}{\partial t}\right]_\sigma = -\nabla_\sigma\cdot\left[\hbar\,\boldsymbol{u}\,Q + \hat{\boldsymbol{z}}\times\dot\sigma\,\partial_\sigma\boldsymbol{u} + \hat{\boldsymbol{z}}\times\boldsymbol{F}^{\text{h}}\right]. \tag{65.50}$$

We again emphasize that $\dot\sigma$ is generally non-zero, even for a perfect fluid, so that potential vorticity as defined via σ is not generally a material constant for a perfect fluid. It is only when $\dot\sigma = 0$ for a perfect fluid (e.g., σ is buoyancy or specific entropy) that we recover the desirable perfect fluid properties of potential vorticity. We develop the theory for this case in Sections 66.3 and 66.4.

65.4 Exercises

EXERCISE 65.1: CHECKING THE VORTICITY EQUATION
Verify that for $2\,\boldsymbol{\Omega} = f\,\hat{\boldsymbol{z}}$ the choice $\sigma = z$ reduces the vorticity equation (65.46) to the vertical component of the vorticity equation (40.42).

Chapter 66

ISOPYCNAL PRIMITIVE EQUATIONS

For stably stratified fluids, buoyancy is a particularly useful generalized vertical coordinate. Most notably, physical processes away from turbulent boundary layers are oriented according to buoyancy surfaces, and horizontal buoyancy gradients give rise to thermal wind shears in a geostrophically balanced flow. For this reason buoyancy (or entropy) plays a key role in theoretical and numerical models of ocean and atmospheric circulation.

In this chapter we study the hydrostatic Boussinesq equations using buoyancy as the vertical coordinate. The resulting primitive equation set forms the basis for *isopycnal* models of the ocean or isentropic models of the atmosphere. We pay particular attention to the needs of vertically integrating the equations over discrete layers, as required to develop discrete numerical models. In the adiabatic limit, the isopycnal equations reduce to the stacked shallow water equations. After deriving the primitive equations using isopycnal coordinates, we derive the corresponding vorticity and potential vorticity equations. Throughout this chapter we expose details for the practitioner interested in the mathematical formalism for the purpose of analyzing ocean momentum, vorticity and potential vorticity budgets using isopycnal models.

READER'S GUIDE FOR THIS CHAPTER

We assume an understanding of the generalized vertical coordinate mathematics in Chapter 63, kinematics in Chapter 64, and dynamics in Chapter 65. Furthermore, we are concerned with details of vorticity and PV budgets in isopycnal coordinates, with the presentation building from our study of vorticity and potential vorticity in generalized vertical coordinates from Chapter 65.

66.1 Loose threads

When defining PV using h versus $\hbar$, it is best to use different symbols to avoid confusion.

66.2 Layered isopycnal primitive equations

Rather than specializing the generalized vertical coordinate equations provided in Section 65.1, we find it pedagogical to start from the equations written using the geopotential vertical coordinate (see Section 29.1.6)

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_{\mathrm{h}}\varphi + \boldsymbol{F} \qquad \text{horizontal momentum} \tag{66.1a}$$

$$\frac{\partial \varphi}{\partial z} = b \qquad \text{hydrostatic} \tag{66.1b}$$

$$\nabla_{\mathrm{h}} \cdot \boldsymbol{u} + \frac{\partial w}{\partial z} = 0 \qquad \text{continuity} \tag{66.1c}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = \dot{b} \qquad \text{thermodynamics} \tag{66.1d}$$

$$\frac{\mathrm{D}C}{\mathrm{D}t} = \dot{C} \qquad \text{tracers,} \tag{66.1e}$$

where $\boldsymbol{v} = (\boldsymbol{u}, w)$ is the velocity field, $\boldsymbol{u}$ is its horizontal component, φ is the dynamic pressure, b is the buoyancy, and C is an arbitrary tracer concentration. A discrete realization of the isopycnal layer-integrated form of these equations is depicted in Figure 66.1, with the remainder of this section detailing the formulation using isopycnal coordinates for the vertical.

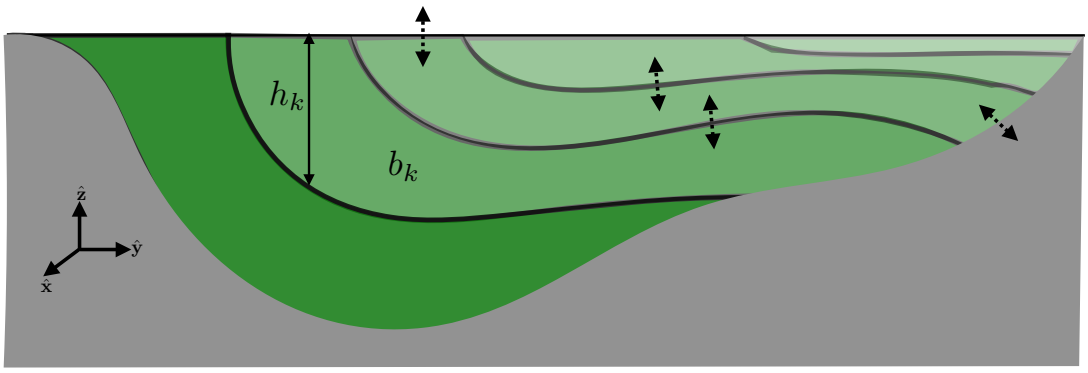

FIGURE 66.1: Schematic of an isopycnal model, formulated as stacked shallow water layers (green layers) that generally allow for the transfer of matter and energy across the layer interfaces as well as across the ocean surface and ocean bottom (as depicted by the double-headed dashed arrows). The dark gray region is land. Discrete layer thicknesses are denoted h_k with corresponding layer buoyancy, b_k.

66.2.1 Montgomery potential and the pressure force

We here consider the horizontal pressure force appearing in isopycnal models, in which we uncover the importance of the Montgomery potential.

Horizontal pressure gradient force

Throughout this chapter we make use of the horizontal derivatives on constant buoyancy surfaces (derived in Section 63.12), written here in the form

$$\nabla_{hb} = \hat{\boldsymbol{x}} \left[\frac{\partial}{\partial x} \right]_b + \hat{\boldsymbol{y}} \left[\frac{\partial}{\partial y} \right]_b . \tag{66.2}$$

Following the discussion in Section 65.1.3, the horizontal pressure thus gradient transforms as

$$\nabla_h \varphi = \nabla_{hb} \varphi - \frac{\partial \varphi}{\partial z} \nabla_{hb} z \tag{66.3a}$$

$$= \nabla_{hb} \varphi - b \nabla_{hb} z \tag{66.3b}$$

$$= \nabla_{hb} (\varphi - b\, z) \tag{66.3c}$$

$$= \nabla_{hb} M, \tag{66.3d}$$

where

$$M = \varphi - b\, z \tag{66.4}$$

defines the Montgomery potential. As the contribution to the horizontal pressure force, the Montgomery potential is the geostrophic streamfunction in buoyancy coordinates (see Section 66.2.4).

The horizontal pressure gradient force for numerical models

It is notable that the horizontal pressure gradient force is determined by the horizontal isopycnal gradient of a single term, the Montgomery potential. Furthermore, as shown below, the Montgomery potential satisfies the buoyancy coordinate form of the hydrostatic balance. Hence, numerical isopycnal models do not suffer from problems with computing the horizontal pressure gradient that can occur with other generalized vertical coordinate models, such as terrain-following models (see Figure 65.1).

Equation (66.3c) is the key step in the formulation, whereby we made use of $\nabla_{hb} b = 0$. This step is available only under certain cases that utilize an idealized equation of state for seawater. In more realistic cases, the buoyancy determining the hydrostatic pressure (i.e., the *mass buoyancy*) is defined locally whereas the generalized vertical coordinate must be defined globally. As a result, there are two terms contributing to the pressure gradient in a manner similar to terrain-following models. *Sun et al.* (1999) and *Hallberg* (2005) discuss this issue in the context of numerical ocean modeling. For present purposes we ignore this detail and continue to assume a simplified equation of state so that $\nabla_{hb} b = 0$.

Hydrostatic balance

Supporting our use of the Montgomery potential as a pressure field, the hydrostatic balance takes the form

$$\frac{\partial M}{\partial b} = \frac{\partial \varphi}{\partial b} - b \frac{\partial z}{\partial b} - z = \frac{\partial \varphi}{\partial z} \frac{\partial z}{\partial b} - b \frac{\partial z}{\partial b} - z = -z, \tag{66.5}$$

where we made use of the hydrostatic balance $\partial \varphi / \partial z = b$ (equation (66.1b)). This result means that M is the buoyancy coordinate version of pressure.

66.2.2 Material time derivative

As seen in Section 64.4, there are two equivalent forms for the material time derivative

$$\frac{\mathrm{D}}{\mathrm{D}t} = \left[\frac{\partial}{\partial t}\right]_z + \boldsymbol{u}\cdot\nabla_{\mathsf{h}} + w\,\frac{\partial}{\partial z} \qquad \text{geopotential form} \tag{66.6a}$$

$$= \left[\frac{\partial}{\partial t}\right]_b + \boldsymbol{u}\cdot\nabla_{\mathsf{hb}} + w^{(\dot{b})}\,\frac{\partial}{\partial z} \qquad \text{isopycnal form,} \tag{66.6b}$$

where

$$w^{(\dot{b})} = \frac{\partial z}{\partial b}\,\frac{\mathrm{D}b}{\mathrm{D}t} \tag{66.7}$$

is the diapycnal velocity component that measures the rate of flow crossing buoyancy surfaces (Section 64.3). Besides differences in the spatial operators, it is important to note that the time derivative operators in equations (66.6a) and (66.6b) are computed on constant geopotential and constant buoyancy surfaces, respectively. However, the horizontal velocity component is the *same* for both forms of the material time derivative

$$\boldsymbol{u} = \hat{\boldsymbol{x}}\,u + \hat{\boldsymbol{y}}\,v = (\mathrm{D}/\mathrm{D}t)\,(\hat{\boldsymbol{x}}\,x + \hat{\boldsymbol{y}}\,y). \tag{66.8}$$

66.2.3 Layer thickness and specific thickness

The continuity equation, $\nabla_{\mathsf{h}}\cdot\boldsymbol{u} + \partial_z w = 0$, is an expression of volume conservation. We already derived the generalized vertical coordinate version of this equation in Section 64.9.3, and thus quote the isopycnal layer thickness result here

$$\left[\frac{\partial h}{\partial t}\right]_b + \nabla_{\mathsf{hb}}\cdot(h\,\boldsymbol{u}) + \Delta_b\,w^{(\dot{b})} = 0. \tag{66.9}$$

The field h measures the isopycnal layer thickness (dimensions of length) and is given by the vertical integral over a layer

$$h = \int_{z(b-\delta b/2)}^{z(b+\delta b/2)} \mathrm{d}z = \int_{b-\delta b/2}^{b+\delta b/2} \frac{\partial z}{\partial b}\,\mathrm{d}b = \int_{b-\delta b/2}^{b+\delta b/2} \hbar\,\mathrm{d}b = \int_{b-\delta b/2}^{b+\delta b/2} N^{-2}\,\mathrm{d}b = \overline{\hbar}\,\mathrm{d}b. \tag{66.10}$$

The specific thickness, $\hbar$, equals to the inverse squared buoyancy frequency

$$\hbar = \frac{\partial z}{\partial b} = N^{-2}, \tag{66.11}$$

and its layer averaged value is

$$\overline{\hbar} = h/\delta b. \tag{66.12}$$

Furthermore, the dia-surface transport velocity is given by

$$w^{(\dot{b})} = \hbar\,\dot{b}. \tag{66.13}$$

Its difference across layer interfaces

$$\Delta_b\,w^{(\dot{b})} = \int_{b-\delta b/2}^{b+\delta b/2} \frac{\partial w^{(\dot{b})}}{\partial b}\,\mathrm{d}b = w^{(\dot{b})}(b+\delta b/2) - w^{(\dot{b})}(b-\delta b/2) \tag{66.14}$$

measures the amount of fluid that diverges from the layer through cross-layer transport.

In the limit that $\delta b \to 0$, we find that the non-dimensional vertical difference operator can

be written in one of the following equivalant manners

$$\lim_{\delta b \to 0} \Delta_b = \delta b \frac{\partial}{\partial b} = \delta b \frac{\partial z}{\partial b} \frac{\partial}{\partial z} = \delta z \frac{\partial}{\partial z} = h \frac{\partial}{\partial z}. \tag{66.15}$$

The relations are useful in moving between discrete and continuous formulations of the isopycnal equations.

Specific thickness equation

Inserting $h = \overline{\hbar}\, \delta b$ into the thickness equation (66.9) leads to

$$\left[\frac{\partial \overline{\hbar}}{\partial t}\right]_b + \nabla_{\mathsf{hb}} \cdot (\overline{\hbar}\, \boldsymbol{u}) + \partial_b\, w^{(\dot{b})} = 0, \tag{66.16}$$

where we pulled the buoyancy increment, δb, outside of the time and horizontal derivative operators since δb is a fixed number for a chosen layer. We also used the identity (66.15) relating the difference operator to a differential operator

$$\delta b\, \partial_b = \Delta_b. \tag{66.17}$$

For a vertically continuous treatment, equation (66.16) can be written with $\hbar$ rather than the discrete layer averaged value

$$\left[\frac{\partial \hbar}{\partial t}\right]_b + \nabla_{\mathsf{hb}} \cdot (\hbar\, \boldsymbol{u}) + \partial_b\, w^{(\dot{b})} = 0. \tag{66.18}$$

It is generally more convenient to use the specific thickness when working with the vertically continuous equations, whereas the finite layer thickness, h, is more suitable for the layer integrated equations.

Adiabatic limit

When $w^{(\dot{b})} \neq 0$, the three terms in the thickness equation (66.9) or the specific thickness equation (66.16) are coupled. We discussed this coupling in Section 64.5 as part of our broader study of the vertical velocity and the dia-surface velocity. When considering perfect fluids, we can set $w^{(\dot{b})} = \hbar\, \dot{b} = 0$ since the fluid has no mixing. In this case the layer thickness is altered only through horizontal rearrangements of volume within a layer according to the adiabatic thickness equation

$$\left[\frac{\partial h}{\partial t}\right]_b + \nabla_{\mathsf{hb}} \cdot (h\, \boldsymbol{u}) = 0. \tag{66.19}$$

As further discussed in Section 66.2.7, the adiabatic limit brings the discrete isopycnal model into accord with the immiscible stacked shallow water models discussed in Part VI of this book.

66.2.4 Ocean equations

Bringing the pieces together leads to the isopycnal version of the hydrostatic Boussinesq equations, which are the basis for numerical isopycnal ocean models

$$\left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_b + (\boldsymbol{u} \cdot \nabla_{\mathsf{hb}})\, \boldsymbol{u} + (w^{(\dot{b})}\, \partial_z)\, \boldsymbol{u} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_{\mathsf{hb}}\, M + \boldsymbol{F}^h \tag{66.20a}$$

$$\frac{\partial M}{\partial b} = -z \tag{66.20b}$$

$$\left[\frac{\partial h}{\partial t}\right]_b + \nabla_{\mathsf{hb}} \cdot (h\,\boldsymbol{u}) + \Delta_b w^{(\dot{b})} = 0 \tag{66.20c}$$

$$\left[\frac{\partial (h\,C)}{\partial t}\right]_b + \nabla_{\mathsf{hb}} \cdot (h\,C\,\boldsymbol{u} + h\,\boldsymbol{J}^h) + \Delta_b(C\,w^{(\dot{b})} + J^{(b)}) = 0, \tag{66.20d}$$

where the tracer equation includes possible subgrid scale flux contributions as well as advective transport. Notice how the advective transport is two-dimensional in the adiabatic case with $\dot{b} = 0$, in which case layer-integrated scalar properties, such as volume and tracer content, are constant within buoyancy layers. Also note that geostrophic balance in the horizontal momentum equation (66.20a) gives

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathsf{g}} = -\nabla_{\mathsf{hb}}\,M \implies f\,u_{\mathsf{g}} = -\left[\frac{\partial M}{\partial y}\right]_b \qquad \text{and} \qquad f\,v_{\mathsf{g}} = \left[\frac{\partial M}{\partial x}\right]_b . \tag{66.21}$$

Hence, the Montgomery potential is the streamfunction for geostrophic flow as represented using buoyancy coordinates.

66.2.5 Thickness weighted velocity equation

As in our discusion of the stacked shallow water system in Section 36.3, we can write the velocity equation (66.20a) in its thickness weighted form, with this form suited to studying momentum balances and pressure form stresses. The manipulations are directly analogous to the shallow water case in Section 36.3, whereby we multiply equation (66.20a) by the thickness, h, and multiply the thickness equation (66.20c) by the horizontal velocity, $\boldsymbol{u}$, and then summing to find

$$\left[\frac{\partial (h\,\boldsymbol{u})}{\partial t}\right]_b + \nabla_{\mathsf{hb}} \cdot (h\,\boldsymbol{u} \otimes \boldsymbol{u}) + \Delta_b(w^{(\dot{b})}\,\boldsymbol{u}) + f\,\hat{\boldsymbol{z}} \times (h\,\boldsymbol{u}) = -h\,\nabla_{\mathsf{hb}}\,M + h\,\boldsymbol{F}^h. \tag{66.22}$$

For the diapycnal transfer term, we made use of the identity

$$\lim_{\delta b \to 0} \Delta_b = h\,\partial_z \tag{66.23}$$

from equation (66.15).

66.2.6 Vector-invariant horizontal momentum equation

It is common for isopycnal models to make use of the vector-invariant form of the momentum equation derived in Section 65.1.5. Introducing the isopycnal version of the relative vorticity

$$\hat{\boldsymbol{z}}\,\widetilde{\zeta} \equiv \nabla_{\mathsf{hb}} \times \boldsymbol{u} = \left[\frac{\partial v}{\partial x}\right]_b - \left[\frac{\partial u}{\partial y}\right]_b \tag{66.24}$$

renders the vector-invariant horizontal momentum equation

$$\left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_b + w^{(\dot{b})}\,\partial_z \boldsymbol{u} + \widetilde{\zeta}_{\mathsf{a}}\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_{\mathsf{hb}}\mathcal{B} + \boldsymbol{F}^h, \tag{66.25}$$

where

$$\mathcal{B} = M + \boldsymbol{u} \cdot \boldsymbol{u}/2 = \varphi - b\,z + \boldsymbol{u} \cdot \boldsymbol{u}/2 \tag{66.26}$$

is the Bernoulli potential for a hydrostatic Boussinesq fluid (see Section 26.9.3), and

$$\widetilde{\zeta}_{\mathsf{a}} = \widetilde{\zeta} + f \tag{66.27}$$

is the vertical component to the absolute vorticity using isopycnal coordinates. Note that we can further introduce the isopycnal potential vorticity (Section 66.3.2)

$$h\,Q = \widetilde{\zeta}_{\mathsf{a}} \tag{66.28}$$

to bring the momentum equation to the form

$$\left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_b + w^{(\dot{b})}\,\partial_z \boldsymbol{u} + Q\,\hat{\boldsymbol{z}} \times (h\,\boldsymbol{u}) = -\nabla_{\mathsf{hb}}\mathcal{B} + \boldsymbol{F}^h. \tag{66.29}$$

This form is commonly used as the starting point for certain theoretical analyses, particularly when considering the adiabatic limit in which $w^{(\dot{b})} = 0$.

66.2.7 Connection to the stacked shallow water equations

We can make use of the material time derivative operator (66.6b) to write the material form of the adiabatic and inviscid equations (66.20a)-(66.20c)

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_{\mathsf{hb}}\,M \tag{66.30a}$$

$$\frac{\partial M}{\partial b} = -z \tag{66.30b}$$

$$\frac{\mathrm{D}h}{\mathrm{D}t} + h\,\nabla_{\mathsf{hb}} \cdot \boldsymbol{u} = 0. \tag{66.30c}$$

These isopycnal momentum and thickness equations are isomorphic to those for a single layer of adiabatic shallow water fluid (see Section 35.2). This isomorphism allows us to derive the vorticity and potential vorticity equations in Section 66.3, making use of the shallow water manipulations from Section 39.3.

66.2.8 Diapycnal transfer

At ocean boundaries, the diapycnal term, $w^{(\dot{b})}$, acccounts for the transfer of matter across the ocean boundaries via precipitation, evaporation, ice melt/form, and river runoff. Notably, this matter transfer also generally gives rise to a transfer of trace matter (tracers), heat (evaporation and precipitation carry a heat content), and momentum (precipitation generally has nonzero momentum). In the ocean interior, $w^{(\dot{b})}$ affects the transfer of volume, tracer, and momentum between layers as induced by irreversible processes such as mixing.

66.2.9 Momentum transfer

Pressure form stress mechanically couples isopycnal layers even in the absence of diapycnal matter transfer. We discussed the physics of form stress for the shallow water system in Section 36.4 and more generally in Section 28.1. Furthermore, there are a suite of unresolved processes giving rise to lateral and vertical stresses. Typical ocean model treatments incorporate a turbulent friction in the ocean interior, with lateral stresses acting within a layer and diapycnal stresses acting across isopycnal layer interfaces. A bottom drag is typically applied at the ocean bottom and a turbulent stress applied at the ocean surface. Details for the boundary stresses involve the physics of boundary layer turbulence, which is a topic outside of our scope.

66.2.10 Allowing for layers to vanish and reappear

Isopycnal layers have a transient existence at any particular horizontal position since a layer can incrop at the ocean bottom and outcrop at the ocean surface (see Figure 66.1). The seasonal

cycle of warming and cooling is a canonical example of layer outcropping at the surface ocean. A formulational expedient to handle vanishing layers is to assume that all layers exist everywhere horizontally across the ocean domain, but to allow for zero layer thickness where a layer has zero volume. We made use of this approach when discussing available potential energy in Section 29.9. To admit this feature in a discrete model requires a careful realization of L'Hôpital's rule of differential calculus, thus ensuring the discrete model conserves properties in the presence of layers that can appear and disappear at any particular point in the domain.

66.3 Perfect fluid PV using isopycnal coordinates

In Section 41.5, we showed that the absolute vorticity in a Boussinesq hydrostatic fluid with a simplified seawater equation of state (Section 42.3), when projected into the direction normal to constant buoyancy surface, $\boldsymbol{\omega}_a \cdot \nabla b$, is not affected by baroclinicity; i.e., that projection annihilates the baroclinicity vector. From that property we conclude that $\boldsymbol{\omega}_a \cdot \nabla b$ is the potential vorticity for the Boussinesq hydrostatic fluid.

For a Boussinesq hydrostatic fluid, isopycnal coordinates build in the above feature of buoyancy surfaces. Indeed, as shown in Section 65.3.3, the vertical component to baroclinicity vanishes for any generalized vertical coordinate representation of a Boussinesq fluid. Hence, buoyancy coordinates are not special from this perspective. Instead, they are special since in the case of a perfect fluid, the buoyancy based potential vorticity is materially invariant. Deriving this result is one purpose of this section. Note that in Section 65.3, we derived the potential vorticity equation for a hydrostatic fluid represented with generalized vertical coordinates. We could merely specialize that result to the current case. However, we prefer to here work through the maths to help further our experience performing certain of the key manipulations arising with vorticity in rotating and stratified fluids. Hence, consider this section, as well as Section 66.4, to be extended worked exercises.

66.3.1 Derivation of the vorticity equation

Acting with the vertical projection of the curl, $\hat{\boldsymbol{z}} \cdot (\nabla_{hb} \times)$, onto the adiabatic and inviscid form of the vector-invariant velocity equation (66.25) leads to the isopycnal vorticity equation

$$\left[\frac{\partial \widetilde{\zeta}_a}{\partial t}\right]_b + (\boldsymbol{u} \cdot \nabla_{hb})\, \widetilde{\zeta}_a = -\widetilde{\zeta}_a\, \nabla_{hb} \cdot \boldsymbol{u} \tag{66.31}$$

where

$$\widetilde{\zeta}_a = f + \hat{\boldsymbol{z}} \cdot (\nabla_{hb} \times \boldsymbol{u}) = f + \widetilde{\zeta} \tag{66.32}$$

is the absolute vorticity, written as the planetary vorticity plus the isopycnal relative vorticity. The left hand side of equation (66.31) is the material time derivative of absolute vorticity (see equation (66.6b)), so that we can write

$$\frac{\mathrm{D}\widetilde{\zeta}_a}{\mathrm{D}t} = -\widetilde{\zeta}_a\, \nabla_{hb} \cdot \boldsymbol{u}. \tag{66.33}$$

As advertised above, there is no baroclinicity vector on the right hand side of this vorticity equation. Again, that property results from our choice to use isopycnal coordinates.

66.3.2 Derivation of the potential vorticity equation

We now make use of the thickness equation derived in Section 66.2.3, here realized in its material form to eliminate the convergence $\nabla_{hb} \cdot \boldsymbol{u}$ on the right hand side of equation (66.33), thus leading

to

$$\frac{\mathrm{D}\widetilde{\zeta}_{\mathsf{a}}}{\mathrm{D}t} - \frac{\widetilde{\zeta}_{\mathsf{a}}}{h}\frac{\mathrm{D}h}{\mathrm{D}t} = 0. \tag{66.34}$$

Introducing the isopycnal potential vorticity

$$Q = \frac{\widetilde{\zeta}_{\mathsf{a}}}{h} = \frac{f + \widetilde{\zeta}}{h} \tag{66.35}$$

leads to

$$\frac{\mathrm{D}Q}{\mathrm{D}t} = 0. \tag{66.36}$$

Expanding the material time derivative into its components according to equation (66.6b), and making use of the adiabatic form of the thickness equation leads to the flux-form equation

$$\left[\frac{\partial (h\,Q)}{\partial t}\right]_b + \nabla_{\mathsf{hb}} \cdot (h\,Q\,\boldsymbol{u}) = 0. \tag{66.37}$$

As noted in Section 66.2.3, when formulating the vertically continuous equations rather than finite thickness layered equations, it is more convenient to make use of the specific thickness, $\hbar$, rather than the layer thickness, h. In this case we are motivated to define the potential vorticity as

$$Q = \frac{\widetilde{\zeta}_{\mathsf{a}}}{\hbar} = \frac{f + \widetilde{\zeta}}{\hbar} = (f + \widetilde{\zeta})\, N^2. \tag{66.38}$$

The corresponding PV equation is identical to equation (66.37), only now with h replaced by $\hbar$.

66.3.3 Coordinate transforming vorticity and potential vorticity

As just shown, PV for a hydrostatic Boussinesq fluid can be written in the relatively simple form of a shallow water PV when choosing isopycnal coordinates. Here is a direct transformation from Cartesian to isopyncal coordinates that also reveals this form

$$(\boldsymbol{\omega}^{\mathrm{hy}} + f\,\hat{\boldsymbol{z}}) \cdot \nabla b = -\frac{\partial v}{\partial z}\frac{\partial b}{\partial x} + \frac{\partial u}{\partial z}\frac{\partial b}{\partial y} + \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} + f\right)\frac{\partial b}{\partial z} \tag{66.39a}$$

$$= \frac{\partial b}{\partial z}\left[f + \left(\frac{\partial v}{\partial x} - \frac{\partial v}{\partial z}\frac{\partial b/\partial x}{\partial b/\partial z}\right) - \left(\frac{\partial u}{\partial y} - \frac{\partial u}{\partial z}\frac{\partial b/\partial y}{\partial b/\partial z}\right)\right] \tag{66.39b}$$

$$= \frac{\partial b}{\partial z}\left[f + \left(\frac{\partial v}{\partial x}\right)_b - \left(\frac{\partial u}{\partial y}\right)_b\right] \tag{66.39c}$$

$$= \frac{f + (\partial v/\partial x)_b - (\partial u/\partial y)_b}{\partial z/\partial b} \tag{66.39d}$$

$$= \frac{f + \widetilde{\zeta}}{\hbar} \tag{66.39e}$$

$$= Q. \tag{66.39f}$$

66.4 Isopycnal coordinate PV with irreversible processes

In Section 66.3, we considered the PV equation for an adiabatic, inviscid, hydrostatic, Boussinesq fluid using isopycnal vertical coordinates. We here extend to the case of friction in the momentum equation and diabatic heating in the buoyancy equation. We consider two ways to derive the governing equations. One is to convert the non-hydrostatic PV equation in Exercise 41.2 to isopycnal coordinates, after making the hydrostatic approximation. The second is to start from the equations of motion in isopycnal coordinates and derive the vorticity equation and then the

PV equation. We make use of the vertically continuous equations, thus warranting our use of specific thickness, $\hbar$, rather than layer thickness, h (see Section 66.2.3).

Note that much of this section is a specialization of the more general considerations of Section 65.3. Nonetheless, we here revisit some of the earlier derivations as a means to bolster our mathematical manipulation muscle.

66.4.1 Derivation method I

As derived earlier in this chapter, the equations of motion with diabatic heating and friction, written using isopycnal (or buoyancy) vertical coordinates, take the form

$$\left[\frac{\partial \boldsymbol{u}}{\partial t}\right]_b + (\boldsymbol{u}\cdot\nabla_{\mathsf{hb}})\,\boldsymbol{u} + \dot{b}\,\frac{\partial \boldsymbol{u}}{\partial b} + \boldsymbol{f}\times\boldsymbol{u} = -\nabla_{\mathsf{hb}}\,M + \boldsymbol{F} \tag{66.40a}$$

$$\frac{\partial M}{\partial b} = -z \tag{66.40b}$$

$$\left[\frac{\partial \hbar}{\partial t}\right]_b + \nabla_{\mathsf{hb}}\cdot(\hbar\,\boldsymbol{u}) = -\frac{\partial(\hbar\,\dot{b})}{\partial b} \tag{66.40c}$$

$$\frac{\mathrm{D}\,b}{\mathrm{D}t} = \dot{b}. \tag{66.40d}$$

Note that in this section choose to write the dia-surface transport operator in the form

$$w^{(\dot{b})}\,\partial_z = \dot{b}\,\partial_b. \tag{66.41}$$

We can make use of the material time derivative operator (66.6b) to write the material form of the equations

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + \boldsymbol{f}\times\boldsymbol{u} = -\nabla_{\mathsf{hb}}\,M + \boldsymbol{F} \tag{66.42a}$$

$$\frac{\partial M}{\partial b} = -z \tag{66.42b}$$

$$\frac{\mathrm{D}\hbar}{\mathrm{D}t} + \hbar\,\nabla_{\mathsf{hb}}\cdot\boldsymbol{u} = -\hbar\,\frac{\partial \dot{b}}{\partial b}. \tag{66.42c}$$

Curl of the velocity equation

We start taking the curl, $\nabla_{\mathsf{hb}}\times$, of the velocity equation (66.40a), thus leading to the isopycnal vorticity equation

$$\left[\frac{\partial \widetilde{\zeta}_{\mathsf{a}}}{\partial t}\right]_b + (\boldsymbol{u}\cdot\nabla_{\mathsf{hb}})\,\widetilde{\zeta}_{\mathsf{a}} + \dot{b}\left[\frac{\partial \widetilde{\zeta}_{\mathsf{a}}}{\partial b}\right] = -\widetilde{\zeta}_{\mathsf{a}}\,\nabla_{\mathsf{hb}}\cdot\boldsymbol{u} + \hat{\boldsymbol{z}}\cdot\left[\frac{\partial \boldsymbol{u}}{\partial b}\times\nabla_{\mathsf{hb}}\dot{b} + \nabla_{\mathsf{hb}}\times\boldsymbol{F}\right]. \tag{66.43}$$

The left hand side of equation (66.43) is the material time derivative of absolute vorticity (see equation (66.6b)), so that

$$\frac{\mathrm{D}\widetilde{\zeta}_{\mathsf{a}}}{\mathrm{D}t} = -\widetilde{\zeta}_{\mathsf{a}}\,\nabla_{\mathsf{hb}}\cdot\boldsymbol{u} + \hat{\boldsymbol{z}}\cdot\left[\frac{\partial \boldsymbol{u}}{\partial b}\times\nabla_{\mathsf{hb}}\dot{b} + \nabla_{\mathsf{hb}}\times\boldsymbol{F}\right]. \tag{66.44}$$

Now make use of the thickness equation in the material form (66.42c) to eliminate the convergence $\nabla_{\mathsf{hb}}\cdot\boldsymbol{u}$ on the right hand side, thus leading to

$$\frac{\mathrm{D}\widetilde{\zeta}_{\mathsf{a}}}{\mathrm{D}t} - \frac{\widetilde{\zeta}_{\mathsf{a}}}{\hbar}\left[\frac{\mathrm{D}\hbar}{\mathrm{D}t} - \hbar\,\frac{\partial \dot{b}}{\partial b}\right] = \hat{\boldsymbol{z}}\cdot\left[\frac{\partial \boldsymbol{u}}{\partial b}\times\nabla_{\mathsf{hb}}\dot{b} + \nabla_{\mathsf{hb}}\times\boldsymbol{F}\right]. \tag{66.45}$$

Introducing the isopycnal potential vorticity

$$Q = \frac{\widetilde{\zeta}_{\mathsf{a}}}{\hbar} = \frac{\widetilde{\zeta} + f}{\hbar} \tag{66.46}$$

leads to

$$\hbar \, \frac{\mathrm{D}Q}{\mathrm{D}t} = \zeta_a \, \frac{\partial \dot{b}}{\partial b} + \hat{\boldsymbol{z}} \cdot \left[\frac{\partial \boldsymbol{u}}{\partial b} \times \nabla_{\mathsf{hb}} \dot{b} + \nabla_{\mathsf{hb}} \times \boldsymbol{F} \right]. \tag{66.47}$$

Massaging the diabatic terms

The diabatic terms can be written

$$\zeta_a \, \frac{\partial \dot{b}}{\partial b} + \hat{\boldsymbol{z}} \cdot \left[\frac{\partial \boldsymbol{u}}{\partial b} \times \nabla_{\mathsf{hb}} \dot{b} \right] = \zeta_a \, \frac{\partial \dot{b}}{\partial b} + \dot{b} \, \frac{\partial \widetilde{\zeta}}{\partial b} - \hat{\boldsymbol{z}} \cdot \left[\nabla_{\mathsf{hb}} \times \dot{b} \frac{\partial \boldsymbol{u}}{\partial b} \right] \tag{66.48a}$$

$$= \zeta_a \, \frac{\partial \dot{b}}{\partial b} + \dot{b} \, \frac{\partial \widetilde{\zeta}_{\mathsf{a}}}{\partial b} - \hat{\boldsymbol{z}} \cdot \left[\nabla_{\mathsf{hb}} \times \dot{b} \frac{\partial \boldsymbol{u}}{\partial b} \right] \tag{66.48b}$$

$$= \frac{\partial (\widetilde{\zeta}_{\mathsf{a}} \, \dot{b})}{\partial b} - \hat{\boldsymbol{z}} \cdot \left[\nabla_{\mathsf{hb}} \times \dot{b} \frac{\partial \boldsymbol{u}}{\partial b} \right] \tag{66.48c}$$

$$= \frac{\partial (\widetilde{\zeta}_{\mathsf{a}} \, \dot{b})}{\partial b} + \nabla_{\mathsf{hb}} \cdot \left[\hat{\boldsymbol{z}} \times \dot{b} \frac{\partial \boldsymbol{u}}{\partial b} \right], \tag{66.48d}$$

where the second equality follows since the Coriolis parameter is independent of the buoyancy.

The PV equation

The PV equation takes the material form

$$\hbar \left[\frac{\mathrm{D}Q}{\mathrm{D}t} \right] = \frac{\partial (\widetilde{\zeta}_{\mathsf{a}} \, \dot{b})}{\partial b} + \nabla_{\mathsf{hb}} \cdot \left[\hat{\boldsymbol{z}} \times \dot{b} \frac{\partial \boldsymbol{u}}{\partial b} - \hat{\boldsymbol{z}} \times \boldsymbol{F} \right]. \tag{66.49}$$

Expanding the material time derivative into its components (66.6b), and making use of the thickness equation (66.40c), leads to the flux-form equation

$$\left[\frac{\partial (\hbar \, Q)}{\partial t} \right]_b + \nabla_{\mathsf{hb}} \cdot (\hbar \, Q \, \boldsymbol{u}) + \frac{\partial (\hbar \, Q \, \dot{b})}{\partial b} = \frac{\partial (\widetilde{\zeta}_{\mathsf{a}} \, \dot{b})}{\partial b} + \nabla_{\mathsf{hb}} \cdot \left[\hat{\boldsymbol{z}} \times \dot{b} \frac{\partial \boldsymbol{u}}{\partial b} - \hat{\boldsymbol{z}} \times \boldsymbol{F} \right]. \tag{66.50}$$

Since $\hbar \, Q = \widetilde{\zeta}_{\mathsf{a}}$, the ∂_b terms cancel, thus leaving the flux-form PV equation

$$\left[\frac{\partial (\hbar \, Q)}{\partial t} \right]_b = -\nabla_{\mathsf{hb}} \cdot \left[\hbar \, Q \, \boldsymbol{u} - \hat{\boldsymbol{z}} \times \dot{b} \frac{\partial \boldsymbol{u}}{\partial b} + \hat{\boldsymbol{z}} \times \boldsymbol{F} \right]. \tag{66.51}$$

66.4.2 Derivation method II

The alternative method to derive the PV equation in isopycnal coordinates is to start from the hydrostatic Boussinesq PV equation in geopotential vertical coordinates, and directly transform to isopycnal coordinates. For this purpose we start from the discussion in Section 41.5.2 to write the material evolution of PV for a hydrostatic and Boussinesq fluid

$$\frac{\mathrm{D}Q}{\mathrm{D}t} = \nabla \cdot \left[(f \, \hat{\boldsymbol{z}} + \boldsymbol{\omega}_{\mathrm{hy}}) \, \dot{b} + b \, \nabla \times \boldsymbol{F} \right], \tag{66.52}$$

where

$$Q = \boldsymbol{\omega}_{\text{a}}^{\text{hy}} \cdot \nabla b = \boldsymbol{\omega}^{\text{hy}} \cdot \nabla b + f \, \frac{\partial b}{\partial z} \qquad \text{and} \qquad \boldsymbol{\omega}_{\text{hy}} = -\hat{\boldsymbol{x}} \frac{\partial v}{\partial z} + \hat{\boldsymbol{y}} \frac{\partial u}{\partial z} + \hat{\boldsymbol{z}} \left[\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right]. \tag{66.53}$$

The simplest term in equation (66.52) to transform to isopycnal coordinates is the curl of the horizontal friction vector

$$\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}) = \hat{\boldsymbol{z}} \cdot \nabla \times (F^x, F^y, 0), \tag{66.54}$$

which takes the form

$$\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}) = \hbar^{-1} \, \hat{\boldsymbol{z}} \cdot (\nabla_{\text{hb}} \times \boldsymbol{F}) = -\hbar^{-1} \, \nabla_{\text{hb}} \cdot (\hat{\boldsymbol{z}} \times \boldsymbol{F}). \tag{66.55}$$

The diabatic term requires some more work. Since the vorticity has zero divergence, the diabatic term can be written as

$$\nabla \cdot \left[(f \, \hat{\boldsymbol{z}} + \boldsymbol{\omega}_{\text{hy}}) \, \dot{b} \right] = (f \, \hat{\boldsymbol{z}} + \boldsymbol{\omega}_{\text{hy}}) \cdot \nabla \dot{b} \tag{66.56a}$$

$$= f \, \frac{\partial \dot{b}}{\partial z} - \frac{\partial v}{\partial z} \frac{\partial \dot{b}}{\partial x} + \frac{\partial u}{\partial z} \frac{\partial \dot{b}}{\partial y} + \left[\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right] \frac{\partial \dot{b}}{\partial z}. \tag{66.56b}$$

We now introduce horizontal derivatives on isopycnal surfaces according to the following relation (see Section 63.12.2)

$$\nabla_{\text{h}} = \nabla_{\text{hb}} + \nabla_{\text{h}} b \left[\frac{\partial z}{\partial b} \right] \frac{\partial}{\partial z} \tag{66.57}$$

Doing so leads to

$$\begin{aligned}
\nabla \cdot \left[(f \, \hat{\boldsymbol{z}} + \boldsymbol{\omega}_{\text{hy}}) \, \dot{b} \right] &= f \, \frac{\partial \dot{b}}{\partial z} - \frac{\partial v}{\partial z} \frac{\partial \dot{b}}{\partial x} + \frac{\partial u}{\partial z} \frac{\partial \dot{b}}{\partial y} + \left[\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right] \frac{\partial \dot{b}}{\partial z} \\
&= f \, \frac{\partial \dot{b}}{\partial z} - \frac{\partial v}{\partial z} \left(\left[\frac{\partial \dot{b}}{\partial x} \right]_b + \left[\frac{\partial b}{\partial x} \right]_z \frac{\partial z}{\partial b} \frac{\partial \dot{b}}{\partial z} \right) + \frac{\partial u}{\partial z} \left(\left[\frac{\partial \dot{b}}{\partial y} \right]_b + \left[\frac{\partial b}{\partial y} \right]_z \frac{\partial z}{\partial b} \frac{\partial \dot{b}}{\partial z} \right) \\
&\quad + \frac{\partial \dot{b}}{\partial z} \left(\left[\frac{\partial v}{\partial x} \right]_b + \left[\frac{\partial b}{\partial x} \right]_z \frac{\partial z}{\partial b} \frac{\partial v}{\partial z} \right) - \frac{\partial \dot{b}}{\partial z} \left(\left[\frac{\partial u}{\partial y} \right]_b + \left[\frac{\partial b}{\partial y} \right]_z \frac{\partial z}{\partial b} \frac{\partial u}{\partial z} \right) \\
&= f \, \frac{\partial \dot{b}}{\partial z} - \frac{\partial v}{\partial z} \left[\frac{\partial \dot{b}}{\partial x} \right]_b + \frac{\partial u}{\partial z} \left[\frac{\partial \dot{b}}{\partial y} \right]_b + \widetilde{\zeta} \left[\frac{\partial \dot{b}}{\partial z} \right] \\
&= \frac{\partial b}{\partial z} \left(\widetilde{\zeta}_{\text{a}} \left[\frac{\partial \dot{b}}{\partial b} \right] - \frac{\partial v}{\partial b} \left[\frac{\partial \dot{b}}{\partial x} \right]_b + \frac{\partial u}{\partial b} \left[\frac{\partial \dot{b}}{\partial y} \right]_b \right) \\
&= \hbar^{-1} \left(\widetilde{\zeta}_{\text{a}} \left[\frac{\partial \dot{b}}{\partial b} \right] + \hat{\boldsymbol{z}} \cdot \left[\frac{\partial \boldsymbol{u}}{\partial b} \times \nabla_{\text{hb}} \dot{b} \right] \right) \\
&= \hbar^{-1} \left(\widetilde{\zeta}_{\text{a}} \left[\frac{\partial \dot{b}}{\partial b} \right] + \dot{b} \left[\frac{\partial \widetilde{\zeta}_{\text{a}}}{\partial b} \right] + \nabla_{\text{hb}} \cdot \left[\hat{\boldsymbol{z}} \times \dot{b} \, \frac{\partial \boldsymbol{u}}{\partial b} \right] \right) \\
&= \hbar^{-1} \left(\frac{\partial (\dot{b} \, \widetilde{\zeta}_{\text{a}})}{\partial b} + \nabla_{\text{hb}} \cdot \left[\hat{\boldsymbol{z}} \times \dot{b} \, \frac{\partial \boldsymbol{u}}{\partial b} \right] \right).
\end{aligned} \tag{66.58}$$

To reach the penultimate step we noted that $\partial f / \partial b = 0$ so that we could form the derivative of the absolute vorticity. Bringing the pieces together leads to the PV equation (66.49) derived starting from the isopycnal version of the equations of motion.

66.4.3 Comments

The flux-form PV equation (66.51) manifests the impermeability theorem of Chapter 42 since the right hand side is the isopycnal convergence of a flux.

Chapter 67

SHALLOW WATER THICKNESS WEIGHTED AVERAGING

There are a variety of mathematical formalisms used to frame the study of how linear waves, nonlinear waves, eddies, and fully developed turbulence interact with a mean flow. A distinctly geophysical element enters these studies through the primary role of vertical stratification arising from gravitation, with stratification particularly important for large scales flows where motions are approximately hydrostatic. A further specialization to the oceanographic context arises since there are few regions where zonal averages apply, which contrasts to the atmospheric case.[1] The *thickness weighted averaging* (TWA) method has emerged as a useful formalism for stratified flows, with particular use for studies of geostrophic eddies and their parameterization. In this chapter, we develop the TWA equations for the adiabatic stacked shallow water model. Our focus concerns the derivation of the TWA equations as well as their physical interpretation.

As noted in the introduction to Part VI of this book, the adiabatic stacked shallow water model exposes key facets of stratified geophysical flows without requiring the mathematics of generalized vertical coordinates developed in Chapters 63, 64, 65, and 66. The core simplification arises by assuming that horizontal motion has no vertical dependence within each shallow water layer, which then means that vertical motion as well as the hydrostatic pressure are linear functions of vertical position within each layer. That is, the shallow water fluid moves as extensible vertical columns (Section 35.2.8). It follows that horizontal pressure gradients do not need to be projected along the slope of the layer since they are vertically constant within a layer. In contrast, this projection is needed for a continuously stratified fluid described by generalized vertical coordinates, as illustrated in Figure 63.4. Hence, the shallow water equations for momentum, thickness, and tracers retain their use of Cartesian coordinates even though the layer interfaces undulate and are thus not generally horizontal. This mathematical feature of shallow water fluids aids in our pedagogical development of the TWA method.

Young (2012) offers an elegant application of the TWA to the continuously stratified Boussinesq hydrostatic fluid, with this paper the culmination of many years of prior work (see *Young* (2012) for citations). Penetrating the TWA approach for continuously stratified fluids requires an understanding of generalized vertical coordinates and the attendant tensor analysis such as that developed in Chapters 63, 64, 65, and 66. In the present chapter, we focus on the TWA equations for the adiabatic shallow water model. Doing so minimizes the mathematical requirements while exposing the key physical concepts. It also offers a useful baseline for those using stacked shallow water models for studies of adiabatic waves and geostrophic turbulence. Digesting the material in this chapter, and then coupling to skills in generalized vertical coordinate tensor analysis, prepares one for penetrating *Young* (2012). Afterward, the mathematically inclined reader may study the work of *Maddison and Marshall* (2013), who provide a somewhat more general mathematical framework for thickness weighted averaging.

[1] The Southern Ocean is a notable ocean exception, as discussed in Sections 28.5 and 36.7.

READER'S GUIDE FOR THIS CHAPTER

In this chapter we assume a working knowledge of the shallow water model presented in Chapters 35, 36, and 39, with particular attention given to the pressure force as realized both as a contact force and a body force (see Chapter 28 and Section 36.4). The TWA equations offer a useful framework for eddy parameterizations, with parameterizations for the tracer equation discussed in Chapters 70 and 71. Parameterizations for both the tracer equation and the momentum equation remain a topic of ongoing research, particularly in the oceanography literature.

67.1 Loose threads

- Build more into the bolus discussion in Section 67.3 as per Section 4.5 of *McWilliams* (2006).
- More discussion of Taylor-Bretherton relation (67.92).
- Write the EP fluxes for quasi-geostrophic shallow water Rossby waves.
- Write the EP fluxes for 2d non-divergent Rossby waves.
- Formulate the TWA energy equations as in Loose et al.

- Is there a gauge that offers good options for parameterization?

67.2 The unaveraged thickness weighted equations

The thickness weighted averaging formalism starts from flux-form evolution equations rather than advective form equations. Applying this approach to the shallow water model means that we focus on the thickness equation (35.79a), the thickess weighted tracer equation (35.79b), and the thickness weighted velocity equation (36.45) (also called the momentum equation)

$$\frac{\partial h_{\mathsf{k}}}{\partial t} + \nabla \cdot (h_{\mathsf{k}} \, \boldsymbol{u}_{\mathsf{k}}) = 0 \tag{67.1a}$$

$$\frac{\partial (h_{\mathsf{k}} \, C)}{\partial t} + \nabla \cdot (h_{\mathsf{k}} \, \boldsymbol{u}_{\mathsf{k}} \, C) = 0 \tag{67.1b}$$

$$\frac{\partial (h_{\mathsf{k}} \, \boldsymbol{u}_{\mathsf{k}})}{\partial t} + \nabla \cdot [h_{\mathsf{k}} \, \boldsymbol{u}_{\mathsf{k}} \otimes \boldsymbol{u}_{\mathsf{k}}] + f \, \hat{\boldsymbol{z}} \times (h_{\mathsf{k}} \, \boldsymbol{u}_{\mathsf{k}}) = -(h_{\mathsf{k}}/\rho_{\mathsf{ref}}) \, \nabla p_{\mathsf{k}}. \tag{67.1c}$$

The density, ρ_{ref}, appearing in the momentum equation (67.1c) is the Boussinesq reference density, pften chosen as the density of the uppermost layer,

$$\rho_{\mathsf{ref}} = \rho_1. \tag{67.2}$$

The thickness and tracer equations do not couple to other layers, and as such we can drop the layer index, $\mathsf{k} = 1, N$, when analyzing these equations. For the momentum equation, we expose the interface indices, $\mathsf{k} \pm 1/2$, when considering pressure form stresses.

For this chapter, it proves useful to move seamlessly between the thickness weighted pressure gradient body force and its equivalent contact force version studied in Section 36.4. The contact force version of the momentum equation reveals the pressure form stresses acting on the upper and lower interfaces of a shallow water layer. It also brings stresses (kinetic stresses and pressure stresses) together into the divergence of a momentum flux. As such, this formulation follows that of Cauchy as discussed in Section 24.2.3. The eddy correlation portion of the momentum flux is known as the *Eliassen-Palm* flux.[2]

When the dust settles, the TWA equations are isomorphic to the unaveraged equations (67.1a)-(67.1c), yet with the addition of momentum flux convergences to the right hand sides that arise from subgrid correlations (i.e., convergence of the Eliassen-Palm flux). The momentum eddy fluxes are connected to the potential vorticity fluxes, with the connection known as the *Taylor-Bretherton identity*. The isomorphism provides some motivation to favor the TWA approach since properties of the unaveraged equations are directly reflected in the TWA equations. It also provides a suitable framework for parameterizing the subgrid correlations within the context of flux-form conservation laws. Even so, any formalism for an eddy and mean decomposition is subjective since the mean flow and eddying fluctuations are defined by the analyst not by the physics. Hence, arguments concerning what is a preferable framework are subject to the needs of the analyst and have no physically objective foundation.

67.3 Thickness transport by the bolus velocity

Prior to diving into the formalism of thickness weighted averaging, we study the eddy-induced volume transport (more precisely, thickness transport) realized by linear waves within a layer of shallow water fluid. This discussion provides a specific example of the thickness transport

[2] See *Bühler* (2014b) for a historical perspective on the Eliassen-Palm flux, which was introduced by *Eliassen and Palm* (1960) in their study of stationary mountain waves.

by the *bolus velocity*, with further discussion offered in Sections 67.5.1 and 70.4.5. Much of our intuition for bolus transport is based on the following relatively simple example of Stokes drift.[3]

Part of the motivation for TWA is that we do not need to compute the bolus velocity. Even so, understanding the basic physics of the bolus velocity renders useful insights into how eddies, even eddies as simple as linear waves, can provide a rectified transport of properties. We also comment on this point in Section 36.4.

67.3.1 Rectified effects

Rectification is the conversion of a fluctuating motion into motion in a particular direction. For example, the transformation of an alternating electrical current into a direct electrical current occurs through a rectifier. More generally, rectification arises from the breaking of a symmetry typically through a nonlinear mechanism. The primary example in fluid mechanics is the Stokes drift discussed in Section 52.11 as well as the current section. Stokes drift arises when linear waves have an amplitude that is a function of space, with this spatial dependence giving rise to net particle transport (the Stokes drift) in a preferred direction. Another example concerns the turbulent Stokes drift arising from nonlinear geostrophic waves and eddies in the ocean and atmosphere that lead to a net transport of buoyancy. In Section 36.7 we discuss the meridional transport of buoyancy by eddies in a channel, which is the canonical geophysical example of eddy induced transport.

67.3.2 An undulating fluid layer

Figure 67.1 shows a layer of constant density shallow water fluid within an adiabatic stacked shallow water model. Since the layers are immiscible, the total volume of fluid within this layer remains constant. In its unperturbed state with flat layer interfaces, the meridional velocity in the fluid layer is zero and the thickness is a constant, h_o. When perturbed, the thickness is written

$$h(y,t) = h_o + h'(y,t), \tag{67.3}$$

where we assume the perturbation only depends on (y,t) for simplicity. The layer thickness changes in time according to the convergence of the advective transport of thickness as found by the thickness equation (67.1a)

$$\frac{\partial h}{\partial t} = -\nabla \cdot (h\,\mathbf{u}), \tag{67.4}$$

where the convergence is computed within the layer and we drop the κ layer index for brevity. As seen by Figure 67.1, undulations of the layer thickness at a point arise from the convergence of thickness advected to that point. Further assuming that there is no zonal dependence ($\partial_x = 0$) leads to the one-dimensional thickness equation

$$\frac{\partial h}{\partial t} = -\frac{\partial (h\,v)}{\partial y}. \tag{67.5}$$

67.3.3 Stokes drift

Consider a linear wave perturbation in the meridional velocity that propagates in the meridional direction

$$v'(y,t) = v_o \sin(\kappa\, y - \omega\, t), \tag{67.6}$$

where κ is a constant wave number and ω is a constant frequency. This longitudinal wave is depicted in Figure 67.1. We now follow the general formalism developed in Section 52.11 (or

[3] This example is based Section 2 of *Lee et al.* (1997).

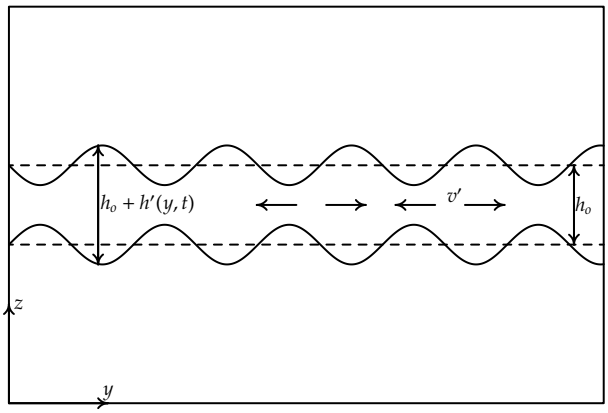

FIGURE 67.1: Shown here is a single layer of constant density fluid, with resting thickness $h = h_o$ and instantanous thickness $h = h_o + h'(y,t)$. Associated with the undulations in thickness are fluctuations in the meridional velocity $v' = v_o \sin(k\,y - \omega\,t)$, depicted here by the alternating vectors within the layer. Vertical-meridional axes are shown in the lower left corner for orientation. We are not concerned with boundaries in the meridional direction.

equivalently in Section 70.2.4) to determine the Stokes drift associated with this wave.

We are only concerned with the meridional component of the velocity, so the fluid particle trajectory equation is given by

$$\frac{\mathrm{d}Y}{\mathrm{d}t} = v_o \sin(\kappa\, Y - \omega\, t), \tag{67.7}$$

where $Y = Y(Y_o, t)$ is the meridional trajectory with initial postion Y_o. Following equation (52.194) we can write the difference between the velocity following a fluid particle (the Lagrangian velocity for the moving fluid particle) from the velocity at the initial particle point (the Eulerian velocity at the initial point of the trajectory)

$$\frac{\mathrm{d}Y}{\mathrm{d}t} - v(y,t) = v_o^2\, \kappa \cos(\kappa y - \omega t) \int_0^t \sin(\kappa y - \omega t')\, \mathrm{d}t' \tag{67.8a}$$

$$= \frac{v_o^2\, \kappa}{\omega} \left[\cos^2(\kappa y - \omega t) - \cos(\kappa y - \omega t)\cos(\kappa y)\right]. \tag{67.8b}$$

Time averaging over a single wave period,

$$T = 2\pi/\omega \tag{67.9}$$

leads to the Stokes drift as per the general expression in equation (52.196)

$$V_{\text{Stokes}} = \frac{v_o^2\, \kappa}{2\omega}. \tag{67.10}$$

Introducing the phase speed for the monochromatic wave,

$$c = \omega/\kappa \tag{67.11}$$

allows us to write the Stokes drift as

$$V_{\text{Stokes}} = \frac{v_o^2}{2\, c}. \tag{67.12}$$

Notice how the Stokes drift becomes small when the phase speed is large. The reason is that for this case, the fluid particles have only a short time to feel each wave, and thus can only experience a relatively small amount of drift. Correspondingly, there is only a small difference between the Eulerian and Lagrangian velocities. The converse holds for slow phase speeds, where

Eulerian and Lagrangian velocities have a relatively large difference.[4]

67.3.4 Linearized thickness perturbations

The velocity and thickness are written in terms of their rest state plus a perturbation due to the wave

$$h = h_o + h' \quad \text{and} \quad v = v', \tag{67.13}$$

where the velocity vanishes when the wave is absent. The thickness equation (67.5) thus takes the form

$$\frac{\partial h'}{\partial t} + h_o \frac{\partial v'}{\partial y} + v' \frac{\partial h'}{\partial y} = 0. \tag{67.14}$$

Linearizing this equation, and using the wave perturbation (67.6), leads to

$$\frac{\partial h'}{\partial t} + h_o \, v_o \, \kappa \cos(\kappa y - \omega t) = 0. \tag{67.15}$$

Time integrating this equation, and making use of the velocity perturbation in the form of equation (67.6), renders the thickness perturbation

$$h' = h_o \, v'/c. \tag{67.16}$$

Hence, to leading order, the thickness perturbation is directly proportional to and in phase with the velocity perturbation.

67.3.5 Correlation between thickness and velocity

Over a single wave period, $T = 2\pi/\omega$, the temporal correlation between the linear thickness perturbation and velocity perturbation is given by

$$\begin{aligned}
\overline{h' \, v'} &= \frac{1}{T} \int_0^T h' \, v' \, \mathrm{d}t && \text{(67.17a)} \\
&= \frac{h_o}{c\,T} \int_0^T v' \, v' \, \mathrm{d}t && \text{(67.17b)} \\
&= \frac{v_o^2 \, h_o}{c\,T} \int_0^T \sin^2(\kappa y - \omega t) \, \mathrm{d}t && \text{(67.17c)} \\
&= \frac{v_o^2 \, h_o}{2\,c} && \text{(67.17d)} \\
&= h_o \, V_{\text{Stokes}}, && \text{(67.17e)}
\end{aligned}$$

where we introduced the Stokes drift (67.12) to reach the final equality. A nonzero correlation $\overline{h' \, v'}$ means that the thickness has a nonzero tendency when averaged over a wave period.

The nonzero correlation in equation (67.17e) induces a thickness transport from the one-dimensional linear longitudinal waves. This transport arises from the Stokes drift induced by the waves; without Stokes drift there is no eddy thickness transport. This behavior exemplifies the case for more general waves and nonlinear eddies moving through fluid layers. For the general case, a nonzero bolus velocity (Section 67.5.1), as determined by velocity-thickness correlations, induces an eddy thickness transport. We see that for the one-dimensional linear longitudinal wave example, the bolus velocity is the Stokes velocity, thus prompting certain authors to make the equality in general.

[4] If we were to consider a formal asymptotic expansion, then the case of relatively slow phase speeds would require us to keep more terms in the expansion than those carried here.

67.3.6 Do we need the bolus velocity?

The bolus transport is of fundamental importance for how we think about eddy induced Stokes transport from shallow water waves. More general fluctuations, such as those from turbulent geostrophic eddies, require a parameterization to determine the thickness transport. We consider such in Section 31.7 when studying geostrophic eddies in a zonally reentrant channel. As we see in the remainder of the current chapter, the allure of the thickness weighted averaging formalism is that it dispenses with the need to parameterize the bolus velocity. Instead, the TWA equations absorb the bolus transport into the residual mean advection operator. Operationally, the TWA exposes the eddy correlation terms only in the momentum equation, leaving the TWA thickness and TWA tracer equations in a form directly parallel to the unaveraged equations.

67.4 Averaging operators

There are many averaging operators used in fluid mechanics, such as the wave average from Section 67.3, which is useful when the flow is dominantly linear waves; a long time average (formally an infinitely long time average), which is commonly used for climate studies; a space average, which is appropriate when the spatial sampling is coarse; general space filters or kernels, which are commonly used in large eddy simulations; and ensemble averages, which are generally assumed in traditional studies of turbulence. In the following, we denote the averaging or mean operator by an overbar

$$\text{average}(\Phi) = \overline{\Phi}, \tag{67.18}$$

where Φ is any field such as velocity, thickness, or tracer concentration. Deviations (also called fluctations) from the mean are denoted by a prime so that the full field is decomposed into a mean and eddy term according to

$$\Phi = \overline{\Phi} + \Phi'. \tag{67.19}$$

Since the equations of fluid mechanics are nonlinear, this decomposition into eddy and mean leads to nonlinear eddy correlation terms, which are the source of both the richness and complexity of eddying fluid flows.

67.4.1 Reynolds average

A *Reynolds average* is an operator that annihilates its corresponding fluctuating quantity, which then means that the average of an average is the identity operator

$$\overline{\Phi'} = 0 \Longleftrightarrow \overline{\overline{\Phi}} = \overline{\Phi}, \tag{67.20}$$

which in turn means that

$$\overline{\Phi}\,\overline{\Psi} = \overline{(\overline{\Phi} + \Phi')}\,\overline{\Psi} = \overline{\Phi}\,\overline{\Psi}. \tag{67.21}$$

Reynolds averages are commonly used when deriving mean field equations. Even so, the assumptions of Reyynolds averaging operators are not satisfied by many operators in practice. Extra technical issues arise when averaging operators do not satisfy the properties of a Reynolds average, with these issues beyond our aims in the present chapter. Hence, in this chapter we retain the Reynolds average assumption (67.20) for the averaging operator.

67.4.2 Ensemble average

A further assumption we make is that the average operator commutes with space and time derivatives as well as integrals. This assumption does not strictly hold if the operator is a space and/or time average operator, at least not without a bit of work. However, this assumption holds

for ensemble averages. An *ensemble average* is computed over an infinite number of realizations of the fluid flow, with approximations to this average afforded by finite sized ensembles.

Ensemble averages are typically assumed in traditional fluid turbulence studies. However, they are not always very practical nor are they the obvious choice when targeting a frameowork for parameterization. Even so, we prefer ensemble averages for this chapter in order to dispense with concerns about commutation of the averaging operator with derivative and integral operators. We also make use of ensemble averaging for our discussion of tracer kinematics in Chapter 70.

67.4.3 Thickness weighted average

The thickness weighted average of a field is defined as the ensemble average of the thickness weighted field, and then divided by the averaged thickness:

$$\widehat{\Phi} \equiv \frac{\overline{h\,\Phi}}{\overline{h}} \Longleftrightarrow \overline{h}\,\widehat{\Phi} = \overline{h\,\Phi}, \tag{67.22}$$

with widehats adorning a thickness weighted average. Deviations from the thickness weighted average are denoted with two primes so that the unaveraged field is decomposed into its average plus fluctuation

$$\Phi = \widehat{\Phi} + \Phi''. \tag{67.23}$$

Since the overline average from Section 67.4.1 satisfies the Reynolds averaging assumption, so too does the thickness weighted average

$$\Phi = \widehat{\Phi} + \Phi'' \Longrightarrow \widehat{\Phi''} = \frac{\overline{h\,\Phi''}}{\overline{h}} = 0. \tag{67.24}$$

We are thus able to derive the following related identities

$$\Phi\,\Psi = (\widehat{\Phi} + \Phi'')\,(\widehat{\Phi} + \Phi'') \Longrightarrow \widehat{\Phi\,\Psi} = \widehat{\Phi}\,\widehat{\Psi} + \widehat{\Phi''\,\Psi''} \Longrightarrow \overline{h\,\Phi\,\Psi} = \overline{h}\,\widehat{\Phi}\,\widehat{\Psi}. \tag{67.25}$$

We sometimes need to consider mixed averages and primes, such as for

$$\overline{\overline{h}\,\widehat{\Phi}} = \overline{h\,\Phi} = \overline{h}\,\widehat{\Phi}, \tag{67.26}$$

in which case[5]

$$\overline{h}\,\overline{\Phi''} = \overline{h}(\overline{\Phi} - \widehat{\Phi}) = \overline{h}\,\overline{\Phi} - \overline{h'\,\Phi'} \neq 0. \tag{67.27}$$

Hence, the ensemble average of a fluctuation, Φ'' (which is computed relative to the thickness weighted mean), is generally nonzero. Furthermore, we sometimes find it useful to write the ensemble mean correlation between thickness and a field according to

$$\overline{h}\,\widehat{\Phi'} = \overline{h\,\Phi'} = \overline{h'\,\Phi'}, \tag{67.28}$$

with the second equality following since

$$\overline{\overline{h}\,\Phi'} = \overline{h}\,\overline{\Phi'} = 0. \tag{67.29}$$

The identity (67.28) allows us to write equation (67.27) as

$$\overline{h}\,\overline{\Phi''} = \overline{h}\,(\overline{\Phi} - \widehat{\Phi'}). \tag{67.30}$$

[5]Footnote #4 in *Young* (2012) is missing the $\overline{h}\,\overline{\Phi}$ term appearing in equation (67.27).

A similar identity holds according to the following manipulations

$$\overline{h' \Phi'} = \overline{h \Phi'} = \overline{h (\Phi - \overline{\Phi})} = \overline{h \Phi} - \overline{h} \, \overline{\Phi} = \overline{h} (\widehat{\Phi} - \overline{\Phi}), \tag{67.31}$$

so that

$$\widehat{\Phi}' = \widehat{\Phi} - \overline{\Phi} = \frac{\overline{h' \Phi'}}{\overline{h}}. \tag{67.32}$$

Derivative operators *do not* commute with the thickness weighted average, so that, for example,

$$\partial_x \widehat{u} \neq \widehat{\partial_x u}. \tag{67.33}$$

Hence, when deriving differential equations for thickness weighted fields, we first derive equations for the unaveraged thickness weighted quantities, and only thereafter do we apply the ensemble mean operator.

67.4.4 Comments

For the most part, we follow the notation of *Young* (2012). Nonetheless, we caution that notational clutter and variations on conventions can present a nontrivial barrier to penetrating the TWA literature. Indeed, for our purposes with the stacked shallow water model, there is one additional piece of notation concerning the discrete layer indices. Fortunately, much of the discrete layer notation can be streamlined by exposing just the half-integer indices for fields situated at layer interfaces, along with the layer density.

67.5 Thickness equation and tracer equation

In this section we derive the TWA versions of the thickness equation (67.1a) and the tracer equation (67.1b). The derivations involve straightforward applications of the TWA averaging properties (67.24) and (67.25).

67.5.1 TWA thickness equation

Taking the ensemble average of the thickness equation (67.1a) renders

$$\partial_t \overline{h} + \nabla \cdot \overline{h \, \boldsymbol{u}} = 0, \tag{67.34}$$

where we dropped the layer index, κ, to reduce notation. Introducing the thickness weighted average according to equation (67.22) brings the thickness equation to the form

$$\partial_t \overline{h} + \nabla \cdot (\overline{h} \, \widehat{\boldsymbol{u}}) = 0. \tag{67.35}$$

Consequently, the mean layer thickness, $\overline{h}$, evolves at a point in space according to the convergence of the thickness flux, $-\nabla \cdot (\overline{h} \, \widehat{\boldsymbol{u}})$, with the flux determined by the thickness weighted velocity, $\widehat{\boldsymbol{u}}$.

We find it useful to introduce the material time derivative operator defined with the thickness weighted velocity

$$\frac{\mathrm{D}^\sharp}{\mathrm{D}t} = \frac{\partial}{\partial t} + \widehat{\boldsymbol{u}} \cdot \nabla = \frac{\partial}{\partial t} + \widehat{u} \, \partial_x + \widehat{v} \, \partial_y, \tag{67.36}$$

so that the flux-form thickness equation (67.35) can be written in the material time derivative or advective form

$$\frac{\mathrm{D}^\sharp \overline{h}}{\mathrm{D}t} = -\overline{h} \, \nabla \cdot \widehat{\boldsymbol{u}}. \tag{67.37}$$

The $\mathrm{D}^\sharp/\mathrm{D}t$ notation is based on that used by *Young* (2012). The alternative $\widehat{\mathrm{D}}/\mathrm{D}t$ is less suitable since $\overline{h\,(\mathrm{D}/\mathrm{D}t)} \neq \overline{(\mathrm{D}/\mathrm{D}t)\,h}$. In brief, an object adorned with a sharp symbol is consistent with thickness weighted averaging but is itself not the direct result of a thickness weighted average. In the following, we find it useful to also introduce the vertical velocity, $w^\sharp$, in equation (67.43), and the potential vorticity, $\Pi^\sharp$, in equation (67.91).

The isomorphism between the TWA thickness equation (67.35) with the unaveraged thickness equation (67.1a) illustrates a distinct advantage of using the thickness weighted velocity, $\widehat{\boldsymbol{u}}$. Even so, for some purposes it is useful to unpack the thickness weighted velocity into its two components

$$\widehat{\boldsymbol{u}} = \overline{u} + \frac{\overline{h'\,\boldsymbol{u}'}}{\overline{h}} \equiv \overline{u} + \boldsymbol{u}^{\text{bolus}}, \tag{67.38}$$

where we defined the bolus velocity via

$$\overline{h}\,\boldsymbol{u}^{\text{bolus}} = \overline{h'\,\boldsymbol{u}'} = \overline{h}\,\widehat{\boldsymbol{u}'}, \tag{67.39}$$

where the second equality follows from the identity (67.28).

We discussed the bolus velocity in Section 67.3 and see it again in Section 70.4.5 when developing the ensemble mean tracer equation in isopycnal coordinates. However, as per our discussion in Section 67.3.6, we do not need to know the bolus velocity if we write the averaged tracer and momentum equations in terms of the thickness weighted velocity, $\widehat{\boldsymbol{u}}$.

67.5.2 Tracer equation

Taking the ensemble average of the tracer concentration equation (67.1b) for a shallow water fluid layer renders

$$\partial_t(\overline{h\,C}) + \nabla \cdot \overline{h\,C\,\boldsymbol{u}} = 0. \tag{67.40}$$

Making use of the thickness weighted averages from Section 67.4.3 allows us to write

$$\overline{h\,C} = \overline{h}\,\widehat{C} \quad \text{and} \quad \overline{h\,C\,\boldsymbol{u}} = \overline{h}\,(\widehat{C}\,\widehat{\boldsymbol{u}} + \widehat{C''\,\boldsymbol{u}''}), \tag{67.41}$$

thus yielding the TWA tracer equation

$$\partial_t(\overline{h}\,\widehat{C}) + \nabla \cdot (\overline{h}\,\widehat{C}\,\widehat{\boldsymbol{u}}) = -\nabla \cdot (\overline{h}\,\widehat{C''\,\boldsymbol{u}''}). \tag{67.42}$$

The right hand side is the convergence of the thickness weighted eddy tracer flux. As seen in Section 70.5, the isopycnal form of the tracer equation is identical to that given here for a shallow water layer. In that discussion we present methods commonly used to parameterize the eddy flux convergence.

67.5.3 Vertical velocity

We generally have no need for the vertical velocity when working with the adiabatic stacked shallow water model. Nonetheless, it is interesting to define a vertical velocity component, $w^\sharp$, satisfying the continuity equation

$$\nabla_{\mathsf{h}} \cdot \widehat{\boldsymbol{u}} + \partial_z w^\sharp = 0. \tag{67.43}$$

As for the unaveraged vertical velocity component discussed in Section 35.2.8, $w^\sharp$ is a linear function of z within the ensemble mean shallow water layers (see equation (35.39)). Note that $w^\sharp$ is not a thickness weighted velocity. Rather, it is the vertical velocity that is compatible, through the continuity equation, with the thickness weighted horizontal velocity. A vertical velocity is needed for the continuously stratified Boussinesq fluid, and it is defined as done here

for the shallow water.[6]

67.6 Horizontal momentum equation

Taking the ensemble mean of the horizontal momentum equation (67.1c) renders

$$\partial_t(\overline{h\,\boldsymbol{u}}) + \nabla\cdot[\overline{h\,\boldsymbol{u}\otimes\boldsymbol{u}}] + f\,\hat{\boldsymbol{z}}\times(\overline{h\,\boldsymbol{u}}) = -\overline{h\,\nabla p}/\rho_{\text{ref}}, \tag{67.44}$$

where we dropped the layer interface lable, k, for brevity. Again, we make use of the thickness weighted averages from Section 67.4.3 to write

$$\overline{h\,\boldsymbol{u}} = \overline{h}\,\widehat{\boldsymbol{u}} \tag{67.45a}$$

$$\overline{h\,\boldsymbol{u}\otimes\boldsymbol{u}} = \overline{h}\,(\widehat{\boldsymbol{u}}\otimes\widehat{\boldsymbol{u}} + \widehat{\boldsymbol{u}''\otimes\boldsymbol{u}''}), \tag{67.45b}$$

so that equation (67.44) becomes

$$\partial_t(\overline{h}\,\widehat{\boldsymbol{u}}) + \nabla\cdot[\overline{h}\,\widehat{\boldsymbol{u}}\otimes\widehat{\boldsymbol{u}}] + f\,\hat{\boldsymbol{z}}\times(\overline{h}\,\widehat{\boldsymbol{u}}) = -\nabla\cdot[\overline{h}\,\widehat{\boldsymbol{u}''\otimes\boldsymbol{u}''}] - \overline{h\,\nabla p}/\rho_{\text{ref}}. \tag{67.46}$$

The first term on the right hand side is similar to the eddy tracer flux convergence appearing in the TWA tracer equation (67.42). In contrast, the thickness weighted pressure gradient is fundamentally distinct from anything appearing in the tracer equation. Much in the remainder of this section is devoted to developing a physical and mathematical understanding of $\overline{h\,\nabla p}$.

67.6.1 Kinetic stress and Reynolds stress

Following our discussion in Section 25.6, we introduce the shallow water kinetic stress tensor

$$\mathbb{T}^{\text{sw kinetic}} = -\rho_{\text{ref}}\,\boldsymbol{u}\otimes\boldsymbol{u}. \tag{67.47}$$

The kinetic stress arises from motion of the fluid, with its divergence, $\nabla\cdot(h\,\mathbb{T}^{\text{kinetic}})$, contributing to changes in the momentum of a shallow water fluid column. Decomposing the velocity into the TWA velocity and fluctuation leads to the ensemble mean of the thickness weighted kinetic stress

$$\overline{h\,\mathbb{T}^{\text{kinetic}}(\boldsymbol{u})} = -\rho_{\text{ref}}\,\overline{h\,\boldsymbol{u}\otimes\boldsymbol{u}} \tag{67.48a}$$

$$= -\rho_{\text{ref}}\,\overline{h}\,[\widehat{\boldsymbol{u}}\otimes\widehat{\boldsymbol{u}} + \widehat{\boldsymbol{u}''\otimes\boldsymbol{u}''}] \tag{67.48b}$$

$$= \overline{h}\,\mathbb{T}^{\text{kinetic}}(\widehat{\boldsymbol{u}}) + \overline{h}\,\mathbb{T}^{\text{Reynolds}}, \tag{67.48c}$$

where the eddy correlation is known as the *Reynolds stress*. The divergence of the thickness weighted Reynolds stress provides a rectified effect onto the mean flow due to nonzero eddy correlations.

67.6.2 Thickness and pressure gradient correlation

The ensemble mean of the thickness weighted pressure gradient can be written

$$\overline{h_{\text{k}}\,\nabla p_{\text{k}}} = \overline{h}_{\text{k}}\,\widehat{\nabla p_{\text{k}}} \qquad \text{equation (67.22) defining the TWA} \tag{67.49a}$$

$$= \overline{h}_{\text{k}}\,\nabla\overline{p}_{\text{k}} + \overline{h'_{\text{k}}\,\nabla p'_{\text{k}}} \qquad \text{expanding the ensemble mean} \tag{67.49b}$$

$$= \overline{h}_{\text{k}}\,(\nabla\overline{p}_{\text{k}} + \widehat{\nabla p'_{\text{k}}}) \qquad \text{equation (67.28).} \tag{67.49c}$$

[6] See equation (73) in *Young* (2012).

The eddy term is the correlation between layer thickness fluctuations and horizontal pressure gradient fluctuations

$$\overline{h}_{\mathsf{k}} \, \widehat{\nabla p'_{\mathsf{k}}} = \overline{h'_{\mathsf{k}} \, \nabla p'_{\mathsf{k}}}, \tag{67.50}$$

which can be written in terms of the eddy geostrophic velocity

$$\overline{h}_{\mathsf{k}} \, \widehat{\nabla p'_{\mathsf{k}}} = -\rho_{\mathsf{ref}} \, f \, \hat{\boldsymbol{z}} \times \overline{h'_{\mathsf{k}} \, \boldsymbol{u}'_{\mathsf{k,g}}} = -\rho_{\mathsf{ref}} \, f \, \hat{\boldsymbol{z}} \times \overline{h}_{\mathsf{k}} \, \widehat{\boldsymbol{u}'_{\mathsf{k,g}}}. \tag{67.51}$$

For geostrophic flows, the bolus velocity (67.39) equals to $\widehat{\boldsymbol{u}'_{\mathsf{k,g}}}$, in which case we write

$$\overline{h}_{\mathsf{k}} \, \widehat{\nabla p'_{\mathsf{k}}} = -\rho_{\mathsf{ref}} \, f \, \hat{\boldsymbol{z}} \times \overline{h}_{\mathsf{k}} \, \boldsymbol{u}^{\mathrm{bolus}}_{\mathsf{k}}. \tag{67.52}$$

67.6.3 Unpacking the thickness and pressure gradient correlation

We here unpack the correlation between eddy thickness and eddy pressure gradient as given by $\overline{h}_{\mathsf{k}} \, \widehat{\nabla p'_{\mathsf{k}}} = \overline{h'_{\mathsf{k}} \, \nabla p'_{\mathsf{k}}}$ in equation (67.50). We do so by writing the pressure as a contact force rather than a body force. Doing so exposes the eddy interfacial form stresses that provide a vertical transfer of horizontal momentum. In addition, there is a term arising from the gradient in the layer depth integrated pressure or, alternatively, the layer potential energy. To proceed we rely on the development given in Section 36.4.9, in which we exposed two equivalent expressions for the contact pressure.

As part of the following derivation we make use of relations for pressure within a layer and at an interface

$$p_{\mathsf{k}}(z) = p_{\mathsf{k}-1/2} + g \, \rho_{\mathsf{k}} \, (\eta_{\mathsf{k}-1/2} - z) \tag{67.53a}$$

$$p_{\mathsf{k}+1/2} - p_{\mathsf{k}-1/2} = g \, \rho_{\mathsf{k}} \, h_{\mathsf{k}} = -g \, \rho_{\mathsf{k}} \, (\eta_{\mathsf{k}+1/2} - \eta_{\mathsf{k}-1/2}) \tag{67.53b}$$

$$p_{1/2} = p_{\mathsf{a}}, \tag{67.53c}$$

with p_{a} the applied (or atmospheric) pressure at the ocean surface. We emphasize that the layer pressure, $p_{\mathsf{k}}(z)$, is a linear function of vertical position within the layer so that its horizontal gradient, $\nabla_{\mathsf{h}} p_{\mathsf{k}}$, is depth independent.

Interfacial form stress plus gradient of layer depth integrated pressure

The first expression for thickness weighted pressure gradient is given by

$$-h_{\mathsf{k}} \nabla p_{\mathsf{k}} = -\nabla P_{\mathsf{k}} + \boldsymbol{F}^{\mathrm{form}}_{\mathsf{k}}. \tag{67.54}$$

In this equation we introduced the pressure vertically integrated over layer-k

$$P_{\mathsf{k}} = \int_{\eta_{\mathsf{k}+1/2}}^{\eta_{\mathsf{k}-1/2}} p_{\mathsf{k}}(z) \, \mathrm{d}z = h_{\mathsf{k}} \, (g \, \rho_{\mathsf{k}} \, h_{\mathsf{k}}/2 + p_{\mathsf{k}-1/2}), \tag{67.55}$$

with its negative gradient

$$-\nabla P_{\mathsf{k}} = -\nabla \left[h_{\mathsf{k}} \, (p_{\mathsf{k}-1/2} + g \, \rho_{\mathsf{k}} \, h_{\mathsf{k}}/2) \right] \tag{67.56a}$$

$$= -\nabla \left[h_{\mathsf{k}} \, (p_{\mathsf{k}+1/2} - g \, \rho_{\mathsf{k}} \, h_{\mathsf{k}}/2) \right] \tag{67.56b}$$

$$= -[h_{\mathsf{k}} \nabla p_{\mathsf{k}+1/2} + p_{\mathsf{k}-1/2} \nabla h_{\mathsf{k}}] \tag{67.56c}$$

leading to a horizontal acceleration from imbalances in the contact pressure acting along the vertical sides of a shallow water column. The second stress in equation (67.54) is the pressure

form stress acting on the upper and lower layer interfaces

$$\boldsymbol{F}_{\mathsf{k}}^{\text{form}} = p_{\mathsf{k}-1/2}\nabla\eta_{\mathsf{k}-1/2} - p_{\mathsf{k}+1/2}\nabla\eta_{\mathsf{k}+1/2} \equiv \delta_{\mathsf{k}}(p_{\mathsf{k}-1/2}\nabla\eta_{\mathsf{k}-1/2}), \tag{67.57}$$

where

$$\delta_{\mathsf{k}}\Phi_{\mathsf{k}-1/2} = \Phi_{\mathsf{k}-1/2} - \Phi_{\mathsf{k}+1/2} = -(\Phi_{\mathsf{k}+1/2} - \Phi_{\mathsf{k}-1/2}) \tag{67.58}$$

is a difference operator acting on interface properties. The use of a backward difference operator is motivated since k increases down whereas $\hat{\boldsymbol{z}}$ points up. Additionally, we define the difference operator to only act on fields defined at the layer interface, with layer fields commuting with this operator so that, for example,

$$\delta_{\mathsf{k}}(h_{\mathsf{k}}\,\eta_{\mathsf{k}-1/2}) = h_{\mathsf{k}}\,\delta_{\mathsf{k}}(\eta_{\mathsf{k}-1/2}). \tag{67.59}$$

This convention helps produce a tidy form of the Eliassen-Palm flux in Sections 67.6.4 and 67.6.5.

Making use of the depth integrated pressure and form stress as given by equation (67.54) allows us to write the ensemble mean thickness weighted pressure gradient as

$$-\overline{h_{\mathsf{k}}\,\nabla p_{\mathsf{k}}} = -\nabla\overline{P_{\mathsf{k}}} + \delta_{\mathsf{k}}[\overline{p_{\mathsf{k}-1/2}\nabla\eta_{\mathsf{k}-1/2}}]. \tag{67.60}$$

Following equation (67.56a), we write the ensemble mean for the layer integrated pressure as

$$-\nabla\overline{P_{\mathsf{k}}} = -\nabla[\overline{h_{\mathsf{k}}}\,(\overline{p_{\mathsf{k}-1/2}} + g\,\rho_{\mathsf{k}}\,\overline{h_{\mathsf{k}}}/2)] - \nabla[\overline{h'_{\mathsf{k}}\,(p'_{\mathsf{k}-1/2} + g\,\rho_{\mathsf{k}}\,h'_{\mathsf{k}}/2)}] \tag{67.61}$$

and the vertical divergence of the form stress is

$$\overline{\boldsymbol{F}_{\mathsf{k}}^{\text{form}}} = \delta_{\mathsf{k}}[\overline{p_{\mathsf{k}-1/2}\,\nabla\eta_{\mathsf{k}-1/2}}] = \delta_{\mathsf{k}}\left[\overline{p_{\mathsf{k}-1/2}}\,\overline{\nabla\eta_{\mathsf{k}-1/2}} + \overline{p'_{\mathsf{k}-1/2}\,\nabla\eta'_{\mathsf{k}-1/2}}\right]. \tag{67.62}$$

We are thus led to the following decomposition of the eddy contribution to the thickness weighted pressure gradient

$$-\overline{h'_{\mathsf{k}}\,\nabla p'_{\mathsf{k}}} = -\nabla[\overline{h'_{\mathsf{k}}\,(p'_{\mathsf{k}-1/2} + g\,\rho_{\mathsf{k}}\,h'_{\mathsf{k}}/2)}] + \delta_{\mathsf{k}}\left[\overline{p'_{\mathsf{k}-1/2}\,\nabla\eta'_{\mathsf{k}-1/2}}\right]. \tag{67.63}$$

For orientation, in Figure 67.2 we illustrate the deviations of the interface positions relative to the ensemble mean.

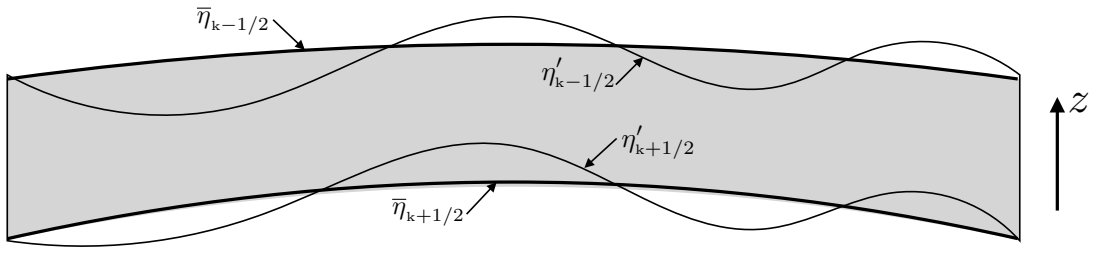

FIGURE 67.2: Schematic of the interface positions for a shallow water layer. The ensemble mean layer interfaces have vertical positions given by $z = \overline{\eta}_{\mathsf{k}\pm1/2}$, whereas the fluctuating interfaces are located at $z = \overline{\eta}_{\mathsf{k}\pm1/2} + \eta'_{\mathsf{k}\pm1/2}$. As depicted here, the ensemble mean interface positions are not generally horizontal.

Dual interfacial pressure form stress plus gradient of layer potential energy

An alternative formulation uses the dual form stress and potential energy, in which case we write the thickness weighted horizontal pressure gradient as

$$-h_{\mathsf{k}}\nabla p_{\mathsf{k}} = -\nabla\mathscr{P}_{\mathsf{k}} + \boldsymbol{F}_{\mathsf{k}}^{\text{dual}}. \tag{67.64}$$

In this equation we introduced the layer gravitational potential energy per area

$$\mathscr{P}_{\mathsf{k}} = g\,\rho_{\mathsf{k}}\int_{\eta_{\mathsf{k}+1/2}}^{\eta_{\mathsf{k}-1/2}} z\,\mathrm{d}z = (g\,\rho_{\mathsf{k}}/2)\,(\eta_{\mathsf{k}-1/2}^2 - \eta_{\mathsf{k}+1/2}^2) = (g\,\rho_{\mathsf{k}}/2)\,\delta_{\mathsf{k}}(\eta_{\mathsf{k}-1/2}^2), \tag{67.65}$$

and the *dual pressure form stress* (see Section 36.4.8),

$$\boldsymbol{F}_{\mathsf{k}}^{\text{dual}} = -\delta_{\mathsf{k}}(\eta_{\mathsf{k}-1/2}\nabla p_{\mathsf{k}-1/2}) = \boldsymbol{F}_{\mathsf{k}}^{\text{form}} - \nabla[\delta_{\mathsf{k}}(\eta_{\mathsf{k}-1/2}\,p_{\mathsf{k}-1/2})]. \tag{67.66}$$

Since they differ by a gradient, the form stress and dual form stress have identical curls and so they contribute the same interfacial pressure torque as part of the layer vorticity evolution

$$-\nabla\times(h_{\mathsf{k}}\nabla p_{\mathsf{k}}) = \nabla\times\boldsymbol{F}_{\mathsf{k}}^{\text{dual}} = \nabla\times\boldsymbol{F}_{\mathsf{k}}^{\text{form}}. \tag{67.67}$$

Making use of the potential energy and dual form stress as given by equation (67.64) allows us to write the ensemble mean thickness weighted pressure gradient as

$$-\overline{h_{\mathsf{k}}\,\nabla p_{\mathsf{k}}} = -\nabla\overline{\mathscr{P}_{\mathsf{k}}} - \delta_{\mathsf{k}}[\overline{\eta_{\mathsf{k}-1/2}\,\nabla p_{\mathsf{k}-1/2}}] \tag{67.68}$$

where minus the potential energy gradient is decomposed as

$$-\nabla\overline{\mathscr{P}_{\mathsf{k}}} = -(g\,\rho_{\mathsf{k}}/2)\,\delta_{\mathsf{k}}\left[\nabla(\overline{\eta_{\mathsf{k}-1/2}})^2 + \nabla\overline{(\eta'_{\mathsf{k}-1/2})^2}\right] \tag{67.69}$$

and the vertical convergence of the dual form stress is

$$-\delta_{\mathsf{k}}[\overline{\eta_{\mathsf{k}-1/2}\,\nabla p_{\mathsf{k}-1/2}}] = -\delta_{\mathsf{k}}\left[\overline{\eta_{\mathsf{k}-1/2}}\,\overline{\nabla p_{\mathsf{k}-1/2}} + \overline{\eta'_{\mathsf{k}-1/2}\,\nabla p'_{\mathsf{k}-1/2}}\right]. \tag{67.70}$$

We are thus led to decompose the thickness weighted pressure gradient correlation as

$$-\overline{h'_{\mathsf{k}}\,\nabla p'_{\mathsf{k}}} = -(g\,\rho_{\mathsf{k}}/2)\,\nabla[\delta_{\mathsf{k}}\overline{(\eta'_{\mathsf{k}-1/2})^2}] - \delta_{\mathsf{k}}[\overline{\eta'_{\mathsf{k}-1/2}\nabla p'_{\mathsf{k}-1/2}}]. \tag{67.71}$$

Again, the first term on the right hand side arises from the eddy potential energy and the second term from the dual eddy form stress.

67.6.4 Zonal and meridional Eliassen-Palm fluxes: Version I

Making use of the thickness and pressure gradient correlation in the form of equation (67.63) (the version with the form stress) leads to the thickness weighted momentum equation

$$\begin{aligned}\partial_t(\overline{h}\,\widehat{\boldsymbol{u}}) + \nabla\cdot(\overline{h}\,\widehat{\boldsymbol{u}}\otimes\widehat{\boldsymbol{u}}) + f\,\hat{\boldsymbol{z}}\times\overline{h}\,\widehat{\boldsymbol{u}} + \overline{h}\,\nabla\overline{p}/\rho_{\text{ref}}&\\ = -\nabla\cdot(\overline{h}\,\widehat{\boldsymbol{u}''\otimes\boldsymbol{u}''}) - \rho_{\text{ref}}^{-1}\,\nabla[\overline{h'_{\mathsf{k}}\,(p'_{\mathsf{k}-1/2} + g\,\rho_{\mathsf{k}}\,h'_{\mathsf{k}}/2)}] + \rho_{\text{ref}}^{-1}\,\delta_{\mathsf{k}}\overline{(p'\,\nabla\eta')_{\mathsf{k}-1/2}},&\end{aligned} \tag{67.72}$$

where we only exposed the interface indices to reduce notational clutter, and where we introduced the shorthand for the eddy form stress at the $\mathsf{k}-1/2$ interface

$$(p'\,\nabla\eta')_{\mathsf{k}-1/2} = p'_{\mathsf{k}-1/2}\,\nabla\eta'_{\mathsf{k}-1/2}. \tag{67.73}$$

The subgrid scale correlations on the right hand side of equation (67.72) can be organized into the divergence of two tensors

$$\begin{aligned}
&\nabla \cdot (\overline{h}\, \widehat{\boldsymbol{u}'' \otimes \boldsymbol{u}''}) + \rho_{\mathsf{ref}}^{-1}\, \nabla[\overline{h'_{\mathsf{k}}\,(p'_{\mathsf{k}-1/2} + g\,\rho_{\mathsf{k}}\,h'_{\mathsf{k}}/2)}] - (\overline{h}\,\rho_{\mathsf{ref}})^{-1}\,\delta_{\mathsf{k}}\left[\overline{h}\,\overline{(p'\,\nabla\eta')_{\mathsf{k}-1/2}}\right] \\
&= \begin{bmatrix} \partial_x & \partial_y & (1/\overline{h})\,\delta_{\mathsf{k}} \end{bmatrix} \begin{bmatrix} \overline{h}\,\widehat{u''\,u''} & \overline{h}\,\widehat{u''\,v''} & 0 \\ \overline{h}\,\widehat{u''\,v''} & \overline{h}\,\widehat{v''\,v''} & 0 \\ 0 & 0 & 0 \end{bmatrix} \\
&+ \rho_{\mathsf{ref}}^{-1} \begin{bmatrix} \partial_x & \partial_y & (1/\overline{h})\,\delta_{\mathsf{k}} \end{bmatrix} \begin{bmatrix} \overline{h'_{\mathsf{k}}\,(p'_{\mathsf{k}-1/2} + g\,\rho_{\mathsf{k}}\,h'_{\mathsf{k}}/2)} & 0 & 0 \\ 0 & \overline{h'_{\mathsf{k}}\,(p'_{\mathsf{k}-1/2} + g\,\rho_{\mathsf{k}}\,h'_{\mathsf{k}}/2)} & 0 \\ -\overline{h}\,\overline{(p'\,\partial_x\eta')_{k-1/2}} & -\overline{h}\,\overline{(p'\,\partial_y\eta')_{k-1/2}} & 0 \end{bmatrix},
\end{aligned} \tag{67.74}$$

where we recall from equation (67.59) that the vertical difference operator, δ_{k}, only acts on layer interface fields so that $\overline{h}_{\mathsf{k}}$ commutes with δ_{k}. The first tensor in equation (67.74) arises from Reynolds stresses and the second tensor arises from eddy pressures, including the eddy form stress in the third row.

When combined, the columns of the tensors appearing in equation (67.74) are the thickness weighted shallow water *Eliassen-Palm fluxes* for the zonal (column 1) and meridional (column 2) momentum equation

$$\boldsymbol{E}^{(\mathrm{uEP})} = \left[\overline{h}\,\widehat{u''\,u''} + \rho_{\mathsf{ref}}^{-1}\,\overline{h'_{\mathsf{k}}\,(p'_{\mathsf{k}-1/2} + g\,\rho_{\mathsf{k}}\,h'_{\mathsf{k}}/2)}\right]\hat{\boldsymbol{x}} + \overline{h}\,\widehat{u''\,v''}\,\hat{\boldsymbol{y}} - (\overline{h}/\rho_{\mathsf{ref}})\,\overline{(p'\,\partial_x\eta')_{k-1/2}}\,\hat{\boldsymbol{z}} \tag{67.75a}$$

$$\boldsymbol{E}^{(\mathrm{vEP})} = \overline{h}\,\widehat{u''\,v''}\,\hat{\boldsymbol{x}} + \left[\overline{h}\,\widehat{v''\,v''} + \rho_{\mathsf{ref}}^{-1}\,\overline{h'_{\mathsf{k}}\,(p'_{\mathsf{k}-1/2} + g\,\rho_{\mathsf{k}}\,h'_{\mathsf{k}}/2)}\right]\hat{\boldsymbol{y}} - (\overline{h}/\rho_{\mathsf{ref}})\,\overline{(p'\,\partial_y\eta')_{k-1/2}}\,\hat{\boldsymbol{z}}. \tag{67.75b}$$

The Eliassen-Palm flux has physical dimensions of thickness times squared velocity. We encountered the unaveraged version of the Eliassen-Palm flux in Sections 36.3.3 and 36.4.9 when studying the shallow water momentum equation. *Maddison and Marshall* (2013) included the third column of zeros in equation (67.74) to emphasize that the Eliassen-Palm fluxes are the first and second columns to the *Eliassen-Palm flux tensor*. They illustrated the utility of this perspective by considering gauge transformations that result in non-zero elements in the third column.

The Eliassen-Palm fluxes are second order in eddy amplitude; i.e., they are quadratic in eddy fluctuations. Furthermore, they bring together the Reynolds stress and eddy pressure terms, including the eddy form stress. The convergence of the Eliassen-Palm fluxes provides an eddy rectified acceleration on the thickness weighted velocity. To explicitly see this forcing, write the components to the mean field momentum equation (67.72) as[7]

$$\partial_t(\overline{h}\,\widehat{u}) + \nabla \cdot (\overline{h}\,\widehat{\boldsymbol{u}}\,\widehat{u}) - f\,\overline{h}\,\widehat{v} + \overline{h}\,\partial_x\overline{p}/\rho = -(\nabla_{\mathsf{h}} + \hat{\boldsymbol{z}}\,\overline{h}^{-1}\delta_{\mathsf{k}}) \cdot \boldsymbol{E}^{(\mathrm{uEP})} \tag{67.76a}$$

$$\partial_t(\overline{h}\,\widehat{v}) + \nabla \cdot (\overline{h}\,\widehat{\boldsymbol{u}}\,\widehat{v}) + f\,\overline{h}\,\widehat{u} + \overline{h}\,\partial_y\overline{p}/\rho = -(\nabla_{\mathsf{h}} + \hat{\boldsymbol{z}}\,\overline{h}^{-1}\delta_{\mathsf{k}}) \cdot \boldsymbol{E}^{(\mathrm{vEP})}. \tag{67.76b}$$

Equations (67.76a) and (67.76b) are isomorphic to the unaveraged horizontal momentum equation (67.1c), yet with the addition of the convergence of the Eliassen-Palm flux on the right hand side that encapsulates rectified effects from eddies. They can be written using the material time

[7] Recall from equation (67.59) that the operator δ_{k} only acts on interface fields, so that $\overline{h}^{-1}\,\delta_{\mathsf{k}}(\overline{h}) = \delta_{\mathsf{k}}$. This convention allows us to combine the horizontal components to the Eliassen-Palm flux with the vertical component, as written in equations (67.80a) and (67.80b).

derivative (67.36)

$$\frac{\mathrm{D}^\sharp \widehat{u}}{\mathrm{D}t} - f\,\widehat{v} + \partial_x \overline{p}/\rho = -\overline{h}^{-1}\,(\nabla_\mathsf{h} + \hat{\boldsymbol{z}}\,\overline{h}^{-1}\delta_\mathsf{k})\cdot \boldsymbol{E}^{(\mathrm{uEP})} \tag{67.77a}$$

$$\frac{\mathrm{D}^\sharp \widehat{v}}{\mathrm{D}t} + f\,\widehat{u} + \partial_y \overline{p}/\rho = -\overline{h}^{-1}\,(\nabla_\mathsf{h} + \hat{\boldsymbol{z}}\,\overline{h}^{-1}\delta_\mathsf{k})\cdot \boldsymbol{E}^{(\mathrm{vEP})}. \tag{67.77b}$$

We emphasize that these equations only make use of the thickness weighted velocity, $\widehat{\boldsymbol{u}}$, as do the averaged thickness equation (67.35) and averaged tracer equation (67.42). We advertised this point near the start of this chapter, noting that it facilitates the practical use of the TWA equations for numerical simulations. We further this correspondence in Section 67.7 by showing that the vorticity and potential vorticity equations also make use of $\widehat{\boldsymbol{u}}$.

67.6.5 Zonal and meridional Eliassen-Palm fluxes: Version II

We here follow the development in Section 67.6.4, only now making use of the thickness and pressure gradient correlation in the form of equation (67.71) (the version with the dual form stress). Our presentation is terse since there are few differences from Section 67.6.4. We start from the thickness weighted momentum equation

$$\begin{aligned}\partial_t(\overline{h}\,\widehat{\boldsymbol{u}}) + \nabla\cdot(\overline{h}\,\widehat{\boldsymbol{u}}\otimes\widehat{\boldsymbol{u}}) + f\,\hat{\boldsymbol{z}}\times\overline{h}\,\widehat{\boldsymbol{u}} + \overline{h}\,\nabla\overline{p}/\rho \\ = -\nabla\cdot(\overline{h}\,\widehat{\boldsymbol{u}''\otimes\boldsymbol{u}''}) - (g\,\rho_\mathsf{k}/2\rho_\mathsf{ref})\,\nabla[\delta_\mathsf{k}\overline{(\eta'_{\mathsf{k}-1/2})^2}] - \delta_\mathsf{k}[\overline{(\eta'\,\nabla p')_{\mathsf{k}-1/2}}/\rho_\mathsf{ref}].\end{aligned} \tag{67.78}$$

The subgrid scale correlations on the right hand side can be organized into the divergence of two tensors

$$\begin{aligned}&\nabla\cdot(\overline{h}\,\widehat{\boldsymbol{u}''\otimes\boldsymbol{u}''}) + (g\,\rho_\mathsf{k}/2\rho_\mathsf{ref})\,\nabla[\delta_\mathsf{k}\overline{(\eta'_{\mathsf{k}-1/2})^2}] + \delta_\mathsf{k}[\overline{(\eta'\,\nabla p')_{\mathsf{k}-1/2}}/\rho_\mathsf{ref}] \\ &= \begin{bmatrix}\partial_x & \partial_y & \overline{h}^{-1}\,\delta_\mathsf{k}\end{bmatrix}\begin{bmatrix}\overline{h}\,\widehat{u''u''} & \overline{h}\,\widehat{u''v''} & 0\\ \overline{h}\,\widehat{u''v''} & \overline{h}\,\widehat{v''v''} & 0\\ 0 & 0 & 0\end{bmatrix} \\ &+ \begin{bmatrix}\partial_x & \partial_y & \overline{h}^{-1}\,\delta_\mathsf{k}\end{bmatrix}\begin{bmatrix}(g\,\rho_\mathsf{k}/2\,\rho_\mathsf{ref})\,[\delta_\mathsf{k}\overline{(\eta'_{\mathsf{k}-1/2})^2}] & 0 & 0\\ 0 & (g\,\rho_\mathsf{k}/2\,\rho_\mathsf{ref})\,[\delta_\mathsf{k}\overline{(\eta'_{\mathsf{k}-1/2})^2}] & 0\\ (\overline{h}/\rho_\mathsf{ref})\,\overline{(\eta'\,\partial_x p')_{k-1/2}} & (\overline{h}/\rho_\mathsf{ref})\,\overline{(\eta'\,\partial_y p')_{k-1/2}} & 0\end{bmatrix}.\end{aligned} \tag{67.79}$$

The first tensor arises from Reynolds stresses and the second arises from eddy potential energy and dual eddy form stresses. When combined, the columns are the thickness weighted *Eliassen-Palm fluxes* for the zonal (column 1) and meridional (column 2), here making use of the dual form stress

$$\boldsymbol{E}^{(\mathrm{uEP})}_{\mathrm{dual}} = \Big[\overline{h}\,\widehat{u''u''} + (g\,\rho_\mathsf{k}/2\rho_\mathsf{ref})\,[\delta_\mathsf{k}\overline{(\eta'_{\mathsf{k}-1/2})^2}]\Big]\,\hat{\boldsymbol{x}} + \overline{h}\,\widehat{u''v''}\,\hat{\boldsymbol{y}} + \overline{h}\,\overline{(\eta'\,\partial_x p')_{k-1/2}}/\rho_\mathsf{ref})\,\hat{\boldsymbol{z}} \tag{67.80a}$$

$$\boldsymbol{E}^{(\mathrm{vEP})}_{\mathrm{dual}} = \overline{h}\,\widehat{u''v''}\,\hat{\boldsymbol{x}} + \Big[\overline{h}\,\widehat{v''v''} + (g\,\rho_\mathsf{k}/2\rho_\mathsf{ref})\,[\delta_\mathsf{k}\overline{(\eta'_{\mathsf{k}-1/2})^2}]\Big]\,\hat{\boldsymbol{y}} + \overline{h}\,\overline{(\eta'\,\partial_y p')_{k-1/2}}/\rho_\mathsf{ref})\,\hat{\boldsymbol{z}}. \tag{67.80b}$$

The convergence of the Eliassen-Palm fluxes provides an eddy rectified acceleration on the thickness weighted velocity

$$\partial_t(\overline{h}\,\widehat{u}) + \nabla\cdot(\overline{h}\,\widehat{\boldsymbol{u}}\,\widehat{u}) - f\,\overline{h}\,\widehat{v} + \overline{h}\,\partial_x\overline{p}/\rho = -(\nabla_\mathsf{h} + \hat{\boldsymbol{z}}\,\overline{h}^{-1}\delta_\mathsf{k})\cdot\boldsymbol{E}^{(\mathrm{uEP})}_{\mathrm{dual}} \tag{67.81a}$$

$$\partial_t(\overline{h}\,\widehat{v}) + \nabla\cdot(\overline{h}\,\widehat{\boldsymbol{u}}\,\widehat{v}) + f\,\overline{h}\,\widehat{u} + \overline{h}\,\partial_y\overline{p}/\rho = -(\nabla_\mathsf{h} + \hat{\boldsymbol{z}}\,\overline{h}^{-1}\delta_\mathsf{k})\cdot\boldsymbol{E}^{(\mathrm{vEP})}_{\mathrm{dual}}. \tag{67.81b}$$

67.6.6 Interfacial stresses from geostrophic eddies

In Section 31.7 we studied the rectified effects from geostrophic eddies in a zonally re-entrant channel for a continuously stratified fluid. In that analysis we found that the zonal mean of isopycnal eddy form stresses are equivalent to the meridional eddy flux of buoyancy. We here consider similar questions within the context of the TWA shallow water fluid, here focusing on the interfacial transfer of momentum due to eddy dual form stresses as given by the vertical vectors

$$\rho_{\text{ref}} \left[\boldsymbol{E}^{(\text{uEP})}_{\text{dual}} \right]_{\text{interface}} = \hat{\boldsymbol{z}}\, \overline{h}\, \overline{(\eta' \partial_x p')_{k-1/2}} \tag{67.82a}$$

$$\rho_{\text{ref}} \left[\boldsymbol{E}^{(\text{vEP})}_{\text{dual}} \right]_{\text{interface}} = \hat{\boldsymbol{z}}\, \overline{h}\, \overline{(\eta' \partial_y p')_{k-1/2}}. \tag{67.82b}$$

Let us now write the interface pressure gradient fluctuation as

$$\nabla p_{\text{k}-1/2} = \nabla p_{\text{k}} - g\, \rho_{\text{k}}\, \nabla \eta_{\text{k}-1/2} \tag{67.83}$$

so that

$$\overline{(\eta' \nabla p')_{k-1/2}} = \overline{\eta'_{k-1/2}\, \nabla p'_{\text{k}}} + g\, \rho_{\text{k}}\, \overline{(\eta' \nabla \eta')_{\text{k}-1/2}}. \tag{67.84}$$

As for the analysis in Section 31.7, we assume the fluctuations are geostrophic so that we can introduce the layer geostrophic velocity corresponding to the gradient of the layer pressure fluctuations

$$\partial_x p'_{\text{k}} = f\, \rho_{\text{ref}}\, v'_{\text{k}} \quad \text{and} \quad \partial_y p'_{\text{k}} = -f\, \rho_{\text{ref}}\, u'_{\text{k}}, \tag{67.85}$$

in which case the dual form stress portion of the Eliassen-Palm fluxes take the form

$$\rho_{\text{ref}} \left[\boldsymbol{E}^{(\text{uEP})}_{\text{dual}} \right]_{\text{interface}} = \hat{\boldsymbol{z}}\, \overline{h} \left[f\, \rho_{\text{ref}}\, \overline{\eta'_{k-1/2}\, v'_{\text{k}}} + g\, \rho_{\text{k}}\, \overline{(\eta' \partial_x \eta')_{\text{k}-1/2}} \right] \tag{67.86a}$$

$$\rho_{\text{ref}} \left[\boldsymbol{E}^{(\text{vEP})}_{\text{dual}} \right]_{\text{interface}} = \hat{\boldsymbol{z}}\, \overline{h} \left[-f\, \rho_{\text{ref}}\, \overline{\eta'_{k-1/2}\, u'_{\text{k}}} + g\, \rho_{\text{k}}\, \overline{(\eta' \partial_y \eta')_{\text{k}-1/2}} \right]. \tag{67.86b}$$

The $\overline{\eta'_{\text{k}-1/2}\, \boldsymbol{u}'_{\text{k}}}$ term is an eddy transport of the area between $z = \overline{\eta}_{\text{k}-1/2}$ and $z = \eta'_{\text{k}-1/2}$ (see Figure 67.2). We studied the same transport for the continuously stratified fluid in Section 31.7. In that discussion, we found that the interface fluctuations, η', can be related to the buoyancy fluctuations, b', in which case $\overline{\eta'_{\text{k}-1/2}\, \boldsymbol{u}'_{k}}$ is proportional to the eddy buoyancy flux for the layer.

67.6.7 Comments

Greatbatch and Lamb (1990) and *Greatbatch* (1998) pursue a similar analysis for the purpose of framing the mesoscale eddy parameterization problem. They focus on the interfacial form stress contribution since, for geostrophic eddies, it dominates over the other terms in the Eliassen-Palm fluxes (67.80a) and (67.80b).

67.7 Vorticity and potential vorticity

We follow the procedure from Chapter 39 to derive the vorticity and potential vorticity for the thickness weighted shallow water equations. In the process, we connect the eddy flux of potential vorticity to the Eliassen-Palm fluxes (67.75a) and (67.75b). Note that the same manipulations also hold for the dual Eliassen-Palm fluxes (67.80a) and (67.80b).

67.7.1 Derivation

Use the vector identities from Sections 35.5 and 39.1 to bring the material evolution equations (67.77a) and (67.77b) into their equivalent vector invariant forms[8]

$$\partial_t \widehat{u} - (f + \widehat{\zeta})\, \widehat{v} = -\partial_x(\overline{p}/\rho + \widehat{\boldsymbol{u}} \cdot \widehat{\boldsymbol{u}}/2) - \overline{h}^{-1}\, (\nabla_{\mathrm{h}} + \hat{\boldsymbol{z}}\, \overline{h}^{-1} \delta_{\mathrm{k}}) \cdot \boldsymbol{E}^{(\mathrm{uEP})} \tag{67.87a}$$

$$\partial_t \widehat{v} + (f + \widehat{\zeta})\, \widehat{u} = -\partial_y(\overline{p}/\rho + \widehat{\boldsymbol{u}} \cdot \widehat{\boldsymbol{u}}/2) - \overline{h}^{-1}\, (\nabla_{\mathrm{h}} + \hat{\boldsymbol{z}}\, \overline{h}^{-1} \delta_{\mathrm{k}}) \cdot \boldsymbol{E}^{(\mathrm{vEP})}, \tag{67.87b}$$

where we introduced the relative vorticity of the thickness weighted horizontal velocity

$$\widehat{\zeta} = \partial_x \widehat{v} - \partial_y \widehat{u}. \tag{67.88}$$

Taking ∂_x of the meridional equation (67.87b) and subtracting ∂_y of the zonal equation (67.87a) renders the evolution equation for absolute vorticity, $\widehat{\zeta}_{\mathrm{a}} = \widehat{\zeta} + f$,

$$\frac{\mathrm{D}^\sharp \widehat{\zeta}_{\mathrm{a}}}{\mathrm{D}t} + \widehat{\zeta}_{\mathrm{a}}\, \nabla \cdot \widehat{\boldsymbol{u}} = \partial_y[\overline{h}^{-1}\, (\nabla_{\mathrm{h}} + \hat{\boldsymbol{z}}\, \overline{h}^{-1} \delta_{\mathrm{k}}) \cdot \boldsymbol{E}^{(\mathrm{uEP})}] - \partial_x[\overline{h}^{-1}\, (\nabla_{\mathrm{h}} + \hat{\boldsymbol{z}}\, \overline{h}^{-1} \delta_{\mathrm{k}}) \cdot \boldsymbol{E}^{(\mathrm{vEP})}]. \tag{67.89}$$

Making use of the thickness equation (67.37) to replace $\nabla \cdot \widehat{\boldsymbol{u}}$ leads to the potential vorticity equation

$$\overline{h}\, \frac{\mathrm{D}^\sharp \Pi^\sharp}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{F}^\sharp \tag{67.90}$$

where

$$\Pi^\sharp = \frac{f + \partial_x \widehat{v} - \partial_y \widehat{u}}{\overline{h}} = \frac{f + \widehat{\zeta}}{\overline{h}} \tag{67.91}$$

is the potential vorticity defined with the thickness weighted velocity and ensemble mean thickness. The corresponding eddy potential vorticity flux is a horizontal vector and given in terms of the divergence of the Eliassen-Palm fluxes

$$\boldsymbol{F}^\sharp = \hat{\boldsymbol{x}}\, [\overline{h}^{-1}\, (\nabla_{\mathrm{h}} + \hat{\boldsymbol{z}}\, \overline{h}^{-1} \delta_{\mathrm{k}}) \cdot \boldsymbol{E}^{(\mathrm{vEP})}] - \hat{\boldsymbol{y}}\, [\overline{h}^{-1}\, (\nabla_{\mathrm{h}} + \hat{\boldsymbol{z}}\, \overline{h}^{-1} \delta_{\mathrm{k}}) \cdot \boldsymbol{E}^{(\mathrm{uEP})}] + \hat{\boldsymbol{z}} \times \nabla \Upsilon, \tag{67.92}$$

where Υ is an arbitrary gauge function.[9] This equation connects the potential vorticity flux to the Eliassen-Palm fluxes and it is known as the *Taylor-Bretherton identity*. Remarkably, the potential vorticity flux also provides the eddy forcing to the thickness weighted velocity equation

$$\partial_t \widehat{\boldsymbol{u}} + (f + \widehat{\zeta})\, \hat{\boldsymbol{z}} \times \widehat{\boldsymbol{u}} + \nabla(\overline{p}/\rho + \widehat{\boldsymbol{u}} \cdot \widehat{\boldsymbol{u}}/2) = -\hat{\boldsymbol{z}} \times (\boldsymbol{F}^\sharp - \hat{\boldsymbol{z}} \times \nabla \Upsilon), \tag{67.93}$$

which can also be written

$$\partial_t \widehat{\boldsymbol{u}} + \hat{\boldsymbol{z}} \times (\overline{h}\, \widehat{\boldsymbol{u}}\, \Pi^\sharp + \boldsymbol{F}^\sharp - \hat{\boldsymbol{z}} \times \nabla \Upsilon) + \nabla(\overline{p}/\rho + \widehat{\boldsymbol{u}} \cdot \widehat{\boldsymbol{u}}/2) = 0, \tag{67.94}$$

where $\overline{h}\, \widehat{\boldsymbol{u}}\, \Pi^\sharp + \boldsymbol{F}^\sharp - \hat{\boldsymbol{z}} \times \nabla \Upsilon$ is the net (mean plus eddy plus gauge) potential vorticity flux.

67.7.2 Concerning the mean field potential vorticity

We emphasize that the mean field potential vorticity arising from our development is $\Pi^\sharp$, which is defined by equation (67.91) using the thickness weighted velocity, $\widehat{\boldsymbol{u}}$ for the relative vorticity.

[8] In Section D.6 of *Griffies et al.* (2020), the authors state "In contrast to the flux-form momentum equation, the vector-invariant velocity equation does not admit a finite volume formulation." That statement is incorrect, with equations (67.87a) and (67.87b) the finite volume vector-invariant velocity equation.

[9] Equation (129) in *Young* (2012) should have a gauge function on its right hand side, which follows from his footnote #3. We provide an example of the need for a gauge function in Section 67.8.

This potential vorticity is distinct from the thickness weighted average potential vorticity

$$\widehat{\Pi} = \frac{\overline{\Pi\, h}}{\overline{h}} = \frac{f + \overline{\zeta}}{\overline{h}} = \frac{f + \partial_x \overline{v} - \partial_y \overline{u}}{\overline{h}}, \tag{67.95}$$

which is the mean field potential vorticity considered by *Greatbatch* (1998) and *Peterson and Greatbatch* (2001). The two forms of potential vorticity differ by the potential vorticity of the bolus velocity

$$\Pi^\sharp - \widehat{\Pi} = \frac{(f + \widehat{\zeta}) - (f + \overline{\zeta})}{\overline{h}} = \frac{\hat{\boldsymbol{z}} \cdot [\nabla \times (\widehat{\boldsymbol{u}} - \overline{\boldsymbol{u}})]}{\overline{h}} = \frac{\hat{\boldsymbol{z}} \cdot (\nabla \times \widehat{\boldsymbol{u}'})}{\overline{h}} = \frac{\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}^{\text{bolus}})}{\overline{h}}, \tag{67.96}$$

where the penultimate equality made use of equation (67.32) for $\widehat{\boldsymbol{u}'}$, and the final equality introduced the bolus velocity according to equation (67.39). Use of $\Pi^\sharp$ allows us to develop a potential vorticity conservation statement solely in terms of $\widehat{\boldsymbol{u}}$, whereas the use of $\widehat{\Pi}$ by *Greatbatch* (1998) and *Peterson and Greatbatch* (2001) requires both $\overline{\boldsymbol{u}}$ and $\widehat{\boldsymbol{u}}$.

67.7.3 Comments

As in *Young* (2012), and as advertised at the start of this chapter, we have developed the equations for the thickness weighted averaged shallow water solely in terms of the thickness weighted velocity, $\widehat{\boldsymbol{u}}$. This development includes the thickness equation (67.35), the tracer equation (67.42), the velocity equation (67.46) and the potential vorticity equation (67.90). There is no need for the ensemble mean velocity, $\overline{\boldsymbol{u}}$, and thus no need to parameterize the bolus velocity.

67.8 Vorticity fluxes for non-divergent barotropic flow

In Chapter 38 we studied the mechanics of a two dimensional fluid whose horizontal flow is non-divergent. As for the shallow water, the fluid moves as columns. However, since the horizontal flow is non-divergent, each column is rigid and so there is no stretching or squashing of columns. Correspondingly, there are no form stresses acting on these columns. We specialize the shallow water analysis in this section to rigid columnar motion as a means to verify that the Reynolds stresses appearing in the Eliassen-Palm flux formulation correspond to that arising in the non-divergent barotropic model.

For rigid fluid columns, the thickness weighted average reduces to just the ensemble mean since all layer thicknesses are fixed. Correspondingly, there are no form stresses acting at the layer interfaces since interfaces are horizontal. Hence, the Eliassen-Palm fluxes (67.75a) and (67.75b) reduce to just their Reynold stress contributions

$$h^{-1}\, \boldsymbol{E}^{(\text{uEP})} = \overline{u'\, u'}\, \hat{\boldsymbol{x}} + \overline{u'\, v'}\, \hat{\boldsymbol{y}} \tag{67.97a}$$

$$h^{-1}\, \boldsymbol{E}^{(\text{vEP})} = \overline{u'\, v'}\, \hat{\boldsymbol{x}} + \overline{v'\, v'}\, \hat{\boldsymbol{y}}. \tag{67.97b}$$

The corresponding eddy potential vorticity flux (67.92), absent the gauge term, is

$$\boldsymbol{F}^\sharp = \hat{\boldsymbol{x}}\, \nabla \cdot [\overline{u'\, v'}\, \hat{\boldsymbol{x}} + \overline{v'\, v'}\, \hat{\boldsymbol{y}}] - \hat{\boldsymbol{y}}\, \nabla \cdot [\overline{u'\, u'}\, \hat{\boldsymbol{x}} + \overline{u'\, v'}\, \hat{\boldsymbol{y}}] \tag{67.98a}$$

$$= \hat{\boldsymbol{x}}\, [\partial_x(\overline{u'\, v'}) + \partial_y(\overline{v'\, v'})] - \hat{\boldsymbol{y}}\, [\partial_x(\overline{u'\, u'}) + \partial_y(\overline{u'\, v'})]. \tag{67.98b}$$

Does the eddy potential vorticity flux (67.98b) agree, to within a gauge function, with the eddy flux resulting from a direct decomposition into eddy and mean within a two dimensional non-divergent model? To address this question, recall that the advective flux of potential vorticity

for the two dimensional non-divergent flow is given by equation (38.52)

$$\boldsymbol{u}\, q = \boldsymbol{u}\, f + \nabla \cdot (\hat{\boldsymbol{z}} \times \mathcal{E}), \tag{67.99}$$

where $\mathcal{E}$ is the trace-free anisotropic portion of the kinetic stress tensor

$$\mathcal{E} = \begin{bmatrix} -(u^2 - v^2)/2 & -u\, v \\ -u\, v & (u^2 - v^2)/2 \end{bmatrix}. \tag{67.100}$$

The mean of the potential vorticity flux is (67.99) is given by

$$\overline{\boldsymbol{u}\, q} = \overline{\boldsymbol{u}}\, \overline{q} + \overline{\boldsymbol{u}'\, q'}, \tag{67.101}$$

where the flux computed from the mean fields is

$$\overline{\boldsymbol{u}}\, \overline{q} = \overline{\boldsymbol{u}}\, (f + \overline{\zeta}), \tag{67.102}$$

whereas the eddy potential vorticity flux is

$$\begin{aligned}
\overline{\boldsymbol{u}'\, q'} &= \nabla \cdot [\hat{\boldsymbol{z}} \times \overline{\mathcal{E}(\boldsymbol{u}')}] && \text{(67.103a)} \\
&= \hat{\boldsymbol{x}}\, [\partial_x(\overline{u'\, v'}) + \partial_y(\overline{v'\, v' - u'\, u'})/2] + \hat{\boldsymbol{y}}\, [\partial_x(\overline{v'\, v' - u'\, u'})/2 - \partial_y(\overline{u'\, v'})] && \text{(67.103b)} \\
&= \hat{\boldsymbol{x}}\, [\partial_x(\overline{u'\, v'}) + \partial_y(\overline{v'\, v'})] - \hat{\boldsymbol{y}}\, [\partial_x(\overline{u'\, u'}) + \partial_y(\overline{u'\, v'})] + (\hat{\boldsymbol{x}}\, \partial_y - \hat{\boldsymbol{y}}\, \partial_x)\, \overline{\boldsymbol{u}' \cdot \boldsymbol{u}'}/2 && \text{(67.103c)} \\
&= \boldsymbol{F}^\sharp - \hat{\boldsymbol{z}} \times \nabla(\overline{\boldsymbol{u}' \cdot \boldsymbol{u}'})/2. && \text{(67.103d)}
\end{aligned}$$

Hence, $\overline{\boldsymbol{u}'\, q'}$ agrees with $\boldsymbol{F}^\sharp$ in equation (67.98b) to within a gauge function given by the rotated gradient of the eddy kinetic energy, so that their divergences are equal

$$\nabla \cdot \boldsymbol{F}^\sharp = \nabla \cdot \overline{\boldsymbol{u}'\, q'}. \tag{67.104}$$

That is, when diagnosing contributions to the potential vorticity flux, the gauge term, $-\hat{\boldsymbol{z}} \times \nabla(\overline{\boldsymbol{u}' \cdot \boldsymbol{u}'})/2$, plays no role in forcing potential vorticity.

Part XIII

Scalar fields

In this part of the book, we study the physics and maths of passive tracers, *conservative tracers*,[10] as well as density and Archimedean buoyancy. Tensorially, these fields are scalars and so they provide a number (e.g., temperature, humidity, mass density) throughout the continuum fluid. This study of *scalar mechanics* complements that of momentum, vorticity, and energy considered in other parts of this book, with each scalar offering information about the mechanics of fluid motion. Much of the material is relevant to both the atmosphere and ocean, though specialized topics are motivated from ocean applications.

Although the physics and maths of scalar fields is simpler than that describing momentum, vorticity, and energy, there is a remarkable richness to the study. We only touch upon a few of the many topics, aiming to provide a theoretical platform for further study by the interested reader. Here is a synopsis of the chapters in this part of the book.

- In Chapter 68 we focus on tracer diffusion in the absence of advection. The diffusion equation is the canonical parabolic partial differential equation, and we studied a variety of its mathematical properties in Chapters 6 and 9. Indeed, there is a long and rich history of research into diffusive (or conductive) processes across science and engineering, with books such as *Crank* (1956) and *Carslaw and Jaeger* (1959) offering a wealth of theoretical results and mathematical methods. Our focus in Chapter 68 is somewhat more physical than our earlier presentations of diffusion, though with much of the physics revealed via deriving mathematical properties of the diffusion equation.

- In Chapter 69 we consider advection along with diffusion in affecting the evolution of tracer concentration. Advection results through viewing evolution from within the Eulerian reference frame. When acting alone on a conservative tracer, advection affects a reversible stirring of tracer concentration that can increase tracer gradients. When diffusion is included along with advection, reversibility is lost and tracer gradients increase or decrease depending on the relative dominance of advection or diffusion.

- In Chapter 70 we introduce notions of wave-mean flow interactions that give rise to eddy-induced advection (or skew diffusion) as well as diffusion. This chapter, which mostly focuses on kinematic properties and is restricted to tracers, makes use of both geopotential coordinates as well as isopycnal coordinate equations from Chapter 66. Doing so provides examples of the dual roles these two vertical coordinate choices fill for describing turbulent geophysical flows.

- In Chapter 71 we study elements of tracer parameterizations used for coarse resolution models of the ocean circulation. We particularly focus on a variety of mathematical properties of the parameterizations, and unpack the physics embodied within the mathematics. This chapter exposes a handful of questions at the leading edge of research, with that material among the less mature found in this book.

- In Chapter 72 we consider ocean density and the budget for global sea level. This study requires us to dive into the niceties of the enthalpy (heat), salt, and mass budgets for the ocean. These budgets are central to climate science through the ocean's role as the dominant sink of anthropogenically induced increase in planetary enthalpy, and with that increase affecting a rise in sea level.

- In Chapter 73 we present fundamental elements to the theory of water mass transformation analysis. This analysis offers a view on ocean circulation mechanics that complements those available from Eulerian and Lagrangian approaches. Many of the methods of ocean water

[10] Conservative tracers evolve only via the convergence of advective and diffusive fluxes within the fluid interior, along with boundary conditions. That is, conservative tracers have no interior sources or sinks. Hence, the net content of a conservatice tracer over any finite volume domain is affected only through transport across boundaries.

mass analysis are relevant to atmospheric analyses as well, though this chapter is written from an oceanographic perspective. Furthermore, this chapter is arguably the toughest in this part of the book, with progress in understanding water mass transformation theory sometimes taking years to ponder the concepts and apply the methods.

Chapter 68

TRACER DIFFUSION

In this chapter we study tracer diffusion in geophysical fluids. Diffusion affects an irreversible exchange of propertes between fluid elements, thus offering a conceptual and mathematical depiction of how such properties are mixed at the microscale through chaotic molecular motions. Furthermore, diffusion forms the null hypothesis for how turbulent eddying flows disperse and mix tracers at scales larger than the microscale. Diffusion is thus central to how environmental and geophysical fluid flows act to transport matter and thermodynamic properties, thus motivating an exploration into a variety of physical and mathematical aspects of tracer diffusion.

CHAPTER GUIDE

We presume an understanding of the tracer equation as studied in Chapter 20. We considered mathematical elements of the diffusion equation in Chapter 6 as part of our study of parabolic partial differential equations. We also considered the diffusion equation when studying Green's function solutions for passive tracers in Chapter 9. Those presentations are very useful for the present chapter, though not essential.

In Section 69.2, we summarize some tensor analysis tools for use in studying tracer diffusion, with that material drawing upon the tensor analysis material in Chapters 1-4. We work in the context of a non-Boussinesq fluid, with results for the Boussinesq ocean of Chapter 29 found merely by setting the density factor, ρ, to the Boussinesq reference density, ρ_o. Chapter 69 is a direct descendant of the current chapter, where we study the combined effects of advection and diffusion.

68.1 Loose threads

- Add a new section working through some of the classic BVPs for diffusion, such as those in *Csanady* (1973). Also add some of these to the exercises.

68.2 Mathematical preliminaries

As derived in Section 20.1, the equation for a *conservative tracer*[1] takes on the form

$$\rho \frac{\mathrm{DC}}{\mathrm{D}t} = -\nabla \cdot \mathbf{J}, \tag{68.1}$$

where C is the tracer concentration scalar, and $\mathbf{J}$ is a tracer flux vector that embodies molecular diffusion as well as subgrid scale advection and subgrid scale diffusion (Chapter 71). Advective transport from the resolved flow, $\mathbf{v}$, appears when transforming to an Eulerian or laboratory reference frame, in which case the tracer equation takes on the equivalent forms

$$\rho \frac{\mathrm{DC}}{\mathrm{D}t} = -\nabla \cdot \mathbf{J} \iff \partial_t(\rho\,\mathrm{C}) + \nabla \cdot (\mathbf{v}\,\rho\,\mathrm{C} + \mathbf{J}) = 0, \tag{68.2}$$

with $\mathbf{v}\,\rho\,\mathrm{C}$ the advective flux. In this chapter we assume $\mathbf{J}$ arises just from diffusion, and we furthermore ignore any flow (i.e., $\mathbf{v} = 0$) so that advection is absent.

68.2.1 Concerning the upright versus slanted notation

The two forms of the tracer in equation (68.2) are written as a tensor equation, prompting the upright C, $\mathbf{v}$, and $\mathbf{J}$, which follows the notation convention of Section 1.2.2. Hence, these equations are valid in any coordinate system. When represented in a particular coordinate system, such as Cartesian, then we write the slanted C, $\boldsymbol{v}$, and $\boldsymbol{J}$, which are particular coordinate representations of the fields C, $\mathbf{v}$, and $\mathbf{J}$.

The upright versus slanted notation is fundamental conceptually, since it is important to appreciate that tensors are geometric objects that are not subject to the whims of a particular coordinate choice. Correspondingly, physically robust differential and integral equations are coordinate invariant. Even so, the upright-slanted notation can be softly adhered to without much cause for concern, so long as we are careful to write the coordinate equations using rules of tensor analysis. In that case, the coordinate equations are unaltered in form when changing coordinates; i.e., they are tensor equations. Developing a practical and conceptual understanding of what careful means in this context requires the tensor analysis material presented in Chapters

[1] Conservative tracers evolve without sources or sinks, and so their material time evolution is only affected by the convergence of a flux.

1 through 4. In the remainder of this section, we summarize salient points from those chapters that are of particular use in the study of tracer diffusion.

68.2.2 Metric tensor allows us to measure distance

The metric tensor, $\mathbb{g}$, is a symmetric and positive-definite (i.e., all eigenvalues are positive) second order tensor that is used to measure the distance between points in space. The *Kronecker tensor* (unit tensor) is the representation of the metric tensor for Euclidean space when using Cartesian coordinates. In this case, $\mathbb{g}_{mn} = \delta_{mn}$, where δ_{mn} is unity when $m = n$ and zero otherwise. In this book, we are only concerned with fluid motion through a background Euclidean space. Even so, we find many occasions to use non-Cartesian coordinates and/or to consider flow constrained to non-Euclidean surfaces that are embedded in Euclidean space (e.g., a spherical planet or an isopycnal surface). Example non-Cartesian coordinates of use for geophysical fluids include spherical coordinates (Section 4.23), cylindrical-polar coordinates (Section 4.22), generalized vertical coordinates (Part XII), and Lagrangian coordinates (Chapter 18). For these cases, and others, a coordinate representation of the metric tensor is distinct from the Kronecker tensor.

We often have need to work with the inverse metric tensor, $\mathbb{g}^{-1}$, which we know exists since the metric is a symmetric and positive-definite tensor. To reduce notational clutter, we write $\mathbb{g}^{mn}$ for the coordinate representation of the inverse metric, rather than the more clunky $(\mathbb{g}^{-1})^{mn}$. By definition of the inverse metric, we have the following identity holding for any coordinate choice

$$\delta^m{}_n = \mathbb{g}^{mp}\, \mathbb{g}_{pn}, \tag{68.3}$$

where $\delta^m{}_n$ is an expression of the identity tensor, which is coordinate invariant.[2] Notably, for Cartesian tensors, where $\mathbb{g}_{mn} = \delta_{mn}$, the identity (68.3) reduces to the identity across Kronecker tensor representations

$$\delta^m{}_n = \delta^{mp}\, \delta_{pn}. \tag{68.4}$$

Since $\delta^{mn} = \delta_{mn}$ (inverse of the Kronecker tensor is the tensor itself), equation (68.4) means that

$$\delta^{mn} = \delta_{mn} = \delta^m{}_n. \tag{68.5}$$

Identities (68.4) and (68.5) are indicative of the relative simplicity of Cartesian tensor analysis, in which there is no distinction between index placement so that there is no quantitative need to keep track of upstairs versus downstairs indices. Yet there is a distinction for general tensors, and so we must be careful to use the metric tensor to raise and lower indices, as now discussed.

68.2.3 Raising and lowering tensor indices via the metric tensor

Besides measuring distance between points in space, the metric tensor provides the operational means to raise and lower indices that appear on the representations of tensors (see Section 4.2.3 for details). For example, consider the second order diffusion tensor, $\mathbf{K}$, with a particular coordinate representation for $K^m{}_n$. The $K^m{}_n$ representation is sometimes referred to as the $(1,1)$ *natural* representation, and it is related to its totally contravariant $(2,0)$ *sharp* representation, K^{mn}, through contraction with the metric tensor,[3]

$$K^m{}_n = \mathbb{g}_{pn}\, K^{mp}. \tag{68.6}$$

[2] Coordinate invariant means that the Kronecker tensor has the same numerical values for all coordinates. Namely, it is unity when its two indices are the same and zero when the indices differ.

[3] In Section 1.6.1 we introduced the musical nomenclature sometimes used for the representations of second order tensors. The *natural* representation of a second order tensor occurs with one tensor index upstairs and the other downstairs. The natural representation is sometimes denoted by $(1,1)$, to indicate the number of indices up and down. The *sharp* or $(2,0)$ representation is when the tensor is represented with both indices upstairs. Finally, the *flat* or $(0,2)$ representation is where both indices are downstairs.

It follows that to relate the *flat* or $(0,2)$ representation to the sharp representation requires two contractions with the metric tensor,

$$K_{mn} = \mathfrak{g}_{mq}\, \mathfrak{g}_{pn}\, K^{qp}. \tag{68.7}$$

Note that since the metric is symmetric, $\mathfrak{g}_{mn} = \mathfrak{g}_{nm}$, there is no need to be concerned with the ordering of its indices.

68.2.4 Divergence of a vector and the divergence theorem

As seen from the tracer equation (68.2), the convergence of the tracer flux drives the time evolution of conservative tracers. It is thus important to know how the divergence is expressed as a tensor equation. In Section 4.15 we derived the coordinate invariant expression (4.134) for the divergence of a vector

$$\nabla \cdot \mathbf{J} = \nabla_m\, J^m = \frac{1}{\sqrt{\det(\mathfrak{g}_{mn})}}\, \partial_m\, [\sqrt{\det(\mathfrak{g}_{mn})}\; J^m], \tag{68.8}$$

where ∇_m are components to the *covariant derivative*. Equation (68.10) is a convenient result since it only requires partial derivatives in the chosen coordinate system, with all the coordinate dependent properties summarized by the square root of the metric determinant, $\sqrt{\det(\mathfrak{g}_{mn})}$. Since $\sqrt{\det(\mathfrak{g}_{mn})}$ appears in many places within this chapter, we find it useful to introduce the shorthand

$$g \equiv \sqrt{\det(\mathfrak{g}_{mn})}, \tag{68.9}$$

in which the covariant divergence (68.10) is written in the more tidy manner

$$\nabla \cdot \mathbf{J} = g^{-1}\, \partial_m\, (g\, J^m). \tag{68.10}$$

For Cartesian coordinates, $g = \sqrt{\det(\mathfrak{g}_{mn})} = 1$, in which case the divergence in equation (68.10) reduces to its familiar Cartesian form (Section 4.21.3). Yet other coordinates have a nonzero g, which accounts for the squeezing and expansion of the coordinate surfaces that affect the divergence. For example coordinate expressions of the divergence, see Section 4.23.8 for spherical coordinates, Section 4.22.10 for cylindrical-polar coordinates, and Sections 63.14 and 63.15 for generalized vertical coordinates.

The $1/g$ factor appearing in the covariant divergence (68.10) is convenient since it cancels the same factor appearing in the invariant volume element (4.60). This cancellation greatly simplifies the divergence theorem as presented in Section 4.19 and given by equation (4.148)

$$\int_{\mathcal{R}} \nabla \cdot \mathbf{J}\, \mathrm{d}V = \int_{\mathcal{R}} \nabla_m\, J^m\, \mathrm{d}V = \int_{\mathcal{R}} \partial_m (g\, J^m)\, \mathrm{d}^3\xi = \oint_{\partial\mathcal{R}} J^m\, \hat{n}_m\, \mathrm{d}\mathcal{S}, \tag{68.11}$$

where $\hat{\boldsymbol{n}}$ is the outward normal, and $\mathrm{d}^3\xi = \mathrm{d}\xi^1\, \mathrm{d}\xi^2\, \mathrm{d}\xi^3$ is the coordinate volume element.

68.2.5 Example tracer fluxes

We here briefly consider example tracer fluxes that are studied later in this chapter or in Chapter 69. We start from their form written in Cartesian coordinates and then transform to general coordinates.

Advective tracer flux

The advective tracer flux has Cartesian coordinates, denoted by ξ^m, written as

$$J^m = \rho\, v^m\, C, \tag{68.12}$$

where ρ, C, and v^m are functions that represent the density, tracer concentration, and velocity using Cartesian coordinates as independent variables. To transform the advective tracer flux to another set of coordinates, $\xi^{\overline{m}}$, requires the transformation matrix as detailed in Section 4.1.4, where

$$J^{\overline{m}} = \overline{\rho}\,\overline{C}\,\Lambda^{\overline{m}}{}_m\, v^m = \overline{\rho}\,\overline{C}\, v^{\overline{m}}. \tag{68.13}$$

In this equation we wrote $\overline{\rho}$, $\overline{C}$, and $v^{\overline{m}}$ for the functions representing the density, tracer concentration, and velocity with $\xi^{\overline{m}}$ as the independent variables. Furthermore, the transformation matrix, $\Lambda^{\overline{m}}{}_m$, is built from the partial derivatives of the two sets of coordinates

$$\Lambda^{\overline{m}}{}_m = \partial \xi^{\overline{m}} / \partial \xi^m. \tag{68.14}$$

For nomenclature brevity in the following, we do not write $\overline{\rho}$ and $\overline{C}$, thus relying on the functional dependence implicit in the coordinate choice.

Isotropic diffusive tracer flux and the Laplace-Beltrami operator

The isotropic diffusive tracer flux has the following representation using Cartesian coordinates

$$J^m = -\rho\,\kappa\,\delta^{mn}\,\partial_n C, \tag{68.15}$$

with $\kappa > 0$ the diffusivity scalar. We generalize the isotropic diffusive flux to arbitrary coordinates, $\xi^{\overline{m}}$, by introducing the inverse metric tensor represented using the $\xi^{\overline{m}}$ coordinates[4]

$$J^{\overline{m}} = -\rho\,\kappa\,\mathbb{g}^{\overline{mn}}\,\partial_{\overline{n}} C. \tag{68.16}$$

Making use of equation (68.10) leads to the flux convergence

$$-\nabla \cdot \mathbf{J} = g^{-1}\,\partial_{\overline{m}}\,(\rho\,\kappa\, g\, \mathbb{g}^{\overline{mn}}\,\partial_{\overline{n}} C). \tag{68.17}$$

If the product, $\rho\,\kappa$, is a constant in space then the resulting flux convergence exposes the *Laplace-Beltrami operator* acting on the tracer concentration

$$-\nabla \cdot \mathbf{J} = \rho\,\kappa\, \underbrace{g^{-1}\,\partial_{\overline{m}}\,(g\,\mathbb{g}^{\overline{mn}}\,\partial_{\overline{n}} C)}_{\text{Laplace-Beltrami acting on C}} \equiv \rho\,\kappa\,\overline{\nabla}^2 C. \tag{68.18}$$

Diffusive tracer flux with an anisotropic diffusion tensor

With a general diffusion tensor (whose form is discussed more in later sections), the Cartesian expression for the diffusive flux is given by

$$J^m = -\rho\, K^{mn}\,\partial_n C. \tag{68.19}$$

The tracer flux has a corresponding expression using arbitrary coordinates

$$J^{\overline{m}} = -\rho\, K^{\overline{mn}}\,\partial_{\overline{n}} C, \tag{68.20}$$

[4]The covariant derivative acting on a scalar field is just the partial derivative. So we could just as well have written $J^{\overline{m}} = -\rho\,\mathbb{g}^{\overline{mn}}\,\nabla_{\overline{n}} C$ for equation (68.16).

which is identical in form to the Cartesian expression (68.19). We make use of the transformation matrix and its inverse to write

$$\partial_{\overline{n}} = \partial_n \, \Lambda^n{}_{\overline{n}} \quad \text{and} \quad K^{\overline{m}\overline{n}} = \Lambda^{\overline{m}}{}_m \, \Lambda^{\overline{n}}{}_n \, K^{mn}. \tag{68.21}$$

Note that we actually only need to perform a single transformation since the contraction between the diffusion tensor and the derivative of the tracer concentration is coordinate invariant

$$J^{\overline{m}} = -\rho \, K^{\overline{m}\overline{n}} \, \partial_{\overline{n}} C = -\rho \, K^{\overline{m}n} \, \partial_n C = -\rho \, \Lambda^{\overline{m}}{}_m \, K^{mn} \, \partial_n C = \Lambda^{\overline{m}}{}_m \, J^m. \tag{68.22}$$

68.2.6 Comments about the tensor tools

Most of this chapter is unconcerned with the niceties of general tensor analysis. Part of the reason is that Cartesian coordinates are sufficient to exemplify the key maths and physics ideas. Even so, we are mindful to use rudimentary tensor notation, thus allowing for the equations derived with Cartesian coordinates to be valid tensor equations that hold for all coordinates. Given the growing suite of coordinates used in geophysical fluid studies, this extra bit of formalism has a nontrivial payoff.

68.3 Basic physics of tracer diffusion

The continuum approximation from Chapter 16 proposes that a macroscopic description of fluid motion does not require direct information about the motion of individual molecules. Nonetheless, random molecular motion and properties of the constituent molecules impact on fluid motion through the process of *molecular diffusion* of matter. Analogously, the random motion of fluid elements within a turbulent fluid give rise to *turbulent diffusive* transport.[5] In this section we explore the basic physical nature of molecular and turbulent diffusion.

68.3.1 Diffusion of matter by random molecular motions

Consider a fluid comprised of a single matter constituent, such as a lake of pure H_2O. As discussed in Section 17.2, for a macroscopic description of this single-component fluid, a constant mass fluid element is identical to a constant mass material fluid parcel. That is, there is no mixing of matter since there is just a single matter component. Now place a dye tracer (Section 20.1.5) into a corner of the lake so that the lake is comprised of two material components (H_2O and dye). Even in the absence of ambient macroscopic fluid motion, the random motion of water and dye molecules produces an exchange of matter constituents between fluid elements. Consequently, the dye spreads outward from its initial position; i.e., it *diffuses* into the surrounding water.

We introduced the notion of matter exchange between fluid elements when discussing the tracer equation in Section 20.1. In the present context, matter exchange occurs through the random motion of molecules acting in the presence of a matter concentration gradient. Even though the continuum approximation has removed all explicit concern for details of molecular motion, we confront the underlying molecular nature of matter since molecular motions have a measurable impact on macroscopic fluid properties. This transport of matter by random molecular motions is known as *molecular diffusion*. A statistical description of molecular diffusion is available for certain ideal-like gases, using methods from kinetic theory. *Einstein* (1905) advanced the theory by studying *Brownian motion*, in which a relatively large particle (e.g., dust) is transported by the random motion of molecules within the fluid. As noted on page 4 of *Csanady* (1973), results from both kinetic theory of gases and Brownian motion suggest

[5] For our purposes, turbulence is characterized by a quasi-random fluid flow that acts on fluid elements and their properties.

that the distance over which a typical mixing "event" occurs is small relative to the macroscopic scales of motion of concern for continuum mechanics. Consequently, we are justified in using the diffusive flux expression (68.23) arising from Fick's law as considered in Section 68.3.3.

68.3.2 Diffusion of matter by random turbulent motions

Diffusion of matter is a familiar process. For example, the odor from an open perfume bottle spreads throughout a room, even in the absence of macroscopic motion of air in the room. When the ambient macroscopic motion is zero (which is rare indeed), spread of the perfume arises solely from random molecular motions whose properties depend on details of the molecules (e.g., their size, speed, inter-molecular forces). The time scale for molecular diffusion is generally much longer than the analogous *turbulent diffusion* that results if there is random motion in the macroscopic fluid, such as occurs by placing a fan next to the perfume bottle.

It is common for environmental and geophysical fluid systems to exhibit some form of turbulent motion. In these systems, the transport of matter by macroscopic turbulent motion is much more efficient than from molecular motion. In the case of turbulent transport, we can generally ignore molecular diffusion since efficiency of the turbulent diffusive transport is far greater than that from molecular diffusion. *Taylor* (1921) described the statistical properties of turbulent diffusion, and many of his insights form the basis for theories of how turbulent motion impacts on matter concentrations. In Taylor's theory, turbulent diffusion is not concerned with molecular properties of the fluid. Rather, the properties of turbulent diffusion (e.g., its efficiency) depend on the nature of the turbulent motion of fluid elements. In this way, turbulent diffusion sits within the realm of continuum mechanics, whereas molecular diffusion is a subject for kinetic theory and statistical mechanics. Each type of turbulent motion gives rise to a distinct form of turbulent diffusion. For example, turbulent diffusion associated with a turbulent field of internal gravity waves is distinct from turbulent diffusion from geostrophic eddies.

68.3.3 Fick's law for matter diffusion

Consider a fluid with a non-uniform tracer concentration such as that drawn for a one-dimensional case in Figure 68.1. Random motion, due either to molecular motion or turbulent fluctuations, will transfer tracer across an arbitrary point, line, or plane. Random motion preferentially moves tracer from regions of high concentration to regions of low concentration, thus smoothing gradients.

To a good approximation, the mass flux (mass per time per cross-sectional area) of a material tracer is linearly proportional to the concentration gradient, and thus can be written in the form

$$\boldsymbol{J} = -\kappa_{\mathrm{c}}\, \rho\, \nabla C. \tag{68.23}$$

In this equation, we introduced the positive proportionality factor, $\kappa_{\mathrm{c}} > 0$, known as the *kinematic diffusivity*, whereas the product $\kappa_{\mathrm{c}}\, \rho$ is known as the *dynamic diffusivity*:

$$\kappa_{\mathrm{c}} \qquad \text{kinematic diffusivity with SI units m s}^{-2} \tag{68.24}$$

$$\rho\, \kappa_{\mathrm{c}} \qquad \text{dynamic diffusivity with SI units kg m}^{-2}\ \text{s}^{-2}. \tag{68.25}$$

The kinematic diffusivity has dimensions of squared length per time and it sets the efficiency or strength of the diffusion. The diffusive flux (68.23) is known as *Fick's law* of matter diffusion, and it is commonly used in geophysical fluid mechanics to represent the mixing of matter through diffusion. The minus sign in the diffusive flux arises since the flux is directed down the concentration gradient. When considering molecular diffusion, we distinguish diffusivities according to their respective tracers since they generally differ, whereas turbulent diffusivities are commonly assumed to be independent of tracer, in which case we write the generic, κ.

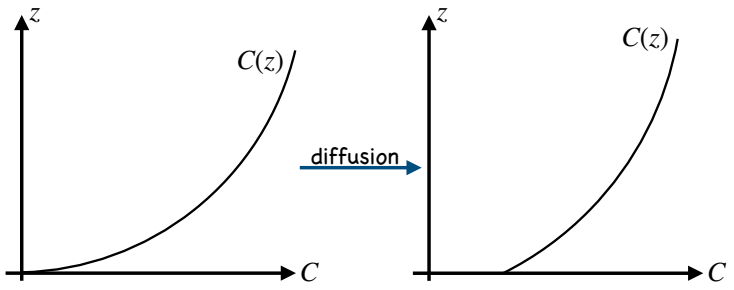

FIGURE 68.1: A graph illustrating a material tracer concentration, C as a function of the space coordinate z, with the left panel showing the concentration at an earlier time than the right panel. Across any arbitrary point, matter is transported through random motions, with this transport generally reducing the magnitude of the concentration gradient. This reduction of concentration gradient is a direct result of the downgradient (i.e., down the concentration gradient) orientation of the diffusive transport. For example, where the concentration is relatively high, random motion mixes this high concentration with adjacent lower concentration, thus acting to lower the concentration in the originally high concentration region and raise the concentration in the originally low concentration region. In this particlar example, $\partial C/\partial z > 0$, so that random fluid motions (either molecular or turbulent) lead to a diffusive flux directed in the $-\hat{\boldsymbol{z}}$ direction; i.e., downward. This downward flux brings high concentration fluid into the lower/deeper regions and low concentration fluid into higher/shallower regions. The concentration is vertically uniform if allowed to equilibrate under the action of diffusion.

The kinematic diffusivity has physical dimensions equal to the product of a length and a speed. For molecular diffusion, the kinematic diffusivity is proportional to the mean free path, $L_{\rm mfp}$ (see Section 16.3.3), and the root-mean-square molecular speed, $v_{\rm rms}$ (see Section 16.3.4). Each of these properties is a function of the molecules comprising the matter. For air, the mean free path is roughly 2×10^{-7} m and the root-mean-square speed is 500 m s^{-1}, so that $L_{\rm mfp}\, v_{\rm rms} \approx 10^{-4}$m^2 s^{-1}. The precise value for the molecular diffusivity depends on the molecular properties of the matter diffusing through the fluid; e.g., molecular size and speed.

For turbulent diffusion, Prandtl suggested that the characteristic length and velocity scales are determined by properties of the turbulent flow, not by the molecular properties of the fluid or the tracer. The turbulent length scale (also called the *mixing length*) is generally much larger than the molecular mean free path, whereas the turbulent velocity scale is much smaller than molecular speeds. Determination of turbulent length and velocity scales is subject to large uncertainties and variations given the multiple regimes of turbulence exhibited by geophysical flows. As a result, tracer transport by turbulent flows has remained a topic of much research since the early 20th century.

In regions where the diffusive flux is not a constant, there is generally a net transport of matter that leads to the reduction of the tracer concentration gradient as determined by the convergence of the diffusive flux

$$\rho \frac{\mathrm{D}C}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J} = \nabla \cdot (\kappa_{\rm c}\, \rho\, \nabla C). \tag{68.26}$$

That is, the concentration increases in regions where the diffusive flux, $\boldsymbol{J}$, converges, and decreases where the flux diverges. Expanding the divergence operator leads to

$$\rho \frac{\mathrm{D}C}{\mathrm{D}t} = \nabla(\kappa_{\rm c}\, \rho) \cdot \nabla C + \kappa_{\rm c}\, \rho\, \nabla^2 C. \tag{68.27}$$

The first term is nonzero in regions where the dynamic diffusivity, $\kappa_{\rm c}\, \rho$, spatially varies. This term vanishes for molecular diffusion, in which case the diffusivity is a spatial constant. However, for turbulent diffusion this term can be quite important given the potential for strong flow dependence to the diffusivity. Indeed, there are cases in which this spatial dependence can enhance tracer gradients, overcoming the effects from the curvature term. We consider an example in Exercise 68.5 known as the *Phillip's layering instability.*

The second term in the diffusion equation (68.27) is proportional to the Laplacian of the tracer concentration, which provides a measure of the curvature in the tracer field. Hence, this term vanishes when the tracer concentration is a constant or a linear function of space, whereas it is nonzero for tracers having less trivial spatial structure. As discussed in Section 68.3.6, this term provides a scale selectivity to the diffusion operator, thus resulting in a preferential dampening of small scale features relative to large scale features.

68.3.4 Fourier's law for heat diffusion

In the same way that matter concentration gradients lead to diffusion by random motions, temperature gradients lead to diffusion of heat. The corresponding phenomenological relation is known as *Fourier's law*, with the diffusive flux given by

$$\boldsymbol{J} = -\kappa_{\mathrm{T}}\, \rho\, \nabla T, \tag{68.28}$$

where $\kappa_{\mathrm{T}} > 0$ is the temperature kinematic diffusivity. As for the matter diffusivity, the molecular thermal diffusivity can be expressed in terms of fundamental properties of the fluid, and it is different from the matter diffusivity. In general, molecular processes diffuse matter slower than heat, so that the matter molecular diffusivity is smaller than the heat molecular diffusivity. The reason for the difference is that matter diffusion requires the movement of matter (molecules), whereas heat diffusion occurs through the exchange of thermal energy between molecules, and that exchange does not require the motion of matter. For turbulent transport, however, the turbulent thermal diffusivity is roughly the same as the turbulent matter diffusivity. The reason is that the turbulent diffusion of both matter and heat are mediated by the same turbulent fluctuations of fluid elements.

68.3.5 Newtonian frictional stress and momentum diffusion

In the same way that matter and temperature gradients lead to diffusion by random molecular and turbulent motions, the momentum of fluid elements is exchanged through diffusion in the presence of viscosity. The corresponding phenomenological relation is known as *Newton's law* of viscous friction. As momentum is a vector, a general treatment of momentum transport through irreversible viscous processes involves a second order stress tensor and a fourth order viscosity tensor. For the specific case shown in Figure 68.2, with shear (i.e., nonzero velocity gradient) in a single direction, Newtonian frictional stress takes the form

$$\tau = \rho\, \mu\, \partial_z u, \tag{68.29}$$

where $\mu > 0$ is the kinematic viscosity. Note the absence of a minus sign, in contrast to diffusive fluxes of scalars. The sign difference arises since it is the divergence of the stress tensor that leads to contact forces on the fluid, whereas it is the convergence of diffusive fluxes that leads to diffusion of matter and heat. We consider these general properties of the stress tensor when exploring the fluid dynamical equations in Chapter 24 and further study the physical nature of stress in Chapter 25.

For geophysical fluid mechanics, we are most generally interested in the molecular viscosity of water and air. Quite generally, the dynamic viscosity of water ($\rho\, \mu$) is about 10^2 times larger than that for air. But since the density of water is about 10^3 times larger than air, the kinematic viscosity of air is roughly 10 times greater than that of water.

The molecular kinematic viscosity can be expressed in terms of fundamental properties of the fluid, and it is different from the molecular matter diffusivity and molecular thermal diffusivity. For some turbulent processes, the turbulent viscosity, μ, is proportional to the turbulent diffusivity, κ, of scalar fields (e.g., temperature, salinity, humidity). In general, the

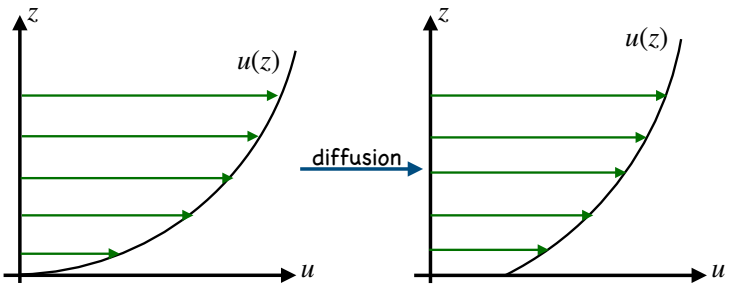

FIGURE 68.2: A graph illustrating the zonal velocity, u, as a function of the space coordinate z, with the left panel showing the velocity at an earlier time than the right panel. Across any arbitrary point, transport of momentum through random motions generally reduces the magnitude of the velocity gradient; i.e., the diffusive transport leads to a viscous stress that acts to reduce the velocity shear.

non-dimensional ratio of the viscosity to the diffusivity is known as the *Prandtl number*

$$\mathrm{Pr} = \mu/\kappa. \tag{68.30}$$

Theories for the turbulent Prandtl number are largely empirical, with first principles arguments elusive.

68.3.6 The scale selectivity of Laplacian diffusion

Let us focus on the Laplacian term appearing in the tracer equation (68.27) to establish some properties characteristic of Laplacian diffusion. Start by considering a tracer concentration whose spatial structure is given by two Fourier modes,

$$C(\boldsymbol{x}) = c_{\boldsymbol{p}} \sin(\boldsymbol{p}\cdot\boldsymbol{x}) + c_{\boldsymbol{q}} \sin(\boldsymbol{q}\cdot\boldsymbol{x}), \tag{68.31}$$

where $\boldsymbol{p}$ and $\boldsymbol{q}$ are specified wavevectors and $c_{\boldsymbol{p}}$, $c_{\boldsymbol{q}}$ are their corresponding amplitudes. In this case the Laplacian of the tracer is given by

$$\nabla^2 C = -[|\boldsymbol{p}|^2 c_{\boldsymbol{p}} \sin(\boldsymbol{p}\cdot\boldsymbol{x}) + |\boldsymbol{q}|^2 c_{\boldsymbol{q}} \sin(\boldsymbol{q}\cdot\boldsymbol{x})]. \tag{68.32}$$

Consequently, the Laplacian diffusion operator acts preferentially on waves of smaller wavelength (and larger wavenumber). For example, assume $|\boldsymbol{p}| \ll |\boldsymbol{q}|$, in which case the $\boldsymbol{q}$-mode is more rapidly damped towards zero than the $\boldsymbol{p}$-mode.[6] For this reason we say that Laplacian diffusion is *scale selective*. Note that zero is the wave averaged concentration for each Fourier mode. We thus see that diffusion acts to dampen each mode towards is average. Scale selectivity results geometrically from a property of the Laplacian operator as a measure of curvature. Tracer features with large curvature have a larger magnitude for their Laplacian, and as such they are damped more rapidly than tracer features with relatively small curvature.[7]

As a second means to understand properties of Laplacian diffusion, consider a Taylor series for the tracer concentration computed relative to an arbitrarily chosen origin,

$$C(\boldsymbol{x}) = C(0) + x^m \, \partial_m C|_{\boldsymbol{x}=0} + (1/2)\, x^m \, x^n \, \partial_n \partial_m C|_{\boldsymbol{x}=0} + \ldots \tag{68.33}$$

Now compute the average of this tracer concentration over a cube centered at the origin with

[6] Figure 8.2 illustrates this idea in the context of Fourier analysis.
[7] Recall our discussion of curvature in Chapter 5.

sides L and volume L^3, and furthermore make use of the identities

$$\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2} x^m \,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z = 0 \tag{68.34a}$$

$$\int_{-L/2}^{L/2}\int_{-L/2}^{L/2}\int_{-L/2}^{L/2} x^m\, x^n \,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z = \delta^{mn}\,(L^5/12). \tag{68.34b}$$

We thus find that the volume averaged tracer concentration, $\langle C\rangle$, deviates from the concentration at the origin by a term proportional to the Laplacian of the concentration evaluated at the origin

$$\langle C\rangle - C(0) = (L^2/24)\,\nabla^2 C\big|_{\boldsymbol{x}=0} \implies \partial_t C\big|_{\boldsymbol{x}=0} = (24\,\kappa_{\mathrm{c}}\,\rho/L^2)\,[\langle C\rangle - C(0)], \tag{68.35}$$

where we made use of the Laplacian portion of the diffusion equation (68.27) for the second expression. Evidently, Laplacian diffusion provides a tendency to bring the tracer concentration at a point towards the average tracer concentration in a region surrounding that point. For example, consider the case where the averaged tracer concentration has no time dependence, as occurs in a region with zero boundary fluxes of tracer. If we are at a point in the region where the concentration is less than the average concentration, $C < \langle C\rangle$, then diffusion provides a positive tendency to increase C towards $\langle C\rangle$, and vice versa if $C > \langle C\rangle$. These results offer another expression of what we found in studying Laplacian diffusion on Fourier modes. In that case, the Laplacian operator, as revealed through equation (68.32), damps each mode towards its average, which is zero.

68.3.7 A Gaussian tracer concentration generated by a Dirac source

Consider a one-dimensional tracer concentration in an unbounded domain whose initial ($t = 0$) value vanishes everywhere except at the origin, where it is given by a Dirac delta

$$C(x, t = 0) = Q\,\delta(x), \tag{68.36}$$

where $\delta(x)$ is the Dirac delta studied in Chapter 7. The Dirac delta has dimensions of inverse length, so that the constant, Q, has dimensions of $[C]\ L$. Integrating over any region containing the origin reveals that Q is the domain integrated tracer concentration at the initial time,

$$\int_{-\infty}^{\infty} C(x, t = 0)\,\mathrm{d}x = Q. \tag{68.37}$$

We are ensured that this integral holds for all time if the domain has no boundary fluxes of tracer nor any interior tracer sources.

Assume now that the tracer concentration evolves according to the one-dimensional (one space dimension) diffusion equation with a constant diffusivity, κ, and in a fluid with a constant density. In the absence of spatial boundaries (i.e., diffusion occurs on the real line, $\mathbb{R}^1$), the concentration is proportional to the causal free space Green's function given by the Gaussian function (9.136)

$$C(x, t) = \frac{Q}{(4\,\pi\,\kappa\,t)^{1/2}}\mathrm{e}^{-x^2/(4\,\kappa\,t)}, \tag{68.38}$$

which indeed satisfies (for any time, t)

$$Q = \int_{-\infty}^{\infty} C(x, t)\,\mathrm{d}x, \tag{68.39}$$

as required by tracer conservation for the infinite domain. We illustrate the Gaussian tracer

concentration (68.38) in Figure 68.3. The variance of the tracer distribution is given by

$$Q^{-1} \int_{-\infty}^{\infty} C\, x^2 \, \mathrm{d}x = 2\,\kappa\, t, \tag{68.40}$$

so that the standard deviation grows according to $\sqrt{2\,\kappa\, t}$.

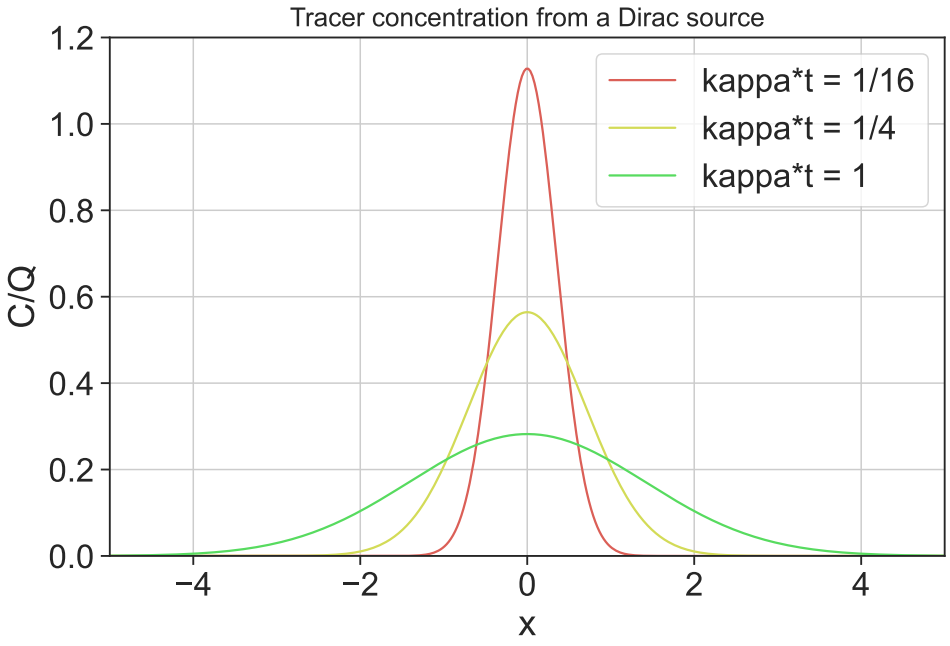

FIGURE 68.3: Illustrating the tracer concentration resulting from a Dirac source at the origin, as given by the Gaussian Green's function (68.38) for three values of $\kappa\, t$. According to equation (68.40), the standard deviation is given by $\sqrt{2\,\kappa\, t}$, with the standard deviation measuring the spread of the distribution.

68.3.8 Further study

The treatment given in this section is consistent with that from Section 1.5 of *Kundu et al.* (2016) and Chapter 1 of *Csanady* (1973). Molecular diffusion for ideal gases is examined in books that consider the kinetic theory of gases, such as *Reif* (1965) and *Huang* (1987). Treatments of Brownian motion in the context of turbulent diffusion can be found in *Csanady* (1973), who focuses on turbulent diffusion in the environment (e.g., for the study of pollution dispersal), and in Chapter 13 of *Vallis* (2017), who focuses on geophysical flows.

68.4 Further properties of tracer diffusion

We considered mathematical properties of the diffusion equation in Chapter 6 as part of our study of parabolic partial differential equations. We also examined the diffusion equation as part of our analysis of Green's function solutions for passive tracers in Chapter 9. Here, we explore further mathematical properties of diffusion motivated in part by the discussion in Section 68.3. In particular, we here allow for distinct behavior of the diffusive fluxes in the different directions. Such distinctions are relevant especially for the turbulent diffusivity arising in stratified fluids, where turbulent mixing across stratification surfaces is suppressed relative to turbulent mixing parallel to these surfaces (see Section 30.4). For this purpose we make use of the second order positive definite and symmetric *diffusion tensor*, $\mathbf{K} = \mathbf{K}^{\mathrm{T}}$, with the resulting downgradient

diffusive tracer flux given by

$$J^m = -\rho\, K^{mn}\, \partial_n C. \tag{68.41}$$

68.4.1 Sample diffusion tensors

For the case of molecular diffusion considered in equation (68.23), the diffusion tensor is generally assumed to be isotropic.[8] Written in Cartesian coordinates, the isotropic diffusion tensor takes the form

$$K^{mn} = \kappa\, \delta^{mn}, \tag{68.42}$$

whereas with general coordinates it is

$$K^{\overline{mn}} = \kappa\, \mathbb{g}^{\overline{mn}}. \tag{68.43}$$

It is notable that the natural or $(1,1)$ form for the diffusion tensor is numerically identical across coordinates, in that

$$K^m{}_p = \kappa\, \delta^m{}_p \quad \text{and} \quad K^{\overline{m}}{}_{\overline{p}} = \kappa\, \mathbb{g}_{\overline{np}}\, \mathbb{g}^{\overline{mn}} = \kappa\, \delta^{\overline{m}}{}_{\overline{p}}, \tag{68.44}$$

where we made use of the identity (68.3) satisfied by the metric and its inverse.

To parameterize flows that are turbulent and larger than the microscale (e.g., ocean mesoscale turbulence), it is common to rotate the diffusive fluxes to be along surfaces of constant scalar field, $\gamma(\boldsymbol{x}, t)$, in which case the diffusion tensor is

$$K^{mn} = \kappa\, (\delta^{mn} - \hat{\gamma}^m\, \hat{\gamma}^n), \tag{68.45}$$

where

$$\hat{\boldsymbol{\gamma}}_n = \frac{\partial_n \gamma}{|\nabla \gamma|} \tag{68.46}$$

is the surface normal direction. The general coordinate representation of this anisotropic diffusion tensor is

$$K^{\overline{mn}} = \kappa\, (\mathbb{g}^{\overline{mn}} - \hat{\gamma}^{\overline{m}}\, \hat{\gamma}^{\overline{n}}). \tag{68.47}$$

One choice for the orientation direction is to set $\hat{\gamma} = \hat{\boldsymbol{z}}$, in which case the diffusion tensor orients the tracer fluxes along surfaces of constant geopotential to thus realize *horizontal diffusion*. Another choice, motivated from the physics of ocean mesoscale eddy transport, sets γ equal to a measure of the local buoyancy. In this case we have the *neutral diffusion* process studied in Section 71.4.

68.4.2 Diffusion of tracer concentration powers

We here establish how diffusion affects the evolution of powers of the tracer concentration. For that purpose, consider the material evolution of C^Γ, where $\Gamma \geq 1$

$$\rho\, \frac{\mathrm{D}C^\Gamma}{\mathrm{D}t} = \Gamma\, C^{\Gamma-1}\, \rho\, \frac{\mathrm{D}C}{\mathrm{D}t} = -\Gamma\, C^{\Gamma-1}\, \nabla \cdot \boldsymbol{J}. \tag{68.48}$$

Making use of equation (68.10) for the covariant divergence leads to

$$\Gamma\, C^{\Gamma-1}\, \nabla \cdot \boldsymbol{J} = g^{-1}\, \Gamma\, C^{\Gamma-1}\, \partial_m (g\, J^m) \tag{68.49a}$$

$$= g^{-1}\, \partial_m (\Gamma\, C^{\Gamma-1}\, g\, J^m) - \Gamma\, (\Gamma - 1)\, C^{\Gamma-2}\, J^m\, \partial_m C. \tag{68.49b}$$

[8] We discussed isotropic tensors in Section 1.11.

Notice that

$$g^{-1}\,\partial_m(\Gamma\,C^{\Gamma-1}\,g\,J^m) = -g^{-1}\,\partial_m(\Gamma\,C^{\Gamma-1}\,g\,\rho\,K^{mn}\,\partial_n C) \tag{68.50a}$$
$$= -g^{-1}\,\partial_m(g\,\rho\,K^{mn}\,\partial_n C^{\Gamma}) \tag{68.50b}$$
$$= \nabla\cdot\boldsymbol{J}(C^{\Gamma}), \tag{68.50c}$$

which leads to the evolution equation

$$\rho\,\frac{\mathrm{D}C^{\Gamma}}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J}(C^{\Gamma}) + \Gamma\,(\Gamma-1)\,C^{\Gamma-2}\,\boldsymbol{J}\cdot\nabla C. \tag{68.51}$$

The first term in equation (68.51) is the convergence of the diffusive flux defined in terms of C^{Γ}. This term acts to diffuse C^{Γ} just like diffusion acts on C. The second term in equation (68.51) is negative since the diffusion tensor is symmetric and positive-definite so that

$$\boldsymbol{J}\cdot\nabla C = -\rho\,K^{mn}\,\partial_m C\,\partial_n C < 0. \tag{68.52}$$

That is, the diffusive flux, by construction, is oriented down the tracer concentration gradient. Consequently, the second term in equation (68.51) always acts to reduce the magnitude of C^{Γ} towards zero.

68.4.3 Moments of tracer concentration

Next we consider the evolution of domain integrated tracer concentration and its powers. To focus on impacts just from diffusion, we assume the boundaries are insulating (i.e., zero normal boundary flux) so that $\boldsymbol{J}\cdot\hat{\boldsymbol{n}} = 0$ with $\hat{\boldsymbol{n}}$ the outward normal at the boundary. We also assume the total fluid mass in the domain remains fixed

$$M = \int \rho\,\mathrm{d}V \quad \text{with} \quad \frac{\mathrm{d}M}{\mathrm{d}t} = 0. \tag{68.53}$$

We can thus treat the domain as material given that there is no exchange of mass or tracer across the boundaries. These assumptions allow us to focus just on the effects from tracer diffusion.

Domain average tracer concentration

The domain averaged tracer concentration is defined by

$$\overline{C} = \frac{\int C\,\rho\,\mathrm{d}V}{M}, \tag{68.54}$$

and it follows that its time derivative vanishes since

$$M\,\frac{\mathrm{d}\overline{C}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\int C\,\rho\,\mathrm{d}V = \int \frac{\mathrm{D}C}{\mathrm{D}t}\,\rho\,\mathrm{d}V = -\int \nabla\cdot\boldsymbol{J}\,\mathrm{d}V = -\oint \boldsymbol{J}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0, \tag{68.55}$$

where $\boldsymbol{J}\cdot\hat{\boldsymbol{n}} = 0$ since we are assuming an insulating boundary. Also note that we brought the time derivative inside the integral as a material derivative since the region is itself material, thus allowing us to make use of Reynold's transport theorem from Section 20.2.6. The result (68.55) follows since there is no change in the total mass of fluid nor is there any exchange of tracer across the boundaries. Hence, the domain averaged tracer concentration remains fixed in time.

Tracer variance within the domain

The variance of the tracer concentration is defined by

$$\text{var}(C) \equiv \frac{\int (C - \overline{C})^2 \, \rho \, \mathrm{d}V}{M} = \overline{C^2} - \overline{C}^2 \geq 0. \tag{68.56}$$

The tracer variance measures the deviation of the tracer concentration relative to the domain averaged concentration. Since the domain average remains fixed in time, the time change of the variance is given by

$$\frac{\mathrm{d}[\text{var}(C)]}{\mathrm{d}t} = \frac{\mathrm{d}\overline{C^2}}{\mathrm{d}t}. \tag{68.57}$$

Thus, it is common to refer to $\overline{C^2}$ as the tracer variance, though strictly speaking only time derivatives of $\overline{C^2}$ and $\text{var}(C)$ are equal as per equation (68.57). Performing the time derivative, and again noting that the domain is material thus allowing us to use Reynolds transport theorem, renders

$$M \frac{\mathrm{d}\overline{C^2}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t} \int C^2 \, \rho \, \mathrm{d}V = 2 \int C \frac{\mathrm{D}C}{\mathrm{D}t} \, \rho \, \mathrm{d}V = -2 \int C \, \nabla \cdot \boldsymbol{J} \, \mathrm{d}V = 2 \int \nabla C \cdot \boldsymbol{J} \, \mathrm{d}V. \tag{68.58}$$

The final equality again made use of the insulating boundary condition, $\boldsymbol{J} \cdot \hat{\boldsymbol{n}} = 0$. The time change in the tracer variance is thus determined by the integral of the projection of the tracer flux onto the tracer gradient. We already saw from equation (68.52) that diffusive fluxes are oriented down the tracer gradient. Consequently, diffusion of the tracer concentration results in a reduction in tracer variance

$$\frac{\mathrm{d}[\text{var}(C)]}{\mathrm{d}t} = \frac{\mathrm{d}\overline{C^2}}{\mathrm{d}t} \leq 0. \tag{68.59}$$

This result further supports our common experience where diffusion removes differences (i.e., gradients) within the tracer field.

Diffusion of arbitrary tracer moments

Proceeding as before, and dropping boundary contributions since the domain is material and insulating, the identity (68.51) shows that the time derivative of an arbitrary tracer moment is given by

$$\frac{\mathrm{d}\overline{C^\Gamma}}{\mathrm{d}t} = \Gamma \left(\Gamma - 1 \right) \int C^{\Gamma - 2} \, \nabla C \cdot \boldsymbol{J} \, \mathrm{d}V \leq 0. \tag{68.60}$$

For $\Gamma = 0$ we have an expression of mass conservation for the domain, whereas $\Gamma = 1$ is an expression of tracer conservation. The case of $\Gamma = 2$ yields the tracer variance result (68.59). The result for higher powers also holds. Hence, we conclude that the downgradient orientation of diffusive tracer fluxes acts to dissipate all powers of tracer concentration when integrated globally; i.e., all tracer moments are dissipated by diffusion.

68.5 Connecting tracer dissipation to the diffusion operator

We here take an excursion into linear operator theory. In particular, we make a connection between the diffusion operator with natural boundary conditions (defined below) and the functional derivative of the global tracer dissipation functional. This connection holds so long as the diffusion operator is self-adjoint and linear, as it is when diffusing passive tracers and

with natural boundary conditions.[9] The connection between a linear self-adjoint operator and a functional is developed in such books as *Courant and Hilbert* (1953, 1962). In the simplest case, the Laplacian of the tracer, $\nabla^2 C$, is equal to the functional derivative,

$$\nabla^2 C = \frac{\delta \mathcal{F}}{\delta C}, \tag{68.61}$$

where[10]

$$\mathcal{F} \equiv -\frac{1}{2} \int |\nabla C|^2 \, \rho \, \mathrm{d}^3 x \tag{68.62}$$

is the associated functional. In the following, we prove this result for a general diffusion tensor acting on an arbitrary tracer concentration, C, with the proof holding so long as the diffusion tensor is not a function of the tracer concentration. Besides offering an interesting theoretical tidbit, this result provides a suitable framework for developing numerical methods for discretizing the diffusion operator, with examples provided by *Griffies et al.* (1998) and Chapter 16 of *Griffies* (2004).

68.5.1 Fréchet derivative of the diffusion dissipation functional

Define the *diffusion dissipation functional*

$$\mathcal{F} = \int \mathcal{L} \, \mathrm{d}^3 x, \tag{68.63}$$

where the integrand is the negative semi-definite quadratic form

$$2 \, \mathcal{L} = \boldsymbol{J} \cdot \nabla C = -\rho \, K^{mn} \, \partial_m C \, \partial_n C \leq 0. \tag{68.64}$$

The goal is to relate the diffusion operator, given by the convergence of the diffusion flux, $-\nabla \cdot \boldsymbol{J}$, to the functional derivative of $\mathcal{F}$, with the derivative taken with respect to the tracer concentration, C. We compute the functional derivative using variational calculus technology detailed in Chapters 10, 46, and 47, mostly in relation to Hamilton's principle for non-dissipative dynamical systems.

For that purpose, consider a functional variation to the tracer concentration, δC, and insert it into the dissipation functional

$$\delta \mathcal{F} = \int \left[\delta C \, \frac{\delta \mathcal{L}}{\delta C} + \delta(\partial_m C) \, \frac{\delta \mathcal{L}}{\delta(\partial_m C)} \right] \mathrm{d}^3 x. \tag{68.65}$$

As discussed in Chapter 46, functional variations are perturbations to the form of the function, in which case

$$C \to C + \delta C \qquad \text{with} \qquad |\delta C| \ll |C|. \tag{68.66}$$

Notably, δC is itself a function of space and time, $\delta C(\boldsymbol{x}, t)$, but it is assumed to have much smaller magnitude than the concentration, $C(\boldsymbol{x}, t)$. Additionally, the functional variation, δC, has no affect on the space-time points so that the variational operator, δ, commutes with space and time derivatives and integrals. Integration by parts on the second term in equation (68.65) leads to

$$\delta \mathcal{F} = \int \left[\delta C \, \frac{\delta \mathcal{L}}{\delta C} + \partial_m \left(\delta C \, \frac{\delta \mathcal{L}}{\delta(\partial_m C)} \right) - \delta C \, \partial_m \left(\frac{\delta \mathcal{L}}{\delta(\partial_m C)} \right) \right] \mathrm{d}^3 x. \tag{68.67}$$

[9] We discussed the self-adjoint nature of the diffusion operator in Section 9.3.6 when developing the Green's function for the diffusion equation.

[10] In this section we write the integration volume element as $\mathrm{d}^3 x = \mathrm{d}V$. Motivation for this notation will become apparent at the point of equation (68.70).

The middle term is a total derivative that integrates to a boundary contribution and the associated *natural boundary condition*

$$\hat{\boldsymbol{n}} \cdot \frac{\delta \mathscr{L}}{\delta \nabla C} = \hat{\boldsymbol{n}} \cdot \boldsymbol{J} = \text{boundary flux}, \tag{68.68}$$

with $\hat{\boldsymbol{n}}$ the boundary outward normal. This natural boundary condition is the *Neumann boundary condition* from Chapter 9.

To focus on the connection between the diffusion operator and the diffusion dissipation functional, we ignore boundary fluxes so that the functional variation is given by

$$\delta \mathscr{F} = \int \delta C \left[\frac{\delta \mathscr{L}}{\delta C} - \partial_m \left(\frac{\delta \mathscr{L}}{\delta (\partial_m C)} \right) \right] \mathrm{d}^3 x. \tag{68.69}$$

Consequently, the functional derivative (also known as the *Fréchet derivative*) is given by

$$(\mathrm{d}^3 y)^{-1} \frac{\delta \mathscr{F}}{\delta C(\boldsymbol{y})} = \frac{\delta \mathscr{L}}{\delta C} - \partial_m \left[\frac{\delta \mathscr{L}}{\delta (\partial_m C)} \right], \tag{68.70}$$

where $\mathrm{d}^3 y$ is the volume element at the field point, $\boldsymbol{y}$. To reach the last step required the identity

$$\frac{\delta C(\boldsymbol{x})}{\delta C(\boldsymbol{y})} = \mathrm{d}^3 y \, \delta(\boldsymbol{x} - \boldsymbol{y}), \tag{68.71}$$

where $\delta(\boldsymbol{x} - \boldsymbol{y})$ is the *Dirac delta*[11] satisfying

$$\int \delta(\boldsymbol{x} - \boldsymbol{y}) \, \mathrm{d}^3 y = 1, \tag{68.72}$$

so long as the integration domain includes the singular point $\boldsymbol{x} = \boldsymbol{y}$. Note that the Dirac delta has dimensions of inverse volume, which necessitates the appearance of the volume factor, $\mathrm{d}^3 y$, on the right hand side of equation (68.71).[12]

68.5.2 Connection to the diffusion operator

Reintroducing the specific form of the diffusion integrand $2\,\mathscr{L} = -\rho\, K^{mn}\, \partial_m C\, \partial_n C$ leads to

$$\frac{\delta \mathscr{F}}{\delta C(\boldsymbol{y})} = -\partial_m \left[\frac{\delta \mathscr{L}}{\delta (\partial_m C)} \right] \mathrm{d}^3 y = \partial_m (\rho\, K^{mn}\, \partial_n C)\, \mathrm{d}\boldsymbol{y}. \tag{68.73}$$

The second equality identifies the diffusion operator, thus revealing the connection between the dissipation functional, the diffusion fluxes, and the diffusion operator

$$\frac{\delta \mathscr{F}}{\delta C(\boldsymbol{y})} = -(\nabla \cdot \boldsymbol{J})\, \mathrm{d}^3 y. \tag{68.74}$$

68.5.3 Why we need to assume K^{mn} is independent of C

There are many geophysical applications in which the diffusion tensor is a function of the tracer concentration, in which case the diffusion equation is no longer a linear differential equation. For

[11] We study the Dirac delta in Chapter 7. Additionally, note the unfortunate, though nearly universal, double meaning for the δ symbol: one referring to the variation operator and one referring to the Dirac delta.

[12] Many treatments of functional derivatives in mathematics texts ignore the volume factor, $\mathrm{d}^3 y$, in equation (68.71). Yet for physical applications it is necessary to maintain dimensional consistency, with the volume factor required for that reason. The volume factor also appears when using functional methods to derive numerical discretizations, with examples provided by *Griffies et al.* (1998), *Griffies and Hallberg* (2000), and *Griffies* (2004).

example, the neutral diffusion of Section 71.4 makes use of a diffusion tensor that is a function of temperature and salinity gradients. In this case the functional derivative in terms of temperature or salinity appearing in equation (68.73) becomes

$$2 \frac{\delta \mathcal{L}}{\delta(\partial_m C)} = -2 \rho K^{mn} \partial_n C - \rho \partial_m C \partial_n C \frac{\delta K^{mn}}{\delta(\partial_m C)}. \tag{68.75}$$

The specific form of the term $\delta K^{mn}/\delta(\partial_m C)$ depends on details of the diffusion tensor. Hence, the general results derived above for the linear diffusion equation no longer hold for this nonlinear diffusion equation. We have more to say about nonlinear advection-diffusion in Section 69.7.

68.5.4 Relation to Hamilton's principle

Recall our application of a functional derivative within the context of Hamilton's principle, which we studied in Chapters 46 and 47 for non-dissipative continuum systems. For those systems, the Euler-Lagrange equations of motion result from setting the functional derivative of the action to zero, which is the mathematical statement of Hamilton's principle. In contrast, we here showed that the functional derivative of the tracer dissipation equals to the diffusion operator. In fact, the construction in this section suggests that linear self-adjoint operators, such as generalized Laplacian operators, can generally be expressed as the functional derivative of its corresponding functional. Chapters 16 and 19 of *Griffies* (2004) provide further examples, with applications to numerical methods. Further mathematical details can be found in such books as *Courant and Hilbert* (1953, 1962).

68.6 Exercises

EXERCISE 68.1: VERTICAL DIFFUSION OF TEMPERATURE IN THE OCEAN (*Vallis*, 2017)
There is a natural time scale associated with diffusive transport. This time scale can be found from scaling the diffusion equation, which reveals that it takes the form

$$\tau_{\text{diffusion}} = \Delta^2/\kappa, \tag{68.76}$$

where Δ is the length scale and κ is the kinematic diffusivity (dimensions of squared length per time). We now make use of this time scale to consider the diffusion of temperature in the ocean, with diffusion due solely to molecular processes.

Using the observed value of molecular diffusivity of temperature in water (look it up), estimate the time for a temperature anomaly to mix from the top of the ocean to the bottom, assuming vertical diffusion through the molecular diffusivity is the only means for mixing. This time scale follows from the one-dimensional diffusion equation and is determined by the diffusivity and the depth of the ocean. Comment on whether you think the real ocean has reached equilibrium after the last ice age (which ended about 12Kyr ago).

EXERCISE 68.2: ANALYTICAL SOLUTION TO ONE-DIMENSIONAL DIFFUSION EQUATION
Consider a one-dimensional diffusion equation

$$\partial_t C = \kappa \partial_{zz} C, \tag{68.77}$$

where C is a tracer concentration (e.g., temperature or salinity), κ is a constant kinematic diffusivity, and z is the vertical coordinate. Assume the domain has fixed boundaries at $z = 0$ and $z = H$.

(a) Assume there is a zero flux of tracer at the two boundaries. Mathematically express this no-flux boundary condition.

(b) Assume that the initial tracer concentration is confined to an area near the center of the domain. Use dimensional analysis to estimate the time scale for the concentration to homogenize throughout the domain.

(c) Consider the initial-boundary value problem

$$\partial_t C = \kappa \partial_{zz} C, \tag{68.78a}$$

$$\text{no-flux boundary condition from part (b)} \tag{68.78b}$$

$$C(z, t = 0) = C_0 \cos(kz), \tag{68.78c}$$

where C_0 is a constant. What values for the wave-number, k, satisfy the no-flux boundary condition?

(d) Solve the diffusion equation analytically for the given initial condition. Hint: consult your favorite partial differential equation book to learn how to solve this linear 1+1 dimensional diffusion equation.

(e) Explain how the analytical answer you obtained is consistent with the dimensional analysis answer from part (b).

EXERCISE 68.3: DISSIPATIVE PROPERTIES OF DIFFUSION

This exercise explores the dissipative property of diffusion when acting on a tracer extrema.

(a) ONE-DIMENSIONAL DIFFUSION

Consider the diffusion equation in one spatial dimension, and assume a Boussinesq ocean in which case the density factors are all constant and so can be dropped

$$\partial_t C = \partial_z(\kappa\, \partial_z C) = \partial_z \kappa\, \partial_z C + \kappa\, \partial_{zz} C, \tag{68.79}$$

where $\kappa(z, t)$ is an *eddy diffusivity* (also *turbulent diffusivity*). The eddy diffusivity is assumed to be a function of (z, t), with the spatial dependence determined by the flow. Show that a tracer extrema, C^*, evolves under diffusion according to

$$\partial_t C^* = \kappa\, \partial_{zz} C^*. \tag{68.80}$$

So what does diffusion do to a local maxima (e.g., a local hot region) in the tracer field? What about a minima (e.g., a local cold region)? To answer this question, discuss the mathematical equation satisfied by the tracer extrema.

(b) THREE-DIMENSIONAL DIFFUSION

Generalize the above one dimensional result to three dimensions, whereby the diffusivity κ becomes a symmetric positive-definite diffusion *tensor*, in which case

$$\partial_t C = \partial_m(K^{mn}\, \partial_n C). \tag{68.81}$$

Now consider an extrema in the tracer field, which is defined by

$$\partial_n C^* = 0 \qquad \forall\ n = 1, 2, 3. \tag{68.82}$$

Prove that three dimensional diffusion acts to *dissipate* an extrema. Hint: recall some linear algebra properties of a symmetric positive-definite matrix. In particular, note that a symmetric positive-definite matrix has positive eigenvalues.

EXERCISE 68.4: DIFFUSION INCREASES INFORMATION ENTROPY OF A TRACER CONCENTRATION
Diffusion is an irreversible process. Here we illustrate this property by considering the *information entropy* associated with a non-negative tracer concentration[13]

$$\mathcal{S}_C \equiv -\int (C \ln C)\, \rho \, \mathrm{d}V. \tag{68.83}$$

Show that

$$\frac{\mathrm{d}\mathcal{S}_C}{\mathrm{d}t} \geq 0 \tag{68.84}$$

over a material region with $C > 0$ and diffusion downgradient, $\boldsymbol{J} \cdot \nabla C < 0$. That is, diffusion always increases the information entropy. Hint: follow the discussion of tracer moments in Section 68.4.3.

EXERCISE 68.5: PHILLIPS LAYERING INSTABILITY
This exercise is based on the discussion in Section 12.2 of *Smyth and Carpenter* (2019), in which we consider an oceanographically relevant example of a turbulent diffusivity that is a function of vertical buoyancy stratification. Under certain circumstances, the flow dependent diffusivity can enhance, rather than reduce, vertical gradients in the buoyancy, with the associated *Phillips layering instability* leading to layering. We here only work through the basic mathematical formulation, leaving the interested reader to consult *Smyth and Carpenter* (2019) for more details.

Consider a buoyancy field that is a function of vertical position and time, $b(z, t)$, and let the squared buoyancy frequency be given by the vertical derivative of the buoyancy

$$N^2 = \partial_z b. \tag{68.85}$$

If buoyancy is affected only by vertical diffusion, then its evolution equation is the one-dimensional vertical diffusion equation

$$\partial_t b = \partial_z(\kappa N^2), \tag{68.86}$$

where $\kappa > 0$ is the vertical diffusivity for buoyancy. Correspondingly, a vertical derivative of the buoyancy equation leads to the evolution equation for the squared buoyancy frequency

$$\partial_t N^2 = \partial_{zz}(\kappa N^2). \tag{68.87}$$

Assume the diffusivity has the following functional dependence

$$\kappa = \kappa(N^2), \tag{68.88}$$

so that it is a function of the squared buoyancy frequency. A physically relevant choice has the diffusivity get smaller as the stratification increases, so that

$$\frac{\mathrm{d}\kappa}{\mathrm{d}N^2} < 0. \tag{68.89}$$

Now consider the case of a squared buoyancy frequency that is a small deviation relative to a constant background value

$$N^2(z, t) = N_0^2 + \epsilon N_1^2(z, t), \tag{68.90}$$

where ϵ is a small non-dimensional number. Derive the condition whereby, to first order in ϵ, we have N_1^2 growing in the presence of downgradient diffusion rather than decaying. That is, what is the condition satisfied by $\mathrm{d}\kappa/\mathrm{d}N^2$, N_0^2, and κ that renders an unstable diffusion equation,

[13] Information entropy is used in statistical physics as a measure of the order/disorder of a probability distribution. We here apply these notions to measure the information entropy of a tracer concentration.

whereby $\kappa > 0$ leads to an increase in N^2 rather than a decrease?

Chapter 69

Tracer advection and diffusion

In this chapter we study tracer advection and diffusion, building on the study of tracer diffusion in Chapter 68. We focus on the particular case of *conservative tracers*, which are tracers whose evolution is only affected by advection and diffusion within the fluid interior, along with boundary conditions. The adjective "conservative" refers to the property that such tracers evolve only through the convergence of a tracer flux vector, and so the net tracer content is altered only through transport across boundaries. That is, conservative tracers have no interior sources or sinks, thus making their budgets simpler than tracers, such as chemical and biogeochemical treacers, that are also affected by sources and sinks.

Example geophysical tracers that are nearly conservative include salinity in the ocean and humidity in the atmosphere. Both of these tracers are *material tracers*, in that they measure the mass of a matter substance within a fluid element, per mass of the fluid element. Hence, these material tracers are non-dimensional scalar fields whose concentrations range from zero to unity. We derived their budget equations in Chapter 20. Conservative Temperature, Θ, as defined in Section 26.11, is a nearly conservative thermodynamical tracer that provides a measure of the relative heat content in a fluid element. Conservative Temperature is typically measured in K in the atmosphere and $^\circ C$ in the ocean. Finally, there are many applications of idealized or theoretical *passive tracers* whose impacts on the flow are assumed to vanish (Section 20.1.5). Passive tracers are versatile theoretical tools for probing aspects of the flow, including pathways and time scales.

CHAPTER GUIDE

This chapter follows directly from our study of tracer diffusion in Chapter 68. We make use of the tracer equation and associated properties (including boundary conditions) studied in Chapter 20, with results relevant for tracer transport in both the atmosphere and ocean. Results for the Boussinesq ocean of Chapter 29 are found merely by setting the density factor, ρ, to the Boussinesq reference density, ρ_o, where it appears in the budget equations of this chapter. The discussion of Green's functions in Section 69.9 assumes familiarity with the Green's function material detailed in Chapter 9. The review paper from *Haine et al.* (2025) offers example applications of passive tracers facilitated by the Green's function method, with Section 69.9 serving as an extended introduction to *Haine et al.* (2025). We generally assume Cartesian coordinates in this chapter. Even so, the equations are written in a tensorially consistent manner to allow them to be valid for arbitrary coordinates.

69.1 Loose threads

- Schematic for the boundary propagator.

69.2 Introduction to advection and diffusion

In this chapter we consider the equation describing the evolution of *conservative tracers*

$$\rho \frac{\mathrm{D}C}{\mathrm{D}t} = -\nabla \cdot \mathbf{J} \iff \partial_t(\rho\, C) + \nabla \cdot (\mathbf{v}\, \rho\, C + \mathbf{J}) = 0, \tag{69.1}$$

where the flow is nonzero, $\mathbf{v} \neq 0$, so that advection contributes to the tracer evolution in addition to subgrid scale fluxes, such as diffusion, captured by the tracer flux $\mathbf{J}$. For the first part of this chapter, we focus on the effects from advection alone, in which $\mathbf{J} = 0$. In this case, the advective

tracer flux renders a reversible stirring and stretching of fluid elements. This stirring, particularly in the presence of turbulent flows, can increase the magnitude of tracer concentration gradients (see Section 69.4.2), and it does so while maintaining, for each fluid element, a fixed mass for all matter constituents and fixed specific entropy.[1]

When diffusion is enabled, as seen in Chapter 68, the fluid experiences an irreversible exchange, or mixing, of properties between fluid elements. Correspondingly, diffusion reduces the magnitude of property gradients between fluid elements. When acting together, advection is no longer a pure stirring and diffusion is no longer a pure mixing. Indeed, in the steady state, advection and diffusion exactly balance. *Eckart* (1948) articulated what has become the standard conceptual paradigm for stirring and mixing in geophysical fluids, with elements of that paradigm reflected in this chapter.

69.3 Perfect fluid tracer advection

A *perfect* fluid is comprised of material fluid elements whose matter content and thermodynamic properties remain fixed. From the discussion of molecular diffusion in Section 68.3, we know that a perfect fluid can at most consist of a single matter constituent and uniform thermodynamic properties. The reason is that in the presence of multiple constituents with non-uniform concentrations, molecular motions irreversibly exchange matter and thermodynamic properties (e.g., temperature, specific entropy) among fluid elements. This exchange, or mixing, breaks the assumption of a perfect fluid. Nonetheless, we find many occasions to ignore molecular diffusion when focusing on macroscopic motions of the continuum fluid. Such is the case when considering the advection equation in the absence of mixing.

69.3.1 The advection equation

In the absence of mixing or other irreversible processes, the matter content of a fluid element remains fixed as the element moves within the fluid environment. Since the total mass of the element is also constant, then the tracer concentration remains constant and thus satisfies the reversible (source-free) *advection equation*

$$\frac{\mathrm{D}C}{\mathrm{D}t} = (\partial_t + \boldsymbol{v} \cdot \nabla)C = 0. \tag{69.2}$$

The first equality relates the material time derivative to the Eulerian time derivative plus advective transport (see Section 17.4), with $\boldsymbol{v}$ the *barycentric velocity* of a fluid element (Section 20.1.2). We can convert the *material* form of the advection equation (69.2) into its flux-form by combining with the mass continuity equation (19.6)

$$\partial_t \rho + \nabla \cdot (\rho \, \boldsymbol{v}) = 0, \tag{69.3}$$

which yields

$$\partial_t (\rho \, C) + \nabla \cdot (\rho \, C \, \boldsymbol{v}) = 0. \tag{69.4}$$

Again, the material form of the advection equation is the trivial statement that tracer concentration remains constant on a fluid element in the absence of sources or mixing. Hence, a general solution to the advection equation is given by

$$C(\boldsymbol{x}, t) = C[\boldsymbol{X}(0)], \tag{69.5}$$

[1] Recall from Chapter 22 that specific entropy remains materially constant on fluid elements in the absence of mixing or diabatic sources.

where $\boldsymbol{X}(0)$ is the initial position of a fluid element that is at the position $\boldsymbol{x}$ at time t. If we know the trajectories for all fluid elements and their initial tracer concentration, then we know the tracer concentration for all space and time. For those cases where trajectories are unknown, it is useful to make use of the Eulerian form of the advection equation in order to deduce the evolution of tracer concentration.

69.3.2 Eulerian time tendencies from advection

At a point in the fluid, the advection equation (69.2) leads to the Eulerian time tendency for tracer concentration

$$\partial_t C = -\boldsymbol{v} \cdot \nabla C. \tag{69.6}$$

Geometrically, the tendency arises from the projection of the fluid velocity onto the normal to concentration iso-surfaces. The concentration remains fixed in time (steady) at points where the velocity is parallel to concentration iso-surfaces. From the flux-form advection equation (69.4), the density-weighted tracer concentration (the tracer mass per volume) has an Eulerian time tendency given by the convergence of the advective flux

$$\partial_t(\rho\, C) = -\nabla \cdot (\rho\, C\, \boldsymbol{v}). \tag{69.7}$$

The tendency vanishes at a point if there is no convergence of tracer mass towards the point.

69.3.3 Impermeability property of tracer isosurfaces

We now offer a geometric interpretation of the advection equation

$$(\partial_t + \boldsymbol{v} \cdot \nabla) C = 0, \tag{69.8}$$

following the discussion of dia-surface transport in Section 64.3. For this purpose, introduce the unit normal on a tracer isosurface

$$\hat{\boldsymbol{n}} = \frac{\nabla C}{|\nabla C|} \tag{69.9}$$

and the normal projection for the velocity of a point on that surface

$$\boldsymbol{v}^{(\mathsf{C})} \cdot \hat{\boldsymbol{n}} = -\frac{\partial_t C}{|\nabla C|}. \tag{69.10}$$

The advection equation (69.8) thus can be written as an impermeability condition for a tracer isosurface

$$\rho\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathsf{C})}) \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{on } C \text{ isosurfaces.} \tag{69.11}$$

We encountered this condition in Section 19.6.2 when studying the kinematics of a moving material surface. Hence, in the absence of mixing, tracer isosurfaces are indeed material surfaces since they allow no fluid elements, moving with the fluid velocity $\boldsymbol{v}$, to cross them. This is an important kinematic result that is extended in Section 69.6.5 to include effects from an eddy induced velocity.

69.4 Some mathematical properties of tracer advection

We now explore various mathematical properties of the advection equation. For that purpose, recall the mass continuity equation (69.3) and flux-form tracer advection equation (69.7)

$$\partial_t \rho + \nabla \cdot (\rho\, \boldsymbol{v}) = 0 \tag{69.12a}$$

$$\partial_t(\rho\, C) + \nabla\cdot(\rho\, C\, \boldsymbol{v}) = 0. \tag{69.12b}$$

These equations are manifestly compatible in that the tracer equation (69.12b) reduces to the continuity equation (69.12a) if the tracer concentration is spatially uniform (see Section 20.1.4 for more discussion of compatibility).

69.4.1 Material constancy of C^Γ

A trivial consequence of the material constancy of tracer concentration is that C^Γ is also materially constant, for Γ an arbitrary number. We show this property mathematically by noting that the chain rule holds for a material time derivative, so that

$$\frac{\mathrm{D}C^\Gamma}{\mathrm{D}t} = \Gamma\, C^{\Gamma-1}\frac{\mathrm{D}C}{\mathrm{D}t} = 0. \tag{69.13}$$

Likewise, making use of the Eulerian form yields

$$\partial_t C^\Gamma + \boldsymbol{v}\cdot\nabla C^\Gamma = \Gamma\, C^{\Gamma-1}\,[\partial_t C + \boldsymbol{v}\cdot\nabla C] = 0. \tag{69.14}$$

We conclude that advection, in the absence of diffusion, serves to reversibly transport the tracer concentration without altering any of its powers. Correspondingly, all tracer moments are untouched by advection, which contrasts to the case of diffusion considered in Section 68.4.3.

69.4.2 Evolution of squared tracer gradient

As noted at the start of Section 69.2, some flows can enhance the magnitude of the tracer concentration gradient, $|\nabla C|^2 = \partial_m C\, \delta^{mn}\, \partial_n C$. The kinematics of that process begin with the following equation for the evolution of the squared gradient

$$\begin{aligned}
(1/2)\,\partial_t(\partial_m C\,\delta^{mn}\,\partial_n C) &= \partial_m C\,\delta^{mn}\,\partial_n\partial_t C && \text{(69.15a)}\\
&= -\partial_m C\,\delta^{mn}\,\partial_n(v^k\,\partial_k C) && \text{(69.15b)}\\
&= -\partial_m C\,\delta^{mn}\,(v^k\,\partial_k\,\partial_n C + \partial_n v^k\,\partial_k C) && \text{(69.15c)}\\
&= -(1/2)\,v^k\,\partial_k\,(\partial_m C\,\delta^{mn}\,\partial_n C) - \partial_m C\,\delta^{mn}\,G^k{}_n\,\partial_k C && \text{(69.15d)}\\
&= -(1/2)\,(\boldsymbol{v}\cdot\nabla)|\nabla C|^2 - \partial_m C\,\delta^{mn}\,S^k{}_n\,\partial_k C && \text{(69.15e)}\\
&= -(1/2)\,(\boldsymbol{v}\cdot\nabla)|\nabla C|^2 - \nabla C\cdot\boldsymbol{S}\cdot\nabla C. && \text{(69.15f)}
\end{aligned}$$

The second equality made use of the advection equation, $\partial_t C = -v^k\,\partial_k C$, and then we introduced the velocity gradient tensor, $\boldsymbol{G}$, from equation (18.86), and its symmetric component, the strain rate tensor, $\boldsymbol{S}$, from equation (18.90a)

$$G^m{}_n = \partial_n v^m \quad\text{and}\quad S^m{}_n = (G^m{}_n + G_n{}^m)/2. \tag{69.16}$$

We are thus led to the material evolution equation

$$\frac{1}{2}\frac{\mathrm{D}|\nabla C|^2}{\mathrm{D}t} = -\nabla C\cdot\boldsymbol{S}\cdot\nabla C. \tag{69.17}$$

The strain rate tensor is symmetric and yet it is not positive-definite. Hence, we can have either growth or decay of the squared tracer gradient depending on details of the velocity gradient and tracer gradient.

69.4.3 Eddy-induced and residual mean

The mass density time tendency

$$\partial_t \rho = -\nabla \cdot (\boldsymbol{v}\, \rho) \tag{69.18}$$

remains unchanged if the advective mass flux, $\rho\, \boldsymbol{v}$ (dimensions of mass per time per area), is modified by the addition of a total curl

$$\rho\, \boldsymbol{v} \to \rho\, \boldsymbol{v}^\dagger = \rho\, \boldsymbol{v} + \nabla \times (\rho\, \boldsymbol{\Psi}^*). \tag{69.19}$$

As in Section 21.5.1, the arbitrariness manifest in equation (69.19) is known as a *gauge symmetry*. The additional mass flux, $\nabla \times (\rho\, \boldsymbol{\Psi}^*)$, leads to no accumulation of mass at a point since it has zero divergence. In the case of a Boussinesq ocean with ρ set to a constant $\rho_\circ$, the divergent-free velocity $\nabla \times \boldsymbol{\Psi}^*$ leads to zero accumulation of volume at a point.

The non-divergent mass flux

$$\rho\, \boldsymbol{v}^* \equiv \nabla \times (\rho\, \boldsymbol{\Psi}^*) \tag{69.20}$$

often arises when we decompose the mass flux into a mean and non-divergent eddy fluctuations. In that context, we make use of the following terminology:

$$\begin{aligned}
\boldsymbol{v} &= \text{Eulerian mean velocity} && \text{(69.21a)}\\
\rho\, \boldsymbol{v} &= \text{Eulerian mean mass flux} && \text{(69.21b)}\\
\boldsymbol{v}^* &= \text{eddy-induced velocity} && \text{(69.21c)}\\
\rho\, \boldsymbol{\Psi}^* &= \text{eddy-induced mass streamfunction} && \text{(69.21d)}\\
\rho\, \boldsymbol{v}^* &= \nabla \times (\rho\, \boldsymbol{\Psi}^*) = \text{eddy-induced mass flux} && \text{(69.21e)}\\
\boldsymbol{v}^\dagger &= \boldsymbol{v} + \boldsymbol{v}^* = \text{residual mean velocity} && \text{(69.21f)}\\
\rho\, \boldsymbol{v}^\dagger &= \rho\, (\boldsymbol{v} + \boldsymbol{v}^*) = \text{residual mean mass flux.} && \text{(69.21g)}
\end{aligned}$$

The name "residual mean" is motivated since the sum $\boldsymbol{v} + \boldsymbol{v}^*$ is often smaller than either term individually. That is, the eddy contribution often compensates for the mean, with sum of the mean and eddy representing a residual. We study particular forms of the eddy induced velocity in Chapter 71.

69.4.4 Advective tracer fluxes and skew tracer fluxes

Following from the previous discussion, we consider the advection equation with the advective tracer transport determined by the residual mean velocity

$$\partial_t(\rho\, C) + \nabla \cdot (\rho\, C\, \boldsymbol{v}^\dagger) = 0. \tag{69.22}$$

Given the form (69.20) for the eddy mass flux $\rho\, \boldsymbol{v}^*$, we can write the *advective tracer flux* as

$$\begin{aligned}
\rho\, C\, \boldsymbol{v}^\dagger &= C\, (\rho\, \boldsymbol{v} + \rho\, \boldsymbol{v}^*) && \text{(69.23a)}\\
&= C\, \rho\, \boldsymbol{v} + C\, \nabla \times (\rho\, \boldsymbol{\Psi}^*) && \text{(69.23b)}\\
&= C\, \rho\, \boldsymbol{v} + \nabla \times (C\, \rho\, \boldsymbol{\Psi}^*) - \nabla C \times \rho\, \boldsymbol{\Psi}^*. && \text{(69.23c)}
\end{aligned}$$

It is the divergence of the tracer flux that determines the time tendency, in which case the total curl plays no role

$$\begin{aligned}
\nabla \cdot (\rho\, C\, \boldsymbol{v}^\dagger) &= \nabla \cdot (\rho\, C\, \boldsymbol{v} + \rho\, C\, \boldsymbol{v}^*) && \text{(69.24a)}\\
&= \nabla \cdot (\rho\, C\, \boldsymbol{v} - \nabla C \times \rho\, \boldsymbol{\Psi}^*). && \text{(69.24b)}
\end{aligned}$$

That is, the divergence of the advective tracer flux equals to the divergence of the *skew tracer flux*

$$\underbrace{\nabla \cdot (\rho\, C\, \boldsymbol{v}^*)}_{\text{advective flux divergence}} = \underbrace{\nabla \cdot (-\nabla C \times \rho\, \boldsymbol{\Psi}^*)}_{\text{skew flux divergence}} \tag{69.25}$$

since the advective flux and skew flux differ by a rotational flux

$$\boldsymbol{J}^{\text{adv}} = \boldsymbol{J}^{\text{skew}} + \boldsymbol{J}^{\text{rot}} \tag{69.26}$$

where

$$\boldsymbol{J}^{\text{adv}} = C\, \rho\, \boldsymbol{v}^* \quad \text{and} \quad \boldsymbol{J}^{\text{skew}} = -\nabla C \times \rho\, \boldsymbol{\Psi}^* \quad \text{and} \quad \boldsymbol{J}^{\text{rot}} = \nabla \times (\rho\, C\, \boldsymbol{\Psi}^*). \tag{69.27}$$

Notably, the skew tracer flux is neither upgradient nor downgradient. Rather, it is oriented parallel to iso-surfaces of tracer concentration

$$\nabla C \cdot \boldsymbol{J}^{\text{skew}} = \nabla C \cdot (-\nabla C \times \rho\, \boldsymbol{\Psi}^*) = 0. \tag{69.28}$$

This orientation serves as motivation for the name *skew*, with Figure 69.1 providing a schematic of these tracer fluxes.

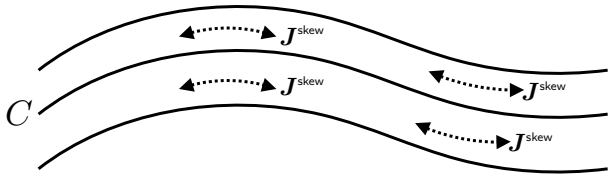

FIGURE 69.1: Skew fluxes (dashed lines with arrows) for a tracer C are oriented parallel to lines of constant tracer concentration (tracer isolines are the solid lines). Even though the skew fluxes are aligned with tracer contours, these fluxes generally affect a time change to the tracer concentration through their convergence.

69.4.5 Skew diffusion

Introducing tensor labels brings the skew tracer flux into the form

$$\begin{aligned} (J^{\text{skew}})^m &= -(\nabla C \times \rho\, \boldsymbol{\Psi}^*)^m && \text{(69.29a)} \\ &= -\epsilon^{mnp}\, \partial_n C\, \rho\, \Psi^*_p && \text{(69.29b)} \\ &= -\rho\, A^{mn}\, \partial_n C, && \text{(69.29c)} \end{aligned}$$

where we defined the anti-symmetric *skew diffusion* tensor

$$A^{mn} = \epsilon^{mnp}\, \Psi^*_p \Longrightarrow \boldsymbol{A} = \begin{bmatrix} 0 & \Psi^*_3 & -\Psi^*_2 \\ -\Psi^*_3 & 0 & \Psi^*_1 \\ \Psi^*_2 & -\Psi^*_1 & 0 \end{bmatrix}. \tag{69.30}$$

Evidently, advection by a non-divergent mass flux is equivalent to skew-diffusion through the action of an anti-symmetric tensor.

Although leading to the same stirring operator, skew and advective fluxes possess the following complementary properties.

- DERIVATIVE OPERATOR: The skew flux is proportional to the vector streamfunction and the gradient of the tracer, whereas the advective flux is related to the curl of the streamfunction and the value of the tracer concentration. In effect, the fluxes swap their placement of the

derivative operator. Correspondingly, the advective flux vanishes if the velocity vanishes, whereas the skew flux vanishes of the tracer gradient vanishes (just as for a diffusive flux).

- FLUX ORIENTATION: The orientation of the advective flux is determined by the velocity field, which is oriented according to trajectories of fluid particles. This orientation is the same regardless of the tracer. In contrast, a skew tracer flux is directed along lines of constant tracer; i.e., it is neither upgradient nor downgradient. Hence, orientation of the skew flux is directly tied to the tracer field, with each tracer yielding a generally distinct flux orientation. The very distinct orientations of the advective and skew fluxes can be the origin of confusion. We explore many features of these geometric distinctions in Section 70.3 in studying eddy induced tracer fluxes.

- MATERIAL FLUX: Fluid elements carry a particular amount of trace matter so that an advective flux of a material tracer measures the passage of matter across an area per unit time (dimensions of mass per area per time). In contrast, a skew flux is not interpreted as the passage of matter across an area per time. This distinction is particularly important when interpreting boundary conditions discussed in Section 69.5.3.

In Section 69.5 we pursue the above points to further reveal the dual relation between advective fluxes and skew fluxes.

69.4.6 A comment about skew fluxes and Lagrangian kinematics

The advective tracer flux and skew tracer flux are very distinct vectors and we further explore the distinction in Sections 69.5 and 70.3. As detailed in each of those sections, it is a matter of convenience how one chooses to formulate the Eulerian tracer equation since the advective flux and skew flux lead to the same tracer evolution. Furthermore, the choice to formulate the tracer equation in terms of a skew flux in no way eliminates the Lagrangian perspective. That is, fluid particles, or fluid elements, still move through the fluid and transport tracer as part of this motion. The Lagrangian formulation of tracer evolution is naturally connected, via a transformation of reference frames, to the Eulerian advection equation. Even so, we do not eliminate fluid particle motion when choosing to work with skew tracer fluxes. Instead, we merely choose to formulate the tracer equation in terms of the vector streamfunction rather than the velocity. This choice is typically based on mathematical and/or physical convenience.

69.4.7 Further reading

The uses of residual-mean transport are many and varied in the ocean and atmospheric literature. *Vallis* (2017) offers a thorough and pedagogical treatment. Skew diffusion is treated in *Moffatt* (1983), in which he raises the connection to fluids with rotation and/or magnetic fields. *Middleton and Loder* (1989) applied these ideas to ocean gravity waves, tides, and Rossby waves. *Griffies* (1998) applied these ideas to the methods used for parameterizing tracer transport from ocean mesoscale eddies.

69.5 Advection and skewsion

We introduced skew diffusion in Section 69.4.5 and will again encounter it in Chapterd 70 and 71. Following the terminology of Section 9.2 of *Griffies* (2004), we refer to *skewsion* as any process that leads to tracer transport via skew fluxes, with skew diffusion a particular example. There are occasions where it is conceptually and operationally more convenient to use advective fluxes, such as when considering the transport of tracers by the flow field explicitly resolved by a numerical simulation. In contrast, skew fluxes are sometimes more convenient for certain subgrid

scale eddy parameterizations, such as the one discussed in Section 71.1. We here consider facets of advection and skewsion for those interested in diving deeper into the mathematical physics.

69.5.1 Choosing a gauge

Consider an arbitrary divergent-free mass transport

$$\nabla \cdot (\rho \boldsymbol{v}^*) = 0, \tag{69.31}$$

where the divergent-free constraint is satisfied by introducing a vector streamfunction

$$\rho \boldsymbol{v}^* = \nabla \times (\rho \boldsymbol{\Psi}^*). \tag{69.32}$$

The streamfunction is arbitrary up to a gauge transformation

$$\rho \boldsymbol{\Psi}' = \rho \boldsymbol{\Psi}^* + \nabla(\rho \Lambda), \tag{69.33}$$

where Λ is a gauge function.

Changes to the skew flux under a gauge transformation

Although the velocity is invariant up to an arbitrary gauge function, the skew flux, $\boldsymbol{J}^{\text{skew}} = -\nabla C \times \rho \boldsymbol{\Psi}^*$, changes. Nonetheless, the divergence of the skew flux is invariant, as we see by noting that

$$\nabla C \times [\rho \boldsymbol{\Psi}^* + \nabla(\rho\Lambda)] = \nabla C \times (\rho \boldsymbol{\Psi}^*) + \nabla \times [C \nabla(\rho\Lambda)]. \tag{69.34}$$

and since $\nabla \cdot \nabla \times [C \nabla(\rho\Lambda)] = 0$, the flux divergence, $\nabla \cdot \boldsymbol{J}^{\text{skew}}$, remains unchanged.

Coulomb gauge

We have some freedom in specifying the gauge function. One choice is to set $\Lambda = 0$. However, there are occasions in which it is useful to set the gauge function in a manner to cancel unwanted terms. The *Coulomb gauge* is commonly used in electrostatics (e.g., *Jackson* (1975)), which is defined by setting

$$\nabla \cdot (\rho \boldsymbol{\Psi}^*) = 0 \qquad \text{Coulomb gauge.} \tag{69.35}$$

Making use of the curl identity (2.42c) leads to the Poisson equation for the vector potential

$$\nabla^2(\rho\boldsymbol{\Psi}^*) = -\nabla \times (\rho \boldsymbol{v}^*). \tag{69.36}$$

In the absence of boundaries, this equation has a *Coulomb-Ampere solution* comprised of the convolution of the source with the free-space Green's function[2]

$$\rho(\boldsymbol{x}, t)\, \boldsymbol{\Psi}^*(\boldsymbol{x}, t) = \int \frac{\nabla \times [\rho(\boldsymbol{x}', t)\, \boldsymbol{v}^*(\boldsymbol{x}', t)]}{4\pi\, |\boldsymbol{x} - \boldsymbol{x}'|}\, \mathrm{d}V', \tag{69.37}$$

where $\mathrm{d}V'$ is the volume element for integration over the test points, $\boldsymbol{x}'$. We know of no geophysical fluid application making use of the Coulomb gauge.

69.5.2 Vertical gauge

As introduced in Section 21.5.5, a gauge commonly used for eddy parameterizations (Section 71.1) sets to zero one of the three components of the vector streamfunction. This gauge choice

[2] See Section 9.3 for a discussion of Green's function methods for elliptic operators.

is available since there are only two independent functional degrees of freedom available from a divergence-free mass transport field. A common choice is the *vertical gauge* in which

$$\Psi_3^* = 0 \qquad \text{vertical gauge.} \tag{69.38}$$

To further specify the vertical gauge we invert the relations

$$\rho\, u^* = -\partial_z(\rho \Psi_2^*) \quad \text{and} \quad \rho\, v^* = \partial_z\,(\rho \Psi_1^*) \quad \text{and} \quad \rho\, w^* = \partial_x\,(\rho \Psi_2^*) - \partial_y(\rho \Psi_1^*) \tag{69.39}$$

to render the vector streamfunction

$$\rho\, \boldsymbol{\Psi}^* = \hat{\boldsymbol{z}} \times \int_{-H}^{z} \rho\, \boldsymbol{u}^*\, \mathrm{d}z' = \hat{\boldsymbol{z}} \times \underline{\boldsymbol{U}}^{(*\rho)} \tag{69.40}$$

where

$$\underline{\boldsymbol{U}}^{(*\rho)}(z) = \int_{-H}^{z} \rho\, \boldsymbol{u}^*\, \mathrm{d}z' \tag{69.41}$$

is the horizontal mass transport associated with $\boldsymbol{u}^*$ passing between the bottom and a depth $z \geq -H$. The anti-symmetric stirring tensor for the vertical gauge is given by

$$\rho\, A^{mn} = \begin{pmatrix} 0 & 0 & \underline{U}^{(*\rho)} \\ 0 & 0 & \underline{V}^{(*\rho)} \\ -\underline{U}^{(*\rho)} & -\underline{V}^{(*\rho)} & 0 \end{pmatrix}, \tag{69.42}$$

and the corresponding skew, rotational, and advective fluxes are

$$\boldsymbol{J}^{\text{skew}} = -\underline{\boldsymbol{U}}^{(*\rho)}\, \partial_z C + \hat{\boldsymbol{z}}\, \underline{\boldsymbol{U}}^{(*\rho)} \cdot \nabla_{\!\text{h}} C \tag{69.43a}$$

$$\boldsymbol{J}^{\text{rot}} = \partial_z(C\, \underline{\boldsymbol{U}}^{(*\rho)}) - \hat{\boldsymbol{z}}\, \nabla_{\!\text{h}} \cdot (C\, \underline{\boldsymbol{U}}^{(*\rho)}) \tag{69.43b}$$

$$\boldsymbol{J}^{\text{adv}} = C\, (\partial_z \underline{\boldsymbol{U}}^{(*\rho)}) - \hat{\boldsymbol{z}}\, C\, \nabla_{\!\text{h}} \cdot \underline{\boldsymbol{U}}^{(*\rho)}. \tag{69.43c}$$

Note that the identity $\boldsymbol{J}^{\text{adv}} = \boldsymbol{J}^{\text{skew}} + \boldsymbol{J}^{\text{rot}}$ is maintained by these expressions. The horizontal components to the skew flux vanish when the tracer is uniform in the vertical, and the vertical skew flux vanishes with a horizontally uniform tracer field. These properties manifest the skewed nature of the fluxes.

69.5.3 Boundary conditions

We assume that all external domain boundaries are material in regards to the velocity $\boldsymbol{v}^*$. Furthermore, even for moving domain boundaries, we assume that the suite of kinematic boundary conditions is based on the barycentric velocity $\boldsymbol{v}$ (see Section 19.6), so that $\boldsymbol{v}^*$ satisfies the no-normal flow condition even on moving boundaries

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{v}^* = 0 \qquad \text{external domain boundaries.} \tag{69.44}$$

As we discuss in Section 69.6.1, this boundary condition is required for the eddy-induced velocity to have zero impact on the total mass of an arbitrary tracer within the full fluid domain.

Correspondingly, the advective tracer flux also satisfies a no-normal boundary condition on all external boundaries

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{adv}} = \hat{\boldsymbol{n}} \cdot \boldsymbol{v}^* \rho\, C = 0. \tag{69.45}$$

The corresponding boundary condition for the skew flux is found by inserting the relation (69.26)

into the advective flux boundary condition (69.45) to render

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{adv}} = \hat{\boldsymbol{n}} \cdot [\boldsymbol{J}^{\text{skew}} + \boldsymbol{J}^{\text{rot}}] = 0. \tag{69.46}$$

Hence, the skew flux generally has a non-zero normal component at the solid boundaries as determined by the rotational flux

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{skew}} = -\hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{rot}}. \tag{69.47}$$

Even so, there might be occasions in which $\hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{skew}} = 0$, which is ensured so long as

$$(-\nabla C \times \rho \boldsymbol{\Psi}^*) \cdot \hat{\boldsymbol{n}} = -(\rho\, \boldsymbol{\Psi}^* \times \hat{\boldsymbol{n}}) \cdot \nabla C = 0. \tag{69.48}$$

A sufficient condition is to have $\boldsymbol{\Psi}^* \times \hat{\boldsymbol{n}} = 0$, in which case the vector streamfunction is parallel to the boundary normal. An alternative sufficient condition is to have the streamfunction vanish at the boundary. Further details for boundary conditions depend on physical properties of the velocity $\boldsymbol{v}^*$. We discuss one example in Section 71.1 as prescribed by the *Gent et al.* (1995) mesoscale eddy parameterization.

69.6 Finite volume budgets with eddy velocities

In this section we examine how an eddy induced velocity modifies the budgets for fluid mass and tracer mass in finite domains. The discussion is nuanced, and yet it is relevant to those aiming to diagnose tracer budgets computed over finite regions. We start by writing the local/differential mass and tracer budgets in the form

$$\partial_t \rho + \nabla \cdot (\rho\, \boldsymbol{v}^\dagger) = 0 \tag{69.49a}$$

$$\partial_t (\rho\, C) + \nabla \cdot (\rho\, \boldsymbol{v}^\dagger\, C + \boldsymbol{J}^{\text{diff}}) = 0, \tag{69.49b}$$

where (see Section 69.5)

$$\boldsymbol{v}^\dagger = \boldsymbol{v} + \boldsymbol{v}^* \quad \text{and} \quad \nabla \cdot (\rho\, \boldsymbol{v}^*) = 0, \tag{69.50}$$

and where $\boldsymbol{J}^{\text{diff}}$ is a subgrid scale flux encompassing all processes, such as diffusion and boundary conditions, that are not represented by an eddy-induced advection. Given that $\nabla \cdot (\rho\, \boldsymbol{v}^*) = 0$, the mass budget (69.49a) can we written in the equivalent manners

$$\partial_t \rho + \nabla \cdot (\rho\, \boldsymbol{v}^\dagger) = \partial_t \rho + \nabla \cdot (\rho\, \boldsymbol{v}) = 0. \tag{69.51}$$

That is, the eddy-induced velocity does not lead to any local sources of fluid mass. This property is very important for the budget analysis in this section.

As shown in the following, the finite volume budgets for fluid mass and tracer mass also make use of the residual mean velocity, $\boldsymbol{v}^\dagger$. That result is not surprising, since the finite volume budgets are consistent with the differential budgets (69.49a) and (69.49b). Nonetheless, it is useful to expose the details as they appear in many budget analysis applications, such as the water mass and tracer mass analysis of Chapter 73. We furthermore explore how the budgets for tracer mass appear when formulated using advective fluxes versus skew fluxes. As we show, the finite volume budgets are consistent across the variety of formulations only if the eddy velocity and eddy vector streamfunction satisfy boundary conditions detailed in Section 69.5.3.

69.6.1 Advective formulation

Making use of the tracer equation (69.49b) in the Leibniz-Reynolds transport theorem (20.49) renders the finite volume tracer mass budget for an arbitrary domain, $\mathcal{R}$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, C\, \mathrm{d}V\right] = -\oint_{\partial\mathcal{R}} \left[\rho\, C\, (\boldsymbol{v}^{\dagger} - \boldsymbol{v}^{(\mathrm{b})}) + \boldsymbol{J}^{\mathrm{diff}}\right] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{69.52}$$

where $\boldsymbol{v}^{(\mathrm{b})}$ is the velocity of a point on the domain boundary. Appearance of the residual mean velocity, $\boldsymbol{v}^{\dagger}$, in the finite volume budget (69.52) follows from its appearance in the local tracer budget (69.49b). We thus see that the eddy-induced velocity impacts on the tracer mass budget for an arbitrary domain. However, its impacts disappear when integrating over a closed or periodic fluid domain so long as

$$\boldsymbol{v}^{*} \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{on all boundaries.} \tag{69.53}$$

We already encountered this boundary condition in Section 69.5.3. It holds on all boundaries, including those such as the ocean free surface that are time dependent and/or permeable. It is required if we assume the eddy-induced velocity does not modify the mass of any tracer in the full fluid domain. That assumption is generally made for eddy-induced velocities such as those associated with mesoscale and submesoscale eddies in the ocean (see Section 71.3).

Setting the tracer concentration to a constant in equation (69.52) leads to the fluid mass budget

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, \mathrm{d}V\right] = -\oint_{\partial\mathcal{R}} \rho\, (\boldsymbol{v}^{\dagger} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{69.54}$$

where we set the diffusive tracer flux, $\boldsymbol{J}^{\mathrm{diff}}$, to zero since there is no diffusion of fluid mass between fluid elements (Section 20.1). As for the differential expression (69.49a), the mass budget for any domain is not changed by the eddy-induced velocity since

$$\nabla \cdot (\rho\, \boldsymbol{v}^{*}) = 0 \Longrightarrow \oint_{\partial\mathcal{R}} \rho\, \boldsymbol{v}^{*} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = 0, \tag{69.55}$$

so that the mass budget is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, \mathrm{d}V\right] = -\oint_{\partial\mathcal{R}} \left[\rho\, (\boldsymbol{v}^{\dagger} - \boldsymbol{v}^{(\mathrm{b})})\right] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{R}} \left[\rho\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})})\right] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{69.56}$$

Hence, the eddy velocity contribution to the mass budget for any finite region vanishes, which is expected since it provides no net mass source to a region. Furthermore, one may choose to diagnose the right hand side of the mass budget in either the residual mean or Eulerian mean form. The choice is based on convenience, such as whether one has easier access to the residual mean velocity or the Eulerian mean velocity. Although the patterns of the fluxes across any particular boundary differs if $\boldsymbol{v}^{*} \neq 0$, the accumulation of mass within the region is identical for the two formulations.

69.6.2 Skew flux formulation

Now consider the complement perspective afforded by the skew flux formulation from Section 69.5. Here we decompose the advective tracer flux according to

$$C\, \rho\, \boldsymbol{v}^{\dagger} = C\, \rho\, \boldsymbol{v} - \nabla C \times \rho\, \boldsymbol{\Psi}^{*} + \nabla \times (C\, \rho\, \boldsymbol{\Psi}^{*}) = C\, \rho\, \boldsymbol{v} + \boldsymbol{J}^{\mathrm{skew}} + \nabla \times (C\, \rho\, \boldsymbol{\Psi}^{*}), \tag{69.57}$$

where we introduced the skew tracer flux arising from the eddy-induced streamfunction

$$\boldsymbol{J}^{\text{skew}} = -\nabla C \times (\rho\, \boldsymbol{\Psi}^*). \tag{69.58}$$

The differential budget for tracer is thus given by

$$\partial_t(\rho\, C) + \nabla \cdot [\rho\, C\, \boldsymbol{v} + \boldsymbol{J}^{\text{skew}} + \boldsymbol{J}^{\text{diff}}] = 0, \tag{69.59}$$

where the rotational term, $\nabla \times (C\, \rho\, \boldsymbol{\Psi}^*)$, has zero divergence and so does not affect the tracer budget. The corresponding finite volume tracer mass budget is

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathscr{R}} \rho\, C\, \mathrm{d}V\right] = -\oint_{\partial\mathscr{R}} \left[\rho\, C\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathsf{b})}) - \nabla C \times (\rho\, \boldsymbol{\Psi}^*) + \boldsymbol{J}^{\text{diff}}\right] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{69.60}$$

In this form, the contribution from the eddy induced transport is now included inside the skew tracer flux rather than in the residual mean advective tracer flux. Setting C to a constant reveals the mass budget as in the second form of equation (69.56).

69.6.3 Domain with a tracer boundary

We now apply the previous general budget discussion to a specific domain that anticipates the more complete budget analysis provided in Section 73.10 as part of our study of water mass analysis. Here, we consider the fluid mass and tracer mass within an ocean region with at least one of its bounds determined by an isosurface of constant tracer concentration, as in Figure 69.2.

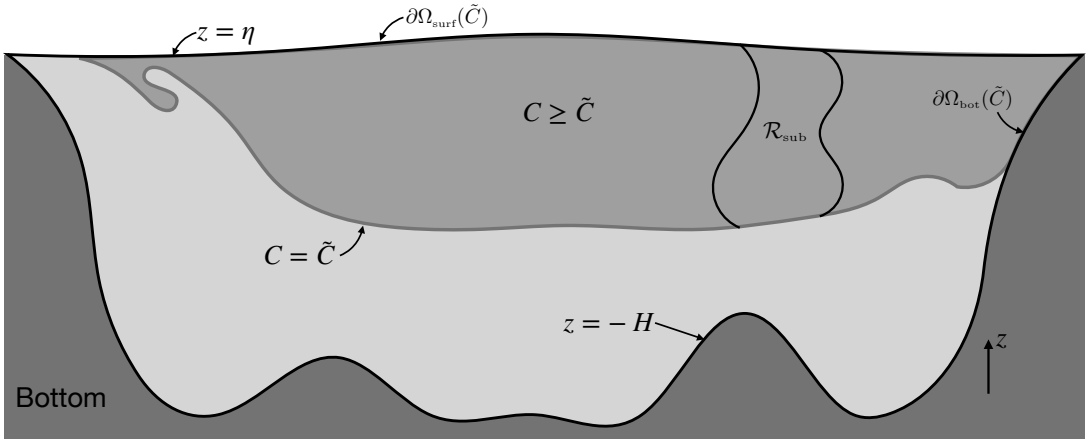

FIGURE 69.2: An ocean region with one of its boundaries set by a surface of constant tracer, $C = \tilde{C}$. Note that the region need not be monotonically stratified in the tracer concentration, nor does it need to be simply connected. The region is bounded at the top by $\partial\Omega_{\text{surf}}(\tilde{C})$, with the geometry of this surface depending on $\tilde{C}$. The bottom boundary is set by the tracer surface, $C = \tilde{C}$, as well as the solid-earth bottom, $\partial\Omega_{\text{bot}}(\tilde{C})$. The region can generally be multiply connected. A subregion, $\mathcal{R}_{\text{sub}}$, is also considered where its sides extend from the free surface to the tracer isosurface, and they are assumed to be fully within the fluid domain. We develop the tracer and fluid mass budgets for region $\mathcal{R}_{\text{sub}}$ in Section 69.6.4, whereas the budget in the full region $C \geq \tilde{C}$ is considered in Section 69.6.3.

Advective formulation

The tracer mass budget written using the advective formulation (69.52) is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathscr{R}} \rho\, C\, \mathrm{d}V\right] = \int_{\partial\Omega_{\text{surf}}(\tilde{C})} Q_{\mathsf{m}}\, C\, \mathrm{d}A - \tilde{C} \int_{C=\tilde{C}} \rho\, (\boldsymbol{v}^{\dagger} - \boldsymbol{v}^{(\mathsf{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \oint_{\partial\mathscr{R}} \boldsymbol{J}^{\text{diff}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{69.61}$$

For the first right hand side term we made use of the surface kinematic boundary condition (19.88c), with $Q_\mathsf{m}\,\mathrm{d}A$ the mass per time crossing the surface interface and where $\mathrm{d}A$ is the horizontal projection of the interface area element, $\mathrm{d}\mathcal{S}$. We also made use of the exterior boundary condition (69.53) for the eddy-induced velocity. For the second term we pulled the tracer concentration outside of the boundary integral over the $C = \tilde{C}$ interface, since the concentration is fixed at $\tilde{C}$ on this interface.

The mass budget for this region, also formulated using advective fluxes, is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\mathrm{d}V\right] = \int_{\partial\Omega_{\mathrm{surf}}(\tilde{C})} Q_\mathsf{m}\,\mathrm{d}A - \int_{C=\tilde{C}} \rho\,(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathsf{b})})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{69.62}$$

Combining this budget with the tracer mass budget allows us to write

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[M_C - \tilde{C}\,M\right] = \int_{\partial\Omega_{\mathrm{surf}}(\tilde{C})} Q_\mathsf{m}\,(C-\tilde{C})\,\mathrm{d}A - \oint_{\partial\mathcal{R}} \boldsymbol{J}^{\mathsf{diff}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{69.63}$$

where we introduced the shorthand for the tracer mass and fluid mass in the region

$$M_C = \int_{\mathcal{R}} C\,\rho\,\mathrm{d}V \qquad \text{and} \qquad M = \int_{\mathcal{R}} \rho\,\mathrm{d}V. \tag{69.64}$$

In Section 73.10.2 we motivate the name *internal tracer mass* for the quantity $M_C - \tilde{C}\,M$.

Skew flux formulation

The tracer mass budget formulated using skew tracer fluxes is generally given by equation (69.60). It takes on the following form for the domain in Figure 69.2

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,C\,\mathrm{d}V\right] = \int_{\partial\Omega_{\mathrm{surf}}(\tilde{C})} Q_\mathsf{m}\,C\,\mathrm{d}A - \tilde{C}\int_{C=\tilde{C}} \rho\,(\boldsymbol{v}-\boldsymbol{v}^{(\mathsf{b})})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \\ - \oint_{\partial\mathcal{R}} [-\nabla C\times(\rho\,\boldsymbol{\Psi}^*) + \boldsymbol{J}^{\mathsf{diff}}]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S},\end{aligned} \tag{69.65}$$

and the corresponding budget for the fluid mass is

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\mathrm{d}V\right] = \int_{\partial\Omega_{\mathrm{surf}}(\tilde{C})} Q_\mathsf{m}\,\mathrm{d}A - \int_{C=\tilde{C}} \rho\,(\boldsymbol{v}-\boldsymbol{v}^{(\mathsf{b})})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{69.66}$$

As for the advective formulation, we combine the fluid mass budget equation (69.66) with the tracer mass equation (69.65) to render a budget equation for the internal mass content

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[M_C - \tilde{C}\,M\right] = \int_{\partial\Omega_{\mathrm{surf}}(\tilde{C})} Q_\mathsf{m}\,(C-\tilde{C})\,\mathrm{d}A - \oint_{\partial\mathcal{R}} \boldsymbol{J}^{\mathsf{diff}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{69.67}$$

which is identical to the advective formulation given by equation (69.63).

Proving the budgets based on the two formulations are equivalent

The two tracer budgets, (69.61) and (69.65), must be the same since they measure changes to the tracer mass within the same region. Likewise, the two mass budgets, (69.62) and (69.66), must be the same, as are the two internal tracer mass budgets (69.63) and (69.67). We here expose the manipulations required to verify these equalities.

To prove the $C = \tilde{C}$ terms in the tracer budget equations (69.61) and (69.65) are the same,

consider the identity (69.55) applied to the region under consideration

$$0 = \oint_{\partial\mathcal{R}} \rho\, \boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\partial\Omega_{\mathrm{surf}}(\tilde{C})} \rho\, \boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{\partial\Omega_{\mathrm{bot}}(\tilde{C})} \rho\, \boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{C=\tilde{C}} \rho\, \boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \quad (69.68)$$

The surface and bottom boundary terms vanish due to the external boundary condition (69.53); namely, $\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}} = 0$ for each point along an external fluid boundary. We are thus led to conclude that

$$\int_{C=\tilde{C}} \rho\, \boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = 0. \quad (69.69)$$

This boundary integral means that there is no net accumulation of mass in the region due to action of the eddy velocity. Notably, we generally have $\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}} \neq 0$ at any particular point on the $C = \tilde{C}$ surface, yet its integral over the $C = \tilde{C}$ interface vanishes. Given the boundary integral (69.69) we are led to conclude

$$\int_{C=\tilde{C}} \rho\, (\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathsf{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{C=\tilde{C}} \rho\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathsf{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \quad (69.70)$$

This identity proves that the two mass budgets (69.62) and (69.66) are indeed measuring changes to the same fluid mass, even though one computes the domain boundary fluxes based on the residual mean velocity, $\boldsymbol{v}^\dagger$, whereas the other uses the Eulerian mean, $\boldsymbol{v}$.

Next we need to show that the skew flux term vanishes when integrated around the domain boundary. For the $C = \tilde{C}$ boundary we have

$$\int_{C=\tilde{C}} [\nabla C \times (\rho\, \boldsymbol{\Psi}^*)] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = 0, \quad (69.71)$$

which follows since $\hat{\boldsymbol{n}}$ is parallel to ∇C along this boundary. For the external boundaries, equality of the tracer mass budgets (69.61) and (69.65) is satisfied for an arbitrary tracer concentration if one of the boundary conditions discussed in Section (69.5.3) is maintained; i.e., if $\boldsymbol{\Psi}^*$ vanishes on an external boundary or if it is parallel to the boundary normal direction ($\hat{\boldsymbol{n}} \times \boldsymbol{\Psi}^* = 0$). Maintenance of either of these two boundary conditions allows us to conclude that the two budgets (69.61) and (69.65) are indeed identical.

69.6.4 Budget for a region with interior sides

Consider the subregion, $\mathcal{R}_{\mathrm{sub}}$, shown in Figure 69.2. This region is bounded above by the free surface and below by the tracer isosurface, $C = \tilde{C}$, just like the region $\mathcal{R}$ encountered in Section 69.6.3. Additionally, region $\mathcal{R}_{\mathrm{sub}}$ is bounded along its sides by surfaces assumed to be within the fluid interior. For much of this discussion we allow the sides to have an arbitrary shape and to move. Towards the end of this section we specialize to the case of static sides, such as relevant for a vertical section through the fluid and/or a numerical model grid cell.

Fluid mass budget

The fluid mass budget for the region, $\mathcal{R}_{\mathrm{sub}}$, can be formulated using either the residual mean velocity or the Eulerian mean velocity

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\mathrm{sub}}} \rho\, \mathrm{d}V\right] = \int_{\partial\Omega_{\mathrm{surf}}(\tilde{C})} Q_{\mathsf{m}}\, \mathrm{d}A - \int_{C=\tilde{C}} \rho\, (\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathsf{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \int_{\mathrm{sides}} \rho\, (\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathsf{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \quad (69.72a)$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho \,\mathrm{d}V\right] = \int_{\partial\Omega_{\text{surf}}(\tilde{C})} Q_{\mathsf{m}} \,\mathrm{d}A - \int_{C=\tilde{C}} \rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \int_{\text{sides}} \rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S}. \tag{69.72b}$$

The two budgets are identical since the eddy velocity satisfies $\oint \rho\, \boldsymbol{v}^* \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} = 0$ for any domain, as well as $\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}} = 0$ along any external domain boundary. Hence, as already noted in Section 69.6.1, the eddy velocity contribution to the right hand side of equation (69.72a) vanishes; it provides no net mass source to any region. We next show the same equality holds for the tracer mass budgets, with that equality requiring a bit more effort.

Tracer mass budget

The advective flux formulation of the tracer mass budget is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho\, C \,\mathrm{d}V\right] = \int_{\partial\Omega_{\text{surf}}(\tilde{C})} Q_{\mathsf{m}}\, C \,\mathrm{d}A - \tilde{C} \int_{C=\tilde{C}} \rho\,(\boldsymbol{v}^{\dagger} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \oint_{\partial\mathcal{R}_{\text{sub}}} \boldsymbol{J}^{\mathsf{diff}} \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \int_{\text{sides}} C\,\rho\,(\boldsymbol{v}^{\dagger} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S}, \tag{69.73}$$

and the corresponding skew flux formulation is

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho\, C \,\mathrm{d}V\right] = \int_{\partial\Omega_{\text{surf}}(\tilde{C})} Q_{\mathsf{m}}\, C \,\mathrm{d}A - \tilde{C} \int_{C=\tilde{C}} \rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \oint_{\partial\mathcal{R}_{\text{sub}}} \boldsymbol{J}^{\mathsf{diff}} \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \int_{\text{sides}} C\,\rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \int_{\text{sides}} [-\nabla C \times (\rho\, \boldsymbol{\Psi}^*)] \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S}. \tag{69.74}$$

As for the discussion in Section 69.6.3, we introduce the internal tracer mass and make use of the fluid mass budgets (69.72a) and (69.72b) to write the advective form of the internal mass budget

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[M_C - \tilde{C}\, M\right] = \int_{\partial\Omega_{\text{surf}}(\tilde{C})} Q_{\mathsf{m}}\,(C - \tilde{C}) \,\mathrm{d}A - \oint_{\partial\mathcal{R}} \boldsymbol{J}^{\mathsf{diff}} \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \int_{\text{sides}} (C - \tilde{C})\,\rho\,(\boldsymbol{v}^{\dagger} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S}, \tag{69.75}$$

and the corresponding skew flux form of the same budget

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[M_C - \tilde{C}\, M\right] = \int_{\partial\Omega_{\text{surf}}(\tilde{C})} Q_{\mathsf{m}}\,(C - \tilde{C}) \,\mathrm{d}A - \oint_{\partial\mathcal{R}} \boldsymbol{J}^{\mathsf{diff}} \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \int_{\text{sides}} (C - \tilde{C})\,\rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} - \int_{\text{sides}} [-\nabla C \times (\rho\, \boldsymbol{\Psi}^*)] \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S}. \tag{69.76}$$

We now examine the right hand side of the budgets (69.75) and (69.76) to show they are indeed measuring the same tracer mass budget. For that purpose, consider the skew flux integral in equation (69.76) and note that the integrand vanishes on both the top of the domain, at $z = \eta$, and bottom at $C = \tilde{C}$, thus allowing us to write

$$-\int_{\text{sides}} [-\nabla C \times (\rho\, \boldsymbol{\Psi}^*)] \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{R}_{\text{sub}}} [-\nabla C \times (\rho\, \boldsymbol{\Psi}^*)] \cdot \hat{\boldsymbol{n}} \,\mathrm{d}\mathcal{S}, \tag{69.77}$$

where the right hand side is an integral around the full domain boundaries. Now reintroduce

the eddy induced velocity and rotational flux to have

$$-\oint_{\partial\mathcal{R}_{\text{sub}}} [-\nabla C \times (\rho\,\boldsymbol{\Psi}^*)] \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{R}_{\text{sub}}} [C\,\rho\,\boldsymbol{v}^* - \nabla \times (C\,\rho\,\boldsymbol{\Psi}^*)] \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{69.78}$$

The rotational flux has zero divergence, so that Gauss's divergence theorem means that the rotational flux vanishes when integrated along the domain boundaries

$$\oint_{\partial\mathcal{R}_{\text{sub}}} \nabla \times (C\,\rho\,\boldsymbol{\Psi}^*) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0. \tag{69.79}$$

The eddy advection term in equation (69.78) vanishes on the top boundary at $z = \eta$ due to the boundary condition $\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}} = 0$, thus yielding

$$\oint_{\partial\mathcal{R}_{\text{sub}}} C\,\rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\text{sides}} C\,\rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + \int_{C=\tilde{C}} C\,\rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{69.80a}$$

$$= \int_{\text{sides}} C\,\rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + \tilde{C} \int_{C=\tilde{C}} \rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{69.80b}$$

Again make use of the property $\nabla \cdot (\rho\,\boldsymbol{v}^*) = 0$ and $\hat{\boldsymbol{n}} \cdot \boldsymbol{v}^* = 0$ at $z = \eta$ to write

$$0 = \oint_{\partial\mathcal{R}_{\text{sub}}} \rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \oint_{\text{sides}} \rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + \oint_{C=\tilde{C}} \rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{69.81}$$

which gives us

$$-\int_{\text{sides}} [-\nabla C \times (\rho\,\boldsymbol{\Psi}^*)] \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{R}_{\text{sub}}} C\,\rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = -\int_{\text{sides}} (C - \tilde{C})\,\rho\,\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{69.82}$$

Making use of this result in the skew flux formulated budget equation (69.76) brings it to the advective flux form found in equation (69.75).

We are thus led to conclude that the right hand side to equation (69.76) does indeed equal to the right hand side of equation (69.75). So although the formulation of the boundary flux contributions is rather distinct between the advective flux and skew flux formulations, the resulting tracer mass budget is the same. The choice for how to formulate the budget is thus a matter of convenience.

69.6.5 Budget for a stirred fluid in a region with interior sides

Although contained within the formalism developed in Section 69.6.4, it is revealing to specialize those budgets to the case of zero mixing, in which $\boldsymbol{J}^{\text{diff}} = 0$, and there is zero boundary mass flux, $Q_{\mathsf{m}} = 0$. In this case the fluid is reversibly stirred. Examining the finite region budgets for this pure stirring case allows us to further reveal the complementary treatments available from advection versus skewsion.

Summary of the differential stirring formalism

As explored in this chapter, an Eulerian description of tracer stirring can arise from either advection or skewsion. In the presence of an eddy induced velocity we here consider two representations of tracer stirring, with the first being advection by the residual mean velocity, $\boldsymbol{v}^\dagger$

$$\rho\,\frac{\mathrm{D}^\dagger C}{\mathrm{D}t} = \partial_t(\rho\,C) + \nabla \cdot (\rho\,\boldsymbol{v}^\dagger\,C) = 0. \tag{69.83}$$

This formulation makes it clear that surfaces of constant C are material as defined by the residual mean velocity rather than by the Eulerian mean, $\boldsymbol{v}$. That is, tracer isosurfaces satisfy the residual mean impermeability condition

$$\rho\,(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{on } C \text{ isosurfaces,} \tag{69.84}$$

with

$$\hat{\boldsymbol{n}} = \frac{\nabla C}{|\nabla C|} \qquad \text{and} \qquad \boldsymbol{v}^{(\mathrm{b})} \cdot \hat{\boldsymbol{n}} = -\frac{\partial_t C}{|\nabla C|}. \tag{69.85}$$

The impermeability condition (69.84) offers a geometric interpretation of the tracer equation (69.83) following from the discussion of dia-surface transport in Section 64.3. Correspondingly, Lagrangian fluid particles moving with the residual mean velocity do not cross tracer isosurfaces even if those isosurfaces move. Furthermore, we observe that the eddy induced velocity has a nonzero projection across tracer isosurfaces

$$(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} = 0 \Longrightarrow (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} = -\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}} \qquad \text{on } C \text{ isosurfaces.} \tag{69.86}$$

This property of the eddy induced velocity was emphasized by *McDougall and McIntosh* (2001). It reveals that in the absence of mixing, eddy motion crossing tracer isosurfaces is exactly balanced by Eulerian motion plus surface motion, thus leaving a net zero residual mean transfer of matter across the surface. Equation (69.86) is a key kinematic property used for interpreting features of the finite volume budgets detailed below.

Our second means to represent tracer stirring makes use of advection by the Eulerian mean velocity plus skewsion by the eddy induced streamfunction

$$\rho \frac{\mathrm{D}C}{\mathrm{D}t} + \nabla \cdot [-\nabla C \times (\rho\, \boldsymbol{\Psi}^*)] = \partial_t(\rho\, C) + \nabla \cdot [\rho\, \boldsymbol{v}\, C - \nabla C \times (\rho\, \boldsymbol{\Psi}^*)] = 0. \tag{69.87}$$

In terms of the eddy streamfunction, $\rho\, \boldsymbol{\Psi}^*$, the impermeability condition (69.84) takes on the form

$$\left[\rho\, \boldsymbol{v} + \nabla \times (\rho\, \boldsymbol{\Psi}^*) - \rho\, \boldsymbol{v}^{(\mathrm{b})}\right] \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{on } C \text{ isosurfaces.} \tag{69.88}$$

Budgets via residual mean advection

The mass budget formulated in terms of residual mean advection, and the corresponding residual mean advective flux formulation of the tracer mass budget, are given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\mathrm{sub}}} \rho\, \mathrm{d}V\right] = -\int_{C=\tilde{C}} \rho\,(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \int_{\mathrm{sides}} \rho\,(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{69.89a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\mathrm{sub}}} \rho\, C\, \mathrm{d}V\right] = -\tilde{C}\int_{C=\tilde{C}} \rho\,(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \int_{\mathrm{sides}} C\,\rho\,(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{69.89b}$$

The residual mean impermeability condition (69.84) for the $C = \tilde{C}$ surface renders a simplification to the flud mass and tracer mass budgets

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\mathrm{sub}}} \rho\, \mathrm{d}V\right] = -\int_{\mathrm{sides}} \rho\,(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{69.90a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\mathrm{sub}}} \rho\, C\, \mathrm{d}V\right] = -\int_{\mathrm{sides}} C\,\rho\,(\boldsymbol{v}^\dagger - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{69.90b}$$

Hence, in the residual mean formulation, the only fluxes that affect changes to the mass budgets are those that cross the side faces of the region.

Budgets via Eulerian mean advection plus eddy skewsion

The mass budget formulated in terms of Eulerian mean advection, and the corresponding tracer mass budget using eddy skewsion, are given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho \,\mathrm{d}V\right] = -\int_{C=\tilde{C}} \rho\,(\boldsymbol{v}-\boldsymbol{v}^{(\mathrm{b})})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} - \int_{\text{sides}} \rho\,(\boldsymbol{v}-\boldsymbol{v}^{(\mathrm{b})})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{69.91a}$$

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho\, C \,\mathrm{d}V\right] &= -\tilde{C}\int_{C=\tilde{C}} \rho\,(\boldsymbol{v}-\boldsymbol{v}^{(\mathrm{b})})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} - \int_{\text{sides}} C\,\rho\,(\boldsymbol{v}-\boldsymbol{v}^{(\mathrm{b})})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \\ &\quad - \int_{\text{sides}} [-\nabla C \times (\rho\,\boldsymbol{\Psi}^{*})]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}.\end{aligned} \tag{69.91b}$$

We already saw in Section 69.6.4 how to bring the right hand side terms into the form realized by the residual mean advective approach. So there is no question concerning the equivalance of the advective and skew flux formulations for the tracer mass budget. Nonetheless, what is here clearly emphasized is that the skew flux approach requires us to account for Eulerian advective transport across the $C = \tilde{C}$ isosurface, whereas for the advective flux approach the only flux in equation (69.90b) is that crossing the region side boundaries. Even so, as stated earlier, an Eulerian mean transport of tracer across the $C = \tilde{C}$ isosurface *does not* correspond to material transport across this surface. The reason is that material transport is determined by the residual mean velocity, $\boldsymbol{v}^{\dagger}$, as per the residual mean impermeability conditions 69.86 and 69.88. So even though there is a contribution to the skew flux formulated budget from Eulerian transport across the $C = \tilde{C}$ material surface, there remains zero net material crossing that surface.

Zero Eulerian mean advection and static side walls

One further specialization serves to clearly emphasize the complementary nature of the advective and skew flux approaches. Here, we assume the sides of the region are static and the Eulerian mean velocity vanishes. With a zero Eulerian velocity, the residual mean impermeability condition (69.86) means that on the $C = \tilde{C}$ isosurface, the normal component of the eddy velocity is balanced by the boundary velocity as per the impermeability condition (69.92):

$$(\boldsymbol{v}^{*}-\boldsymbol{v}^{(\mathrm{b})})\cdot\hat{\boldsymbol{n}} = 0 \qquad \text{on } C \text{ isosurfaces and with } \boldsymbol{v}=0. \tag{69.92}$$

When formulated using the residual mean advection, the fluid mass budget (69.90a) and tracer mass budget (69.90b) reduce in this case to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho \,\mathrm{d}V\right] = -\int_{\text{sides}} \rho\,\boldsymbol{v}^{*}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{69.93a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho\, C \,\mathrm{d}V\right] = -\int_{\text{sides}} C\,\rho\,\boldsymbol{v}^{*}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{69.93b}$$

so that these budgets are only affected by eddy advection across the side boundaries. The corresponding mass budget written in terms of Eulerian mean advection, (69.91a), and tracer mass budget written in terms of skew fluxes, (69.91b), are given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho \,\mathrm{d}V\right] = +\int_{C=\tilde{C}} \rho\,\boldsymbol{v}^{(\mathrm{b})}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{69.94a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}_{\text{sub}}} \rho\, C \,\mathrm{d}V\right] = +\tilde{C}\int_{C=\tilde{C}} \rho\,\boldsymbol{v}^{(\mathrm{b})}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} - \int_{\text{sides}} [-\nabla C \times (\rho\,\boldsymbol{\Psi}^{*})]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{69.94b}$$

For the mass budget, (69.94a), there are no contributions to the side walls since they are static

and the Eulerian advection is assumed to vanish. The only contribution comes from the eddy term acting on the $C = \tilde{C}$ isosurface where $\boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}} = \boldsymbol{v}^{*} \cdot \hat{\boldsymbol{n}}$. For the tracer mass budget, (69.94b), we also have the eddy contribution on the $C = \tilde{C}$ isosurface, plus skew fluxes that penetrate the side walls.

The right hand sides to the fluid mass budgets (69.93a) and (69.94a), and tracer mass budgets (69.93b) and (69.94b), are remarkably distinct. Even so, they both measure the same budgets. Furthermore, in both cases the $C = \tilde{C}$ boundary is a material boundary as defined by the residual mean velocity.

69.7 Active tracers and dia-surface flow

An *active tracer* impacts the fluid flow, with Conservative Temperature and salinity the canonical examples for the ocean. Active tracers directly impact the buoyancy, which in turn affects pressure and velocity. Hence, the advection-diffusion equation for active tracers is nonlinear since the velocity field is dependent on active tracers. We here write the advection-diffusion equation in terms of the residual mean velocity using Conservative Temperature as an example active tracer

$$\rho \frac{\mathrm{D}^{\dagger}\Theta}{\mathrm{D}t} = \rho \, (\partial_t + \boldsymbol{v}^{\dagger} \cdot \nabla)\Theta = -\nabla \cdot \boldsymbol{J}^{\mathrm{diff}}(\Theta). \tag{69.95}$$

Further nonlinearities arise when the subgrid scale diffusion tensor is itself a function of the buoyancy, as discussed at the end of Section 68.5, and/or when the parameterized eddy-induced velocity is a function of the buoyancy, as discussed in Section 71.3.

69.7.1 Adiabatic flow

Conservative Temperature is materially invariant in an adiabatic flow, so that advected by the residual mean velocity we have

$$\frac{\mathrm{D}^{\dagger}\Theta}{\mathrm{D}t} = (\partial_t + \boldsymbol{v}^{\dagger} \cdot \nabla)\Theta = 0 \qquad \text{adiabatic.} \tag{69.96}$$

Furthermore, following the kinematics of Section 19.6.2, the adiabatic residual mean flow field does not penetrate surfaces of constant Conservative Temperature (Θ-isosurfaces are impermeable) since

$$\boldsymbol{v}^{\dagger} \cdot \nabla\Theta = -\partial_t \Theta. \tag{69.97}$$

In this case we say that residual mean advection reversibly stirs the Conservative Temperature field. This property of the residual mean velocity was also considered in the discussion of pure stirring in Section 69.6.4.

69.7.2 Diabatic processes generating dia-Θ transport

Conservative Temperature is not materially invariant in the presence of diabatic processes, such as mixing typically parameterized by diffusion. Correspondingly, the residual mean velocity picks up a component, w^{dia}, that crosses the moving Conservative Temperature surface, thus making Θ surfaces permeable to fluid flow. In turn, advective transport in the presence of mixing is not reversible. We follow the kinematics from Section 64.3 to render the expression (64.26) for w^{dia}, which we here write as

$$w^{\mathrm{dia}} \equiv \hat{\boldsymbol{n}} \cdot (\boldsymbol{v}^{\dagger} - \boldsymbol{v}^{(\Theta)}) = \frac{1}{|\nabla\Theta|} \frac{\mathrm{D}^{\dagger}\Theta}{\mathrm{D}t} \tag{69.98}$$

where

$$\hat{\boldsymbol{n}} = \frac{\nabla\Theta}{|\nabla\Theta|} \qquad \text{and} \qquad \boldsymbol{v}^{(\Theta)} \cdot \nabla\Theta = -\partial_t \Theta. \tag{69.99}$$

Rearrangement of equation (69.98) renders the kinematic identity

$$\frac{\mathrm{D}^{\dagger}\Theta}{\mathrm{D}t} = \partial_t\Theta + \boldsymbol{v}^{\dagger}\cdot\nabla\Theta = w^{\mathsf{dia}}\,|\nabla\Theta|. \tag{69.100}$$

With nonzero w^{dia}, we no longer have residual mean advection preserving properties along fluid element trajectories. There can be many physical processes contributing to a nonzero w^{dia}, such as from the following examples.

Diffusion with no fluid motion

Diffusion is the canonical example of a diabatic process (Section 68.3), with molecular diffusion leading to

$$\rho\,\frac{\mathrm{D}^{\dagger}\Theta}{\mathrm{D}t} = \nabla\cdot(\kappa\,\rho\,\nabla\Theta), \tag{69.101}$$

with $\kappa > 0$ the scalar kinematic diffusivity and the product, $\kappa\,\rho$, the dynamic diffusivity. Following the definition (69.98), we see that diffusion drives the following diabatic transport velocity

$$\rho\,w^{\mathsf{dia}} = \frac{\nabla\cdot(\kappa\,\rho\,\nabla\Theta)}{|\nabla\Theta|}. \tag{69.102}$$

Consider a horizontally homogeneous Conservative Temperature field. If buoyancy is alone determined by Θ, then there is no fluid motion since buoyancy surfaces are flat (and we assume the eddy-induced motion is also zero). Yet in the presence of vertical diffusion and vertical stratification there is a diabatic transport since

$$\rho\,w^{\mathsf{dia}} = \frac{\partial_z(\kappa\,\rho\,\partial_z\Theta)}{|\partial_z\Theta|} \neq 0. \tag{69.103}$$

In the absence of fluid flow, the dia-surface transport is determined solely by movement of the Θ surfaces. Correspondingly, Θ evolution is determined only by vertical diffusion since with $\boldsymbol{v}^{\dagger} = 0$ we have

$$\partial_t\Theta = \rho^{-1}\,\partial_z(\kappa\,\rho\,\partial_z\Theta) = w^{\mathsf{dia}}\,|\partial_z\Theta|. \tag{69.104}$$

Steady state advective-diabatic balance

A steady state Conservative Temperature field in the presence of diabatic processes is realized when there is an exact balance between advective transport and dia-surface transport enabled by diffusion

$$\rho\,\boldsymbol{v}^{\dagger}\cdot\nabla\Theta = \rho\,w^{\mathsf{dia}}\,|\nabla\Theta| = \nabla\cdot(\kappa\,\rho\,\nabla\Theta). \qquad \text{steady state.} \tag{69.105}$$

That is, maintaining static Θ-surfaces ($\partial_t\Theta = 0$) requires the residual mean advective transport to cross Θ surfaces (left hand side) by an amount that exactly balances diabatic processes such as diffusion (right hand side). This example illustrates that in the presence of mixing, advection is no longer an adiabatic stirring process. Indeed, in the steady state, advection exactly balances diffusion.

69.8 Tracer homogenization inside closed tracer contours

In this section we prove a far reaching theorem involving the steady advective-diffusive balance that holds within closed tracer contours. For this purpose, consider the equation for a conservative tracer

$$\partial_t(\rho\,C) + \nabla\cdot(\rho\,\boldsymbol{v}\,C) = -\nabla\cdot\boldsymbol{J} \tag{69.106}$$

where

$$\boldsymbol{J} = -\rho \boldsymbol{K} \cdot \nabla C \tag{69.107}$$

is a downgradient diffusive flux with $\boldsymbol{K}$ a symmetric positive-definite diffusion tensor. In the steady state, the divergence of the advective tracer flux balances the convergence of the diffusive flux

$$\nabla \cdot (\rho \boldsymbol{v} C) = -\nabla \cdot \boldsymbol{J}. \tag{69.108}$$

Now specialize to a two-dimensional steady state flow in a region enclosed by a constant tracer contour. We here prove that the tracer concentration is homogeneous (i.e., a spatially constant) within the contour of constant C, as shown in Figure 69.3. Evidently, in the steady state, diffusion removes all tracer variations within closed tracer contours; i.e., there are no tracer extrema within a closed tracer contour.

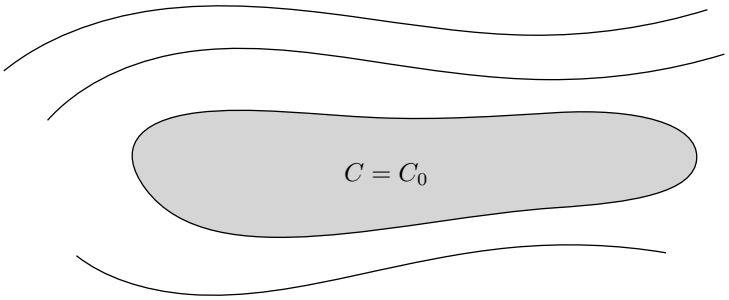

FIGURE 69.3: In a steady flow, the tracer concentration within a region bounded by a constant tracer contour is uniform, with diffusion providing the mechanism for homogenizing the tracer. Evidently, diffusion expells all variations in tracer concentration from the region. In this figure, the concentration within the closed region has constant value $C = C_0$.

69.8.1 Proof of the theorem

The following proof follows that given in Section 3.2 of *Rhines and Young* (1982) and Section 13.5 of *Vallis* (2017) for a horizontally non-divergent flow as per a Boussinesq ocean. Here, we show the result also holds for a steady state divergent flow, as per a non-Boussinesq fluid. The proof is based on a *reductio ad absurdum* argument, whereby we first assume the tracer is not homogeneous within a closed tracer contour, and then show that this assumption leads to an inconsistency and so is wrong. Notably, if the tracer concentration is not homogeneous within a contour, then there is an extrema within that contour.

To start the proof, integrate the left hand side of the steady state advection-diffusion equation (69.108) around an arbitrary simply connected surface and make use of the divergence theorem

$$\int_{\mathcal{S}} \nabla \cdot (\rho \boldsymbol{u} C) \, \mathrm{d}\mathcal{S} = \oint_{\partial \mathcal{S}} \rho \boldsymbol{u} C \cdot \hat{\boldsymbol{n}} \, \mathrm{d}l, \tag{69.109}$$

where $\hat{\boldsymbol{n}}$ is the outward normal along the area's boundary, $\partial \mathcal{S}$, and $\mathrm{d}l$ is the line element around the boundary. Now specify the surface under consideration to be bounded by a constant contour with $C = C_0$. We can thus remove the tracer concentration from the contour integral to have

$$\oint_{\partial \mathcal{S}} \rho \boldsymbol{u} C \cdot \hat{\boldsymbol{n}} \, \mathrm{d}l = C_0 \oint_{\partial \mathcal{S}} \rho \boldsymbol{u} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}l = C_0 \int_{\mathcal{S}} \nabla \cdot (\rho \boldsymbol{u}) \, \mathrm{d}\mathcal{S}, \tag{69.110}$$

where the second equality follows from the divergence theorem. For a steady state flow, mass continuity means that density at a point is time independent, so that the density-weighted velocity has zero divergence

$$\nabla \cdot (\rho \boldsymbol{u}) = 0. \tag{69.111}$$

Consequently, when integrated over a closed tracer contour we have the identity

$$\int_{\mathcal{S}} \nabla \cdot (\rho \, \boldsymbol{u} \, C) \, \mathrm{d}\mathcal{S} = C_0 \int_{\mathcal{S}} \nabla \cdot (\rho \, \boldsymbol{u}) \, \mathrm{d}\mathcal{S} = 0 \qquad \text{with } \mathcal{S} \text{ enclosed by a closed } C \text{ contour.} \tag{69.112}$$

Returning to the steady state advection-diffusion equation (69.108), the identity (69.112) then implies the analogous result for the diffusive flux

$$\int_{\mathcal{S}} \nabla \cdot \boldsymbol{J} \, \mathrm{d}\mathcal{S} = 0 \qquad \text{with } \mathcal{S} \text{ enclosed by a closed } C \text{ contour.} \tag{69.113}$$

We now show that the identity (69.113) holds only if the tracer is homogeneous inside the closed contour; i.e., there are no extrema within a closed contour.

Appealing to a nonzero flux in the presence of an extrema

Consider the right hand side of the steady state advection-diffusion equation (69.108) and integrate it over a closed region

$$-\int_{\mathcal{S}} \nabla \cdot \boldsymbol{J} \, \mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{S}} \boldsymbol{J} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}l = \oint_{\partial\mathcal{S}} (\boldsymbol{K} \cdot \nabla C) \cdot \hat{\boldsymbol{n}} \, \rho \, \mathrm{d}l. \tag{69.114}$$

If the contour surrounds an extremum of the tracer concentration, then a downgradient diffusive flux is nonzero and has a nonzero projection in the outward normal direction.[3] Hence, the integral is nonzero, which then contradicts equation (69.113). Consistency thus implies that the diffusive flux vanishes, which means the tracer contour does not surround an extrema. That is, the tracer concentration is homogeneous inside the closed tracer contour.

Introducing an expression for the outward normal

If the tracer is not homogeneous, so that $\nabla C \neq 0$, then we can introduce the normal direction,

$$\hat{\boldsymbol{n}} = \frac{\nabla C}{|\nabla C|}, \tag{69.115}$$

which is directed orthogonal to a constant tracer contour. Using this expression for the normal direction within the tracer flux integral leads to

$$-\int_{\mathcal{S}} \nabla \cdot \boldsymbol{J} \, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{S}} \nabla C \cdot \boldsymbol{K} \cdot \nabla C \, \frac{\rho \, \mathrm{d}l}{|\nabla C|}. \tag{69.116}$$

The diffusion tensor is a symmetric positive-definite second order tensor, so that the quadratic form in the integral is positive,

$$\nabla C \cdot \boldsymbol{K} \cdot \nabla C = K^{mn} \, \partial_m C \, \partial_n C > 0. \tag{69.117}$$

Furthermore, the line element, $\mathrm{d}l$, is positive, and so are ρ and $|\nabla C|$. Consequently, the integral around a closed tracer contour, where the normal to that contour is given by equation (69.115), is positive

$$-\int_{\mathcal{S}} \nabla \cdot \boldsymbol{J} \, \mathrm{d}\mathcal{S} = \int_{\partial\mathcal{S}} \partial_m C \, K^{mn} \, \partial_n C \, \mathrm{d}\mathrm{d}l > 0 \qquad \text{if } \hat{\boldsymbol{n}} = \nabla C / |\nabla C|. \tag{69.118}$$

[3] For example, consider a circular tracer contour surrounding a circular maximum, and assume isotropic diffusion. In this case the diffusive flux is radial so that it has a nonzero projection onto the outward normal.

However, this inequality contradicts the zero result (69.113). The zero result (69.113) is based only on the steady state assumption, whereas the inequality (69.118) is a direct result of assuming the tracer is inhomogeneous. Dropping the tracer inhomogeneity assumption is the only way to recover consistency.

69.8.2 Comments

Both of the above approaches led us to conclude that the tracer has zero gradient within the interior of a closed constant C contour; i.e., the steady state tracer concentration is homogeneous within a closed tracer contour. Given enough time to reach a steady state, diffusion, no matter how weak, expells all steady state tracer gradients from within regions bounded by closed tracer contours. This result can be extended to three dimensions, in which case steady state tracers are homogenous within closed volumes bounded by a constant tracer concentration. However, such bubble-like regions are less common for geophysical flows. In contrast, they are commonly found in quasi-two dimensional flows, including flows on constant isopycnals. So the theorem is more readily applied to two dimensional (or quasi two dimensional) flows. We offer another proof of the tracer homogenization result in Section 73.10.1 as part of our study of tracer mass analysis.

Furthermore, we assumed that the tracer equation included just a symmetric diffusion tensor, $\boldsymbol{K}$, in defining the subgrid flux (69.107). However, the theorem also holds if there is an additional anti-symmetric tensor, $\boldsymbol{A}$, added to $\boldsymbol{K}$. The reason is that an anti-symmetric tensor vanishes from the quadratic form (69.117)

$$\nabla C \cdot \boldsymbol{A} \cdot \nabla C = A^{mn}\, \partial_m C\, \partial_n C = 0. \tag{69.119}$$

That is, the tracer skew flux, $\boldsymbol{J}^{\text{skew}} = -\boldsymbol{A} \cdot \nabla C$, does not cross tracer isolines: $\nabla C \cdot \boldsymbol{J} = 0$, which we already found when studying skew fluxes in Section 69.5.

69.8.3 Further study

A powerful application of this theorem appears when the tracer, C, is a dynamically active tracer, such as vorticity or quasi-geostrophic potential vorticity (Chapter 45). The case of vorticity was discussed by *Batchelor* (1956), with *Rhines and Young* (1982) extending that work to the case of quasi-geostrophic potential vorticity. For the quasi-geostrophic case, contours of constant potential vorticity are known as *geostrophic contours*. *Rhines and Young* (1982) used the homogenization theorem to develop a theory of ocean circulation. They did so by considering potential vorticity homogenization by the mesoscale eddies that are active in regions of closed geostrophic contours, such as in mid-latitude ocean gyres.

69.9 Green's function method for passive tracers

Passive tracers (Section 20.1.5) have no impact on the flow field, so that they do not impact the fluid density nor the diffusion tensor. Hence, passive tracer patterns serve to "trace" the effects from advective and diffusive transport without affecting the transport velocity or diffusion tensor. Correspondingly, the passive tracer advection-diffusion equation is a linear partial differential equation. With some qualifications identified below, we can make use of the Green's function methods from Chapter 9 when studying solutions to the passive tracer equation. This section offers a supplement to the review paper from *Haine et al.* (2025) who synthesize the variety of Green's function methods of use for studying geophysical fluids. Although our formulation is largely based on ocean applications, the Green's function method for the advection-diffusion equation is also applicable to the atmosphere.

69.9.1 Concerning time dependent domain boundaries

The ocean free surface is time dependent, so that the domain, $\mathcal{R}$, is itself time dependent. Mathematically, this time dependence means that time and space integrations do not commute. In particular, space integration is generally written in the form

$$\int_{\mathcal{R}} \mathrm{d}V = \iint \left[\int_{\eta_b}^{\eta} \mathrm{d}z \right] \mathrm{d}x \, \mathrm{d}y, \tag{69.120}$$

where $z = \eta_b(x, y)$ is the static bottom and $z = \eta(x, y, t)$ is the time dependent free surface. We must, in turn, first compute the space integration over the full domain and then do the time time integration when deriving the reciprocity relation and the Green's function solution.

The free surface undulations make the vertical extent of the domain time dependent. Additionally, in an ocean with sloping sidewalls, the horizontal domain boundaries are also time dependent as the ocean moves up and down the sloping sides. However, allowing for the horizontal domain extent to fluctuate does not introduce any fundamentally new kinematics in our analysis. The reason is that when integrating to the lateral domain boundaries, all terms vanish since the water depth vanishes at the edge of the sloping beaches. We saw this kinematic result in Section 28.5 when integrating the angular momentum budget in a channel with sloping sidewalls.

Therefore, we assume the horizontal extent of the domain to be static in order to slightly ease the analysis. We do so by imagining a few meter high vertical seawall placed around the ocean domain edges, and by assuming a minimum depth so that there is nonzero water everywhere in the domain. These assumptions are common in ocean modeling, except in models allowing for wetting and drying of land/ocean cells. So in conclusion, we limit our analysis to time dependence of the vertical extent of the domain, with the horizontal extent static. Such limitation can be removed without much difficulty but doing so adds nothing new fundamentally.

69.9.2 Passive tracer boundary conditions

In this section, we are concerned with the evolution of a smooth passive tracer concentration, C, which is the dimensionless ratio of the tracer mass to seawater mass. Boundary conditions play a key role in the evolution. We here discuss the boundary conditions placed on the passive tracer along the ocean bottom, at $z = \eta_b(x, y)$, and the free surface, at $z = \eta(x, y, t)$.

Ocean bottom

At the static ocean bottom we generically consider a no-flux condition for the diffusive flux

$$\boldsymbol{J} \cdot \hat{\boldsymbol{n}} = -\rho \, \boldsymbol{K} \cdot \nabla C \cdot \hat{\boldsymbol{n}} = 0 \quad \text{at } z = \eta_b. \tag{69.121}$$

The no-flux condition, along with the kinematic no-normal flow condition, $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0$, means that there is zero tracer flux through the bottom.

Ocean free surface

At the ocean free surface we use results from Section 19.6.3, which developed the boundary conditions for mass flux $\mathcal{Q}_m$ (mass per time per area) across a permeable free surface, as well as Section 20.4, which developed the analogous boundary conditions for tracers. In particular, equation (20.84) provides an expression for the net mass flux of tracer crossing the free surface,

$\mathcal{Q}_C$, written as the sum of an advective flux plus a non-advective flux

$$\mathcal{Q}_C = C\,\mathcal{Q}_m - \boldsymbol{J}\cdot\hat{\boldsymbol{n}} = \underbrace{C\,\mathcal{Q}_m}_{\text{advective}} + \underbrace{\rho\,\boldsymbol{K}\cdot\nabla C\cdot\hat{\boldsymbol{n}}}_{\text{diffusive}} \quad \text{for } \boldsymbol{x}\in\partial\mathcal{R}_{\text{surface}}, \tag{69.122}$$

where C is the concentration at $z=\eta$, and we assumed the non-advective flux is given by a diffusive flux. We consider the following prescribed boundary conditions.

- ROBIN CONDITIONS: Prescribing the boundary tracer mass flux, $\mathcal{Q}_C$, leads to a Robin or mixed boundary condition

$$\mathcal{Q}_C = \text{prescribed} = C\,\mathcal{Q}_m + \rho\,\boldsymbol{K}\cdot\nabla C\cdot\hat{\boldsymbol{n}} \quad \text{for } \boldsymbol{x}\in\partial\mathcal{R}_{\text{surface}}. \tag{69.123}$$

  This boundary condition is relevant for enthalpy and salt, with full discussion given in Section 72.5. However, the Robin condition is rarely used for passive tracers along the ocean surface and so it is not further considered in this section.

- NEUMANN CONDITIONS: Prescribing the diffusive flux leads to the Neumann boundary condition

$$\rho\,\boldsymbol{K}\cdot\nabla C\cdot\hat{\boldsymbol{n}} = \text{prescribed} \equiv \Sigma(\boldsymbol{x},t) \quad \text{for } \boldsymbol{x}\in\partial\mathcal{R}_{\text{surface}}. \tag{69.124}$$

  This surface ocean boundary condition is also rarely used for passive tracers, though we do examine it within the following.

- DIRICHLET CONDITIONS: Prescribing the value of the tracer concentration at the boundary leads to the Dirichlet boundary condition

$$C = \text{prescribed} \equiv \sigma(\boldsymbol{x},t) \quad \text{for } \boldsymbol{x}\in\partial\mathcal{R}_{\text{surface}}. \tag{69.125}$$

  This boundary condition is the most commonly used condition for passive tracers, and thus it is our favored choice in the following. Note that both the Neumann and Dirichlet conditions generally involve a net transport of tracer, $\mathcal{Q}_C \neq 0$, across the ocean boundary.

As shown in Section 69.9.5, the Neumann boundary condition in the presence of a surface mass flux is problematic due to the associated non-closed reciprocity relation satisfied by the Green's function and its adjoint. The absence of a suitable reciprocity relation makes it difficult to use the Green's function method, since one would need to solve for both the Green's function and its adjoint. In contrast, the Dirichlet condition allows for a simple reciprocity relation, identical to that for the diffusion equation (Section 9.5.7), thus making the Green's function method for the advection-diffusion equation with a Dirichlet condition suitable even in the presence of a surface mass flux (see page 2450 of *Larson* (1999) for a similar point).

69.9.3 Advection-diffusion initial-boundary value problem

We study the initial-boundary value problem for a smooth passive tracer concentration, C, which is the dimensionless ratio of the tracer mass to seawater mass. The tracer is affected by advection and diffusion on a spatial domain, $\mathcal{R}$, in the presence of a tracer source, $\rho\,\Lambda$ (with dimensions of tracer mass per volume per time), with initial data available for the density and tracer concentration at time $t = t_{\text{init}}$. The initial-boundary value problem in the presence of Neumann or Dirichlet boundary conditions is given by

$$\partial_t(\rho\,C) + \nabla\cdot(\rho\,\boldsymbol{v}^\dagger\,C - \rho\,\boldsymbol{K}\cdot\nabla C) = \rho\,\Lambda \qquad \boldsymbol{x}\in\mathcal{R}, t\geq t_{\text{init}} \tag{69.126a}$$

$$\rho\,C = \rho\,I \qquad \boldsymbol{x}\in\mathcal{R}, t = t_{\text{init}} \tag{69.126b}$$

$$\hat{\boldsymbol{n}}\cdot\rho\,\boldsymbol{K}\cdot\nabla C = \rho\,\Sigma \quad \text{or} \quad \rho\,C = \rho\,\sigma \qquad \boldsymbol{x}\in\partial\mathcal{R}, t\geq t_{\text{init}}. \tag{69.126c}$$

The prescribed initial condition data for the tracer concentration at time $t = t_{\text{init}}$ is given by $I(\boldsymbol{x})$, and the initial density is also prescribed at this time, $\rho(\boldsymbol{x}, t_{\text{init}})$. We consider two options for the boundary condition at $\boldsymbol{x} \in \partial\mathcal{R}$: (i) the Neumann boundary condition with a prescribed flux, $\hat{\boldsymbol{n}} \cdot \rho \boldsymbol{K} \cdot \nabla C = \rho \Sigma$, or the (ii) Dirichlet boundary condition with a prescribed value, $\rho C = \rho \sigma$. Furthermore, we assume the flow field, $\boldsymbol{v}(\boldsymbol{x}, t)$, the eddy-induced velocity, $\boldsymbol{v}^*(\boldsymbol{x}, t)$, the seawater density, $\rho(\boldsymbol{x}, t)$, and the diffusivity tensor, $\boldsymbol{K}(\boldsymbol{x}, t)$, are known functions of space-time that are determined by solving for the dynamics, kinematics, thermodynamics, and active tracers. Finally, we assume the tracer concentration source, $\Lambda(\boldsymbol{x}, t)$, does not itself depend on the tracer concentration, C, thus ensuring linearity of the partial differential equation (69.126a).

69.9.4 The Green's function and its adjoint

Green's function problem

The Green's function corresponding to the passive tracer advection-diffusion equations (69.126a)-(69.126c) satisfies the following causal boundary value problem

$$\partial_t[\rho\, G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)] + \nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{v}^\dagger\, G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) - \rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)] = \delta(\boldsymbol{x} - \boldsymbol{x}_0)\, \delta(t - t_0) \tag{69.127a}$$

$$G(\boldsymbol{x}, t < t_0|\boldsymbol{x}_0, t_0) = 0 \tag{69.127b}$$

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x} \in \partial\mathcal{R}, t|\boldsymbol{x}_0, t_0) = 0 \;\text{ or }\; G(\boldsymbol{x} \in \partial\mathcal{R}, t|\boldsymbol{x}_0, t_0) = 0. \tag{69.127c}$$

The space-time point, $(\boldsymbol{x}_0, t_0)$, is where the Dirac delta source is located, which is within the spatial domain, $\mathcal{R}$, and it fires at a time after the initial time

$$\boldsymbol{x}_0 \in \mathcal{R} \quad \text{and} \quad t_0 \geq t_{\text{init}}. \tag{69.128}$$

The Green's function satisfies homogeneous boundary conditions that correspond to the boundary conditions satisfied by the passive tracer concentration in equation (69.126c). That is, if the passive tracer satisfies a Dirichlet boundary condition, then the Green's function satisfies a homogeneous Dirichlet condition, and likewise for Neumann boundary conditions. Finally, since the Dirac delta source, $\delta(\boldsymbol{x} - \boldsymbol{x}_0)\, \delta(t - t_0)$, has dimensions of inverse volume times inverse time, the Green's function has dimensions of inverse mass. We physically interpret the Green's function as the tracer concentration resulting from an impulsive tracer concentration source, divided by the mass of tracer injected by the source.

Adjoint Green's function problem

The adjoint Green's function, $G^\ddagger$, satisfies the adjoint problem[4]

$$-\partial_t[\rho\, G^\ddagger(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)] + \nabla_{\boldsymbol{x}} \cdot [-\rho\, \boldsymbol{v}^\dagger\, G^\ddagger(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) - \rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G^\ddagger(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)] = \delta(\boldsymbol{x} - \boldsymbol{x}_0)\, \delta(t - t_0) \tag{69.129a}$$

$$G^\ddagger(\boldsymbol{x}, t > t_0|\boldsymbol{x}_0, t_0) = 0 \tag{69.129b}$$

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G^\ddagger(\boldsymbol{x} \in \partial\mathcal{R}, t|\boldsymbol{x}_0, t_0) = 0 \;\text{ or }\; G^\ddagger(\boldsymbol{x} \in \partial\mathcal{R}, t|\boldsymbol{x}_0, t_0) = 0. \tag{69.129c}$$

Note the sign change on both the time derivative, as for the diffusion equation in Section 9.5.6, as well as the advection term. The sign change on advection is expected since with time running backwards, so too does the velocity of a fluid particle. Hence, the adjoint advection-diffusion equation is a backwards in time advection-diffusion equation.

[4] Note the use of the double dagger, ‡, for the adjoint Green's function, $G^\ddagger$, versus the single dagger, †, for the residual velocity, $\boldsymbol{v}^\dagger$.

69.9.5 Reciprocity relation

We here derive the reciprocity relation satisfied by the Green's function, G, and its adjoint, $G^\ddagger$. The derivation follows that in Section 9.3.6 for the Poisson equation and Section 9.5.7 for the diffusion equation. A new feature here arises from the advection operator, and another arises from allowing the domain boundary to be time dependent as occurs at the ocean free surface. We will see that the reciprocity relation for Neumann boundary conditions (69.127c) and (69.129c) does not "close" when there is mass transport across the ocean free surface (see equation (69.144) below). In contrast, the reciprocity relation closes with Dirichlet boundary conditions, taking the same form as for the diffusion equation in equation (9.156). We have more to say on this distinct behavior after its derivation.

Notation and setup

Consider the Green's function partial differential equation (69.127a) with a Dirac delta source, $\delta(\boldsymbol{x} - \boldsymbol{x}_1)\,\delta(t - t_1)$, along with the adjoint Green's function equation (69.129a) with a Dirac delta source, $\delta(\boldsymbol{x} - \boldsymbol{x}_2)\,\delta(t - t_2)$, where both sources are within the spatial domain and both occur later than the initial time:

$$\boldsymbol{x}_1, \boldsymbol{x}_2 \in \mathcal{R} \quad \text{and} \quad t_{\text{init}} < t_1, t_2. \tag{69.130}$$

We follow the approach in Section 9.5.7 for the diffusion equation by introducing the arbitrarily large time, T, such that $-T < t_1, t_2 < T$. As for the diffusion equation, causality conditions ensure that T drops out from the final expression for the tracer concentration. Additionally, to help ease notational clutter, we make use of the following shorthand where convenient

$$G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1) = G(1) \quad \text{and} \quad G^\ddagger(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2) = G^\ddagger(2). \tag{69.131}$$

Cross-multiplication

Multiply the Green's function equation (69.127a) by $G^\ddagger(2)$ and the adjoint equation (69.129a) by $G(1)$ to find

$$G^\ddagger(2)\left(\partial_t[\rho\, G(1)] + \nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{v}^\dagger\, G(1) - \rho\, \boldsymbol{K} \cdot \nabla_x G(1)]\right) = G^\ddagger(2)\,\delta(\boldsymbol{x} - \boldsymbol{x}_1)\,\delta(t - t_1) \tag{69.132a}$$

$$G(1)\left(-\partial_t[\rho\, G^\ddagger(2)] + \nabla_{\boldsymbol{x}} \cdot [-\rho\, \boldsymbol{v}^\dagger\, G^\ddagger(2) - \rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G^\ddagger(2)]\right) = G(1)\,\delta(\boldsymbol{x} - \boldsymbol{x}_2)\,\delta(t - t_2). \tag{69.132b}$$

In the following, we work from the left hand side of equation (69.132a) and bring the differential operators from $G(1)$ onto $G^\ddagger(2)$. The result of this movement will be equation (69.132b) plus some extra terms whose form depends on the causality condition and boundary conditions. Integration over space and time will then render the reciprocity relation.

Self-adjointness of the generalized Laplacian operator

The generalized Laplacian operator term on the left hand side of equation (69.132a) can be written

$$\begin{aligned} &- G^\ddagger(2)\,\nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G(1)] \\ &= \nabla_{\boldsymbol{x}} \cdot [-G^\ddagger(2)\,\rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G(1) + G(1)\,\rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G^\ddagger(2)] - G(1)\,\nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G^\ddagger(2)]. \end{aligned} \tag{69.133}$$

A spatial integration of this equation over the region $\mathcal{R}$, and use of the homogeneous boundary conditions in equations (69.126c) or (69.129c) eliminates the divergence term to reveal

$$\int_{\mathcal{R}} G^{\ddagger}(\boldsymbol{x},t|\boldsymbol{x}_2,t_2)\,\nabla_{\boldsymbol{x}}\cdot[\rho\,\boldsymbol{K}\cdot\nabla_{\boldsymbol{x}}G(\boldsymbol{x},t|\boldsymbol{x}_1,t_1)]\,\mathrm{d}V = \int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_1,t_1)\,\nabla_{\boldsymbol{x}}\cdot[\rho\,\boldsymbol{K}\cdot\nabla_{\boldsymbol{x}}G^{\ddagger}(\boldsymbol{x},t|\boldsymbol{x}_2,t_2)]\,\mathrm{d}V. \quad (69.134)$$

This equality proves that the generalized Laplacian operator with a symmetric diffusion tensor is self-adjoint, which is a result already encountered in Section 9.5.7 when discussing the diffusion equation. This result holds for either Neumann or Dirichlet boundary conditions.

Time derivative plus advection

Next write the time derivative and advection portion of equation (69.132a) as

$$\begin{aligned}
&G^{\ddagger}(2)\left(\partial_t[\rho\,G(1)]+\nabla_{\boldsymbol{x}}\cdot[\rho\,\boldsymbol{v}^{\dagger}\,G(1)]\right)\\
&=\partial_t[G^{\ddagger}(2)\,\rho\,G(1)]+\nabla_{\boldsymbol{x}}\cdot[G^{\ddagger}(2)\,\rho\,\boldsymbol{v}^{\dagger}\,G(1)]-G(1)\,\rho\left[\partial_t G^{\ddagger}(2)+\boldsymbol{v}^{\dagger}\cdot\nabla_{\boldsymbol{x}}G^{\ddagger}(2)\right]\\
&=\partial_t[G^{\ddagger}(2)\,\rho\,G(1)]+\nabla_{\boldsymbol{x}}\cdot[G^{\ddagger}(2)\,\rho\,\boldsymbol{v}^{\dagger}\,G(1)]-G(1)\left(\partial_t(\rho\,G^{\ddagger}(2))+\nabla\cdot[\rho\,\boldsymbol{v}^{\dagger}G^{\ddagger}(2)]\right), \quad (69.135)
\end{aligned}$$

where we used the mass continuity equation (19.6) for the final equality. Rearrangment thus leads to

$$G^{\ddagger}(2)\left(\partial_t[\rho\,G(1)]+\nabla_{\boldsymbol{x}}\cdot[\rho\,\boldsymbol{v}^{\dagger}\,G(1)]\right)-G(1)\left(-\partial_t[\rho\,G^{\ddagger}(2)]-\nabla\cdot[\rho\,\boldsymbol{v}^{\dagger}G^{\ddagger}(2)]\right) = \partial_t[G^{\ddagger}(2)\,\rho\,G(1)]+\nabla_{\boldsymbol{x}}\cdot[G^{\ddagger}(2)\,\rho\,\boldsymbol{v}^{\dagger}\,G(1)]. \quad (69.136)$$

Space integration

Now integrate equations (69.132a) and (69.132b) over the spatial domain, $\mathcal{R}$, subtract these two equations, and make use of the results (69.134) and (69.136) to reveal

$$G^{\ddagger}(\boldsymbol{x}_1,t|\boldsymbol{x}_2,t_2)\,\delta(t-t_1)-G(\boldsymbol{x}_2,t|\boldsymbol{x}_1,t_1)\,\delta(t-t_2) = \int_{\mathcal{R}}\left[\partial_t[G^{\ddagger}(2)\,\rho\,G(1)]+\nabla_{\boldsymbol{x}}\cdot[G^{\ddagger}(2)\,\rho\,\boldsymbol{v}^{\dagger}\,G(1)]\right]\mathrm{d}V. \quad (69.137)$$

The divergence term on the right hand side takes the form

$$\int_{\mathcal{R}}\nabla_{\boldsymbol{x}}\cdot[G^{\ddagger}(2)\,\rho\,\boldsymbol{v}^{\dagger}\,G(1)]\,\mathrm{d}V = \oint_{\partial\mathcal{R}} G^{\ddagger}(2)\,G(1)\,\rho\,\boldsymbol{v}^{\dagger}\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}}\,\mathrm{d}\mathcal{S} \qquad \text{divergence theorem} \quad (69.138a)$$

$$= \oint_{\partial\mathcal{R}} G^{\ddagger}(2)\,G(1)\,\rho\,\boldsymbol{v}\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}}\,\mathrm{d}\mathcal{S} \qquad \hat{\boldsymbol{n}}\cdot\boldsymbol{v}^{*}=0 \quad (69.138b)$$

$$= \int_{z=\eta} G^{\ddagger}(2)\,G(1)\,\rho\,\boldsymbol{v}\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}}\,\mathrm{d}\mathcal{S} \qquad \boldsymbol{v}\cdot\hat{\boldsymbol{n}}=0 \text{ for } z=\eta_{\mathrm{b}} \quad (69.138c)$$

$$= \int_{z=\eta} G^{\ddagger}(2)\,G(1)\,\rho\,\boldsymbol{v}\cdot\nabla(z-\eta)\,\mathrm{d}A \qquad \text{equation (19.91)} \quad (69.138d)$$

$$= \int_{z=\eta} G^\ddagger(2)\, G(1)\, \rho\, (w - \boldsymbol{u} \cdot \nabla \eta)\, \mathrm{d}A. \tag{69.138e}$$

The time derivative term takes the form

$$\int_{\mathscr{R}} \partial_t [G^\ddagger(2)\, G(1)\, \rho]\, \mathrm{d}V = \frac{\partial}{\partial t} \left[\int_{\mathscr{R}} G^\ddagger(2)\, G(1)\, \rho\, \mathrm{d}V \right] - \int_{z=\eta} \left[G^\ddagger(2)\, G(1)\, \rho\, \partial_t \eta \right] \mathrm{d}A, \tag{69.139}$$

where we made use of Leibniz's rule to bring the time derivative across the integral sign and made note of the time dependent free surface, $z = \eta(x, y, t)$. Combining equations (69.139) and (69.138e) leads to

$$G^\ddagger(\boldsymbol{x}_1, t | \boldsymbol{x}_2, t_2)\, \delta(t - t_1) - G(\boldsymbol{x}_2, t | \boldsymbol{x}_1, t_1)\, \delta(t - t_2) \tag{69.140a}$$

$$= \frac{\partial}{\partial t} \left[\int_{\mathscr{R}} G^\ddagger(2)\, G(1)\, \rho\, \mathrm{d}V \right] + \int_{z=\eta} G^\ddagger(2)\, G(1)\, [\rho\, (w - \boldsymbol{u} \cdot \nabla \eta - \partial_t \eta)]\, \mathrm{d}A \tag{69.140b}$$

$$= \frac{\partial}{\partial t} \left[\int_{\mathscr{R}} G^\ddagger(2)\, G(1)\, \rho\, \mathrm{d}V \right] - \int_{z=\eta} G^\ddagger(2)\, G(1)\, Q_{\mathsf{m}}\, \mathrm{d}A, \tag{69.140c}$$

where the final equality follows from the surface ocean kinematic boundary condition (19.94), with Q_{m} the mass per time per horizontal area crossing the ocean surface.

Time integration

We are now ready to integrate equation (69.140c) over time, with its left hand side leading to

$$\int_{-T}^{T} \left[G^\ddagger(\boldsymbol{x}_1, t | \boldsymbol{x}_2, t_2)\, \delta(t - t_1) - G(\boldsymbol{x}_2, t | \boldsymbol{x}_1, t_1)\, \delta(t - t_2) \right] \mathrm{d}t$$

$$= G^\ddagger(\boldsymbol{x}_1, t_1 | \boldsymbol{x}_2, t_2) - G(\boldsymbol{x}_2, t_2 | \boldsymbol{x}_1, t_1), \tag{69.141}$$

which used the sifting property (7.69). There are two terms that appear when time integrating the time derivative on the right hand side of equation (69.140c), with each term vanishing due to the causality conditions (69.127b) and (69.129b)

$$\int_{\mathscr{R}} G^\ddagger(\boldsymbol{x}, t = T | \boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, t = T | \boldsymbol{x}_1, t_1)\, \rho\, \mathrm{d}V = 0 \quad \Longleftarrow G^\ddagger(\boldsymbol{x}, t = T | \boldsymbol{x}_2, t_2) = 0 \tag{69.142}$$

$$\int_{\mathscr{R}} G^\ddagger(\boldsymbol{x}, t = t_{\text{init}} | \boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, t = t_{\text{init}} | \boldsymbol{x}_1, t_1)\, \rho\, \mathrm{d}V = 0 \quad \Longleftarrow G(\boldsymbol{x}, t = t_{\text{init}} | \boldsymbol{x}_1, t_1) = 0. \tag{69.143}$$

We are thus left with

$$G^\ddagger(\boldsymbol{x}_1, t_1 | \boldsymbol{x}_2, t_2) - G(\boldsymbol{x}_2, t_2 | \boldsymbol{x}_1, t_1)$$

$$= - \int_{t_{\text{init}}}^{t_1} \left[\int_{z=\eta} G^\ddagger(\boldsymbol{x}, t | \boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}_1, t_1 | \boldsymbol{x}, t)\, Q_{\mathsf{m}}\, \mathrm{d}A \right] \mathrm{d}t, \tag{69.144}$$

which we refer to as a *non-closed reciprocity relation* between G and $G^\ddagger$. Note that the time limits on the integral follow from causality on the Green's function and its adjoint.

Closed form reciprocity in special cases

There are two cases in which the relation (69.144) leads to a closed reciprocity relation:

- Zero mass flux across surface: $Q_{\mathsf{m}} = 0$.

- Homogeneous Dirichlet boundary conditions, in which case $G^\ddagger(\boldsymbol{x} \in \partial\mathcal{R}, t|\boldsymbol{x}_0, t_0) = G(\boldsymbol{x} \in \partial\mathcal{R}, t|\boldsymbol{x}_0, t_0) = 0$.

In either case we are led to

$$G^\ddagger(\boldsymbol{x}_1, t_1|\boldsymbol{x}_2, t_2) = G(\boldsymbol{x}_2, t_2|\boldsymbol{x}_1, t_1), \tag{69.145}$$

which is the same reciprocity (9.156) satisfied for the diffusion equation Green's functions.

The more nuanced reciprocity for the advection-diffusion equation arises from the advective mass flux at the ocean free surface boundary. The mass flux couples the ocean with its surrounding media (e.g., the atmosphere, rivers, or cryosphere), and in so doing precludes a general closed reciprocity relation. However, the Dirichlet boundary condition closes the surface boundary through the homogeneous Green's function boundary conditions. Most applications of Green's function methods for passive ocean tracers make use of Dirichlet boundary conditions, in which case we are afforded a closed reciprocity relation even with a free surface open to mass transport.

69.9.6 Composition property

We here follow the analysis of Section 9.5.8 to derive the composition property of the Green's function for the advection-diffusion equation. For this purpose, return to the cross-multiplication equations (69.132a) and (69.132b) used to derive reciprocity, here written as

$$G^\ddagger(2)\left(\partial_t[\rho\, G(1)] + \nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{v}^\dagger\, G(1) - \rho\, \boldsymbol{K} \cdot \nabla_x G(1)]\right) = G^\ddagger(2)\, \delta(\boldsymbol{x} - \boldsymbol{x}_1)\, \delta(t - t_1) \tag{69.146a}$$

$$G(1)\left(\partial_t[\rho\, G^\ddagger(2)] + \nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{v}^\dagger\, G^\ddagger(2) + \rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G^\ddagger(2)]\right) = -G(1)\, \delta(\boldsymbol{x} - \boldsymbol{x}_2)\, \delta(t - t_2). \tag{69.146b}$$

Adding these two equations and use of mass continuity (19.6) brings the left hand side to

$$\text{LHS} = \partial_t[\rho\, G(1)\, G^\ddagger(2)] + \nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{v}^\dagger\, G(1)\, G^\ddagger(2) + \rho\, G(1)\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G^\ddagger(2) - \rho\, G^\ddagger(2)\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G(1)]. \tag{69.147}$$

Integration over the domain $\mathcal{R}$ eliminates the diffusion terms for both the Dirichlet and Neumann boundary conditions. For the time derivative term we use Leibniz's rule to write

$$\int_{\mathcal{R}} \partial_t[\rho\, G(1)\, G^\ddagger(2)]\, \mathrm{d}V = \frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}} \rho\, G(1)\, G^\ddagger(2)\, \mathrm{d}V - \int_{z=\eta} \rho\, G(1)\, G^\ddagger(2)\, \partial_t \eta\, \mathrm{d}A. \tag{69.148a}$$

For the advection term we follow the manipulations used for equation (69.138e) to derive

$$\int_{\mathcal{R}} \nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{v}^\dagger\, G(1)\, G^\ddagger(2)]\, \mathrm{d}V = \int_{z=\eta} \rho\, G(1)\, G^\ddagger(2)\, \boldsymbol{v}^\dagger \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{69.149a}$$

$$= \int_{z=\eta} \rho\, G(1)\, G^\ddagger(2)\, (w - \boldsymbol{u} \cdot \nabla\eta)\, \mathrm{d}A \tag{69.149b}$$

$$= \int_{z=\eta} G(1)\, G^\ddagger(2)\, (\rho\, \partial_t \eta - Q_{\mathsf{m}})\, \mathrm{d}A. \tag{69.149c}$$

Bringing the pieces together and expanding the arguments leads to

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}} \rho(\boldsymbol{x}, t)\, G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\, G^\ddagger(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \mathrm{d}V = G^\ddagger(\boldsymbol{x}_1, t|\boldsymbol{x}_2, t_2)\, \delta(t - t_1) - G(\boldsymbol{x}_2, t|\boldsymbol{x}_1, t_1)\, \delta(t - t_2) - \int_{z=\eta} G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\, G^\ddagger(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, Q_{\mathsf{m}}(\boldsymbol{x}, t)\, \mathrm{d}A. \tag{69.150}$$

As for the derivation of reciprocity in Section 69.9.5, we here assume either $Q_m = 0$ or a homogeneous Dirichlet boundary condition so that

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \rho(\boldsymbol{x},t)\, G(\boldsymbol{x},t|\boldsymbol{x}_1,t_1)\, G^\ddagger(\boldsymbol{x},t|\boldsymbol{x}_2,t_2)\,\mathrm{d}V = G^\ddagger(\boldsymbol{x}_1,t|\boldsymbol{x}_2,t_2)\,\delta(t-t_1) - G(\boldsymbol{x}_2,t|\boldsymbol{x}_1,t_1)\,\delta(t-t_2). \quad (69.151)$$

This equation is directly analogous to equation (9.165) satisfied by the diffusion equation Green's function. Following from that analysis, and making use of reciprocity (69.145), we find the composition property for the advection-diffusion equation

$$G(\boldsymbol{x}_2,t_2|\boldsymbol{x}_1,t_1) = \int_{\mathcal{R}} \rho(\boldsymbol{x},\tau)\, G(\boldsymbol{x}_2,t_2|\boldsymbol{x},\tau)\, G(\boldsymbol{x},\tau|\boldsymbol{x}_1,t_1)\,\mathrm{d}V \quad \text{if } t_1 < \tau < t_2. \quad (69.152)$$

The left hand side of this equation is the response from a Dirac source that is advected-diffused from $(\boldsymbol{x}_1,t_1)$ and measured at the space-time point $(\boldsymbol{x}_2,t_2)$. The right hand side is the composition of a Green's function feeling the source at $(\boldsymbol{x}_1,t_1)$ but now sampled at an intermediate space-time position, $(\boldsymbol{x},\tau)$, and then further advective-diffused to $(\boldsymbol{x}_2,t_2)$, with integration over all possible intermediate positions $\boldsymbol{x}$. The intermediate sampling can occur at an arbitrary intermediate time τ, so long as $t_1 < \tau < t_2$. The composition property (69.152) allows us to conceive of a long-time interval Green's function as the composition of an arbitrary number of shorter time interval Green's functions.

69.9.7 Integral expression for the tracer concentration

We are now ready to express the passive tracer concentration, C, as a suite of integrals involving the Green's function and the known boundary and initial conditions as well as the known source function. The process for deriving this expression is identical to that used in Section 69.9.5 for reciprocity, with the following steps offered for completeness.

Derivation setup

The initial-boundary value problem for the passive tracer is given by

$$\partial_t(\rho C) + \nabla\cdot(\rho\,\boldsymbol{v}^\dagger\, C - \rho\,\boldsymbol{K}\cdot\nabla C) = \rho\,\Lambda \qquad \boldsymbol{x}\in\mathcal{R}, t\geq t_{\text{init}} \quad (69.153a)$$

$$\rho\, C = \rho\, I \qquad \boldsymbol{x}\in\mathcal{R}, t = t_{\text{init}} \quad (69.153b)$$

$$\rho\, C = \rho\,\sigma \qquad \boldsymbol{x}\in\partial\mathcal{R}, t\geq t_{\text{init}} \quad (69.153c)$$

where we only consider the Dirichlet boundary condition to ensure a closed reciprocity relation in the presence of surface mass fluxes (Section 69.9.5). The corresponding adjoint Green's function satisfies

$$-\partial_t[\rho\, G^\ddagger(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)] + \nabla_{\boldsymbol{x}}\cdot[-\rho\,\boldsymbol{v}^\dagger\, G^\ddagger(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) - \rho\,\boldsymbol{K}\cdot\nabla_{\boldsymbol{x}} G^\ddagger(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)] = \delta(\boldsymbol{x}-\boldsymbol{x}_0)\,\delta(t-t_0) \quad (69.154a)$$

$$G^\ddagger(\boldsymbol{x},t>t_0|\boldsymbol{x}_0,t_0) = 0 \quad (69.154b)$$

$$G^\ddagger(\boldsymbol{x}\in\partial\mathcal{R},t|\boldsymbol{x}_0,t_0) = 0, \quad (69.154c)$$

with the reciprocity condition (69.145) holding since we chose Dirichlet boundary conditions. Multiplying the adjoint Green's function equation (69.154a) by $C(\boldsymbol{x},t)$ and performing manipulations just like those for reciprocity leads to

$$-\partial_t(\rho\, C\, G^\ddagger) + \nabla_{\boldsymbol{x}}\cdot\Big[G^\ddagger\,\rho\,\boldsymbol{K}\cdot\nabla C - C\,\rho\,\boldsymbol{K}(\boldsymbol{x},t)\cdot\nabla_{\boldsymbol{x}} G^\ddagger - C\,\rho\,\boldsymbol{v}^\dagger\, G^\ddagger\Big] + G^\ddagger\,\rho\,\Lambda$$

$$= C(\boldsymbol{x}, t)\, \delta(\boldsymbol{x} - \boldsymbol{x}_0)\, \delta(t - t_0). \quad (69.155)$$

With the homogeneous Dirichlet conditions satisfied by $G^\ddagger$ on the spatial boundaries, a space and time integration over $(\boldsymbol{x}, t)$ leads to

$$\begin{aligned} C(\boldsymbol{x}_0, t_0) = &\int_{\mathscr{R}} G^\ddagger(\boldsymbol{x}, t_{\text{init}} | \boldsymbol{x}_0, t_0)\, \rho(\boldsymbol{x}, t_{\text{init}})\, I(\boldsymbol{x})\, \mathrm{d}V \\ &+ \int_{t_{\text{init}}}^{t_0} \left[\int_{\mathscr{R}} G^\ddagger(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0)\, \rho(\boldsymbol{x}, t)\, \Lambda(\boldsymbol{x}, t)\, \mathrm{d}V \right] \mathrm{d}t \\ &- \int_{t_{\text{init}}}^{t_0} \left[\oint_{\partial\mathscr{R}} \sigma(\boldsymbol{x}, t)\, \rho(\boldsymbol{x}, t)\, \boldsymbol{K}(\boldsymbol{x}, t) \cdot \nabla_{\boldsymbol{x}} G^\ddagger(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}}\, \mathrm{d}\mathcal{S} \right] \mathrm{d}t. \quad (69.156) \end{aligned}$$

Use of the reciprocity relation (69.145) allows us to write this equation in terms of the Green's function rather than the adjoint Green's function

$$\begin{aligned} C(\boldsymbol{x}_0, t_0) = &\int_{\mathscr{R}} G(\boldsymbol{x}_0, t_0 | \boldsymbol{x}, t_{\text{init}})\, \rho(\boldsymbol{x}, t_{\text{init}})\, I(\boldsymbol{x})\, \mathrm{d}V \\ &+ \int_{t_{\text{init}}}^{t_0} \left[\int_{\mathscr{R}} G(\boldsymbol{x}_0, t_0 | \boldsymbol{x}, t)\, \rho(\boldsymbol{x}, t)\, \Lambda(\boldsymbol{x}, t)\, \mathrm{d}V \right] \mathrm{d}t \\ &- \int_{t_{\text{init}}}^{t_0} \left[\oint_{\partial\mathscr{R}} \sigma(\boldsymbol{x}, t)\, \rho(\boldsymbol{x}, t)\, \boldsymbol{K}(\boldsymbol{x}, t) \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}_0, t_0 | \boldsymbol{x}, t) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}}\, \mathrm{d}\mathcal{S} \right] \mathrm{d}t. \quad (69.157) \end{aligned}$$

Finally, swapping labels $(\boldsymbol{x}_0, t_0) \leftrightarrow (\boldsymbol{x}, t)$ renders

$$\begin{aligned} C(\boldsymbol{x}, t) = &\int_{\mathscr{R}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_{\text{init}})\, \rho(\boldsymbol{x}_0, t_{\text{init}})\, I(\boldsymbol{x}_0)\, \mathrm{d}V_0 \\ &+ \int_{t_{\text{init}}}^{t} \left[\int_{\mathscr{R}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0)\, \rho(\boldsymbol{x}_0, t_0)\, \Lambda(\boldsymbol{x}_0, t_0)\, \mathrm{d}V_0 \right] \mathrm{d}t_0 \\ &- \int_{t_{\text{init}}}^{t} \left[\oint_{\partial\mathscr{R}} \sigma(\boldsymbol{x}_0, t_0)\, \rho(\boldsymbol{x}_0, t_0)\, \boldsymbol{K}(\boldsymbol{x}_0, t_0) \cdot \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\, \mathrm{d}\mathcal{S}_0 \right] \mathrm{d}t_0. \quad (69.158) \end{aligned}$$

This solution manifests causality since the tracer concentration at time t is a function only of processes occuring from t_{init} up to time t.

69.9.8 Properties of the tracer concentration

The integral solution (69.158) is of the same form as equation (9.176) for the diffusion equation. Properties of this solution, and corresponding properties of the Green's function, follow from those satisfied by the diffusion equation as detailed in Section 9.5. We here summarize these properties for completeness.

The role of advection and diffusion at boundaries

Explicit contributions from the advective flux are absent from the solution (69.158). Namely, there are no advective flux contributions at the surface boundary due to the homogeneous Dirichlet boundary conditions imposed on the Green's function. For the ocean bottom, material and rigid no-flux conditions mean that $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0$ at the bottom. The presence of advection arises only through its effect on the Green's function, which is affected by both advection and diffusion.

Furthermore, notice how in the absence of diffusion (i.e., $\boldsymbol{K} = 0$) the Dirichlet boundary data is unable to penetrate into the ocean interior since the surface boundary integral vanishes from equation (69.158). In effect, the surface boundary becomes a material surface when there

is no diffusion. That is, diffusive mixing is needed for boundary data to move into the interior. This role for diffusion was also identified when studying the surface flux condition for salt and freshwater in Section 72.5 (see also *Nurser and Griffies* (2019)).

Initial conditions

When sampling the tracer concentration at the initial time, $t \to t_{\text{init}}$, all the time integrals vanish from the solution (69.158), thus leaving

$$\lim_{t \to t_{\text{init}}} C(\boldsymbol{x}, t) = \lim_{t \to t_{\text{init}}} \int_{\mathscr{R}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_{\text{init}})\, \rho(\boldsymbol{x}_0, t_{\text{init}})\, I(\boldsymbol{x}_0)\, \mathrm{d}V_0. \tag{69.159}$$

Self-consistency implies that the Green's function satisfies

$$\lim_{t \to t_{\text{init}}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_{\text{init}})\, \rho(\boldsymbol{x}_0, t_{\text{init}}) = \delta(\boldsymbol{x} - \boldsymbol{x}_0) \quad \text{with } \boldsymbol{x}, \boldsymbol{x}_0 \in \mathscr{R}, \tag{69.160}$$

so that

$$\lim_{t \to t_{\text{init}}} \int_{\mathscr{R}} \rho(\boldsymbol{x}, t_{\text{init}})\, G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_{\text{init}})\, I(\boldsymbol{x}_0)\, \mathrm{d}V_0 = \int_{\mathscr{R}} \delta(\boldsymbol{x} - \boldsymbol{x}_0)\, I(\boldsymbol{x}_0)\, \mathrm{d}V_0 = I(\boldsymbol{x}). \tag{69.161}$$

Dirichlet boundary conditions

Evaluating the Dirichlet solution (69.158) on a spatial boundary, $\boldsymbol{x} \in \partial\mathscr{R}$, eliminates both the volume integrals given that the Green's function satisfies homogeneous Dirichlet boundary conditions. The tracer concentration (69.158) thus takes the form

$$C(\boldsymbol{x}, t) = -\int_{t_{\text{init}}}^{t} \left[\oint_{\partial\mathscr{R}} \sigma(\boldsymbol{x}_0, t_0)\, \rho(\boldsymbol{x}_0, t_0)\, \boldsymbol{K}(\boldsymbol{x}_0, t_0) \cdot \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\, \mathrm{d}\mathcal{S}_0 \right] \mathrm{d}t_0 \quad \text{with } \boldsymbol{x} \in \partial\mathscr{R}. \tag{69.162}$$

Self-consistency with the Dirichlet boundary condition (69.126c) implies that the Green's function, when both spatial points are evaluated on the boundary, satisfies

$$\rho(\boldsymbol{x}_0, t_0)\, \boldsymbol{K}(\boldsymbol{x}_0, t_0) \cdot \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0} = -\delta(t - t_0)\, \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0) \quad \text{with } \boldsymbol{x}, \boldsymbol{x}_0 \in \partial\mathscr{R}, \tag{69.163}$$

so that

$$C(\boldsymbol{x}, t) = \int_{t_{\text{init}}}^{t} \left[\oint_{\partial\mathscr{R}} \sigma(\boldsymbol{x}_0, t_0)\, \delta(t - t_0)\, \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0) \mathrm{d}\mathcal{S}_0 \right] \mathrm{d}t_0 = \sigma(\boldsymbol{x}, t) \quad \text{with } \boldsymbol{x} \in \partial\mathscr{R}. \tag{69.164}$$

69.9.9 Boundary propagator

Defining the boundary propagator

As for the diffusion equation in Section 9.5.13, we here introduce the boundary propagator for the advection-diffusion equation with Dirichlet boundary conditions. For this purpose, consider the special case of a passive tracer with zero interior source and with zero initial condition, thus satisfying the initial-boundary value problem

$$\partial_t(\rho\, C) + \nabla \cdot (\rho\, \boldsymbol{v}^{\dagger}\, C - \rho\, \boldsymbol{K} \cdot \nabla C) = 0 \qquad \boldsymbol{x} \in \mathscr{R}, t \geq t_{\text{init}} \tag{69.165a}$$

$$\rho\, C = 0 \qquad \boldsymbol{x} \in \mathscr{R}, t = t_{\text{init}} \tag{69.165b}$$

$$\rho\, C = \rho\, \sigma \qquad \boldsymbol{x} \in \partial\mathscr{R}, t \geq t_{\text{init}}, \tag{69.165c}$$

which leads to the simplification of the Green's function solution (69.158)

$$C(\boldsymbol{x},t) = -\int_{t_{\text{init}}}^{t} \left[\oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0,t_0)\, \rho(\boldsymbol{x}_0,t_0)\, \boldsymbol{K}(\boldsymbol{x}_0,t_0) \cdot \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\, \mathrm{d}\mathcal{S}_0 \right] \mathrm{d}t_0. \quad (69.166)$$

The tracer concentration at a point in space-time is determined by the history of the advection and diffusion that transfers boundary information to this point. To manifest this cause-effect relation, it is useful to define the boundary propagator just as for the diffusion equation

$$G^{\text{bp}}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) \equiv -\rho(\boldsymbol{x}_0,t_0)\, \boldsymbol{K}(\boldsymbol{x}_0,t_0) \cdot \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0} \quad \text{with } \boldsymbol{x}_0 \in \partial\mathcal{R}, \quad (69.167)$$

with G^{bp} having dimensions $\mathrm{L}^{-2}\ \mathrm{T}^{-1}$. The boundary propagator thus brings the tracer concentration (69.166) into the rather tidy form

$$C(\boldsymbol{x},t) = \int_{t_{\text{init}}}^{t} \left[\oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0,t_0)\, G^{\text{bp}}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\, \mathrm{d}\mathcal{S}_0 \right] \mathrm{d}t_0. \quad (69.168)$$

Inhomogeneous Dirichlet at the surface and homogeneous Neumann at the bottom

In applications of passive tracers to study ocean circulation, it is common to apply inhomogeneous Dirichlet boundary conditions just at the ocean surface, and homogeneous Neumann boundary conditions (no-flux) at the ocean bottom

$$\partial_t(\rho\, C) + \nabla \cdot (\rho\, \boldsymbol{v}^{\dagger}\, C - \rho\, \boldsymbol{K} \cdot \nabla C) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, t \geq t_{\text{init}} \quad (69.169a)$$

$$C = 0 \qquad \boldsymbol{x} \in \mathcal{R}, t = t_{\text{init}} \quad (69.169b)$$

$$\rho\, C = \rho\, \sigma \qquad \boldsymbol{x} \in \partial\mathcal{R}_{\text{surface}}, t \geq t_{\text{init}} \quad (69.169c)$$

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} C = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R}_{\text{bottom}}, t \geq t_{\text{init}}. \quad (69.169d)$$

Note that since $\hat{\boldsymbol{n}} \cdot \boldsymbol{v} = 0$ at the solid earth ocean bottom, kinematics imposes no advective flux through the bottom, $\hat{\boldsymbol{n}} \cdot \boldsymbol{v}\, C = 0$. Since the bottom boundary conditions are homogeneous, the solution (69.166) also holds for the initial-boundary value problem (69.169a)-(69.169d). The key distinction, however, is that the Green's function now satisfies the following boundary value problem

$$\partial_t[\rho\, G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)] + \nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{v}^{\dagger}\, G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) - \rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)] = \delta(\boldsymbol{x}-\boldsymbol{x}_0)\, \delta(t-t_0) \quad (69.170a)$$

$$G(\boldsymbol{x},t<t_0|\boldsymbol{x}_0,t_0) = 0 \quad (69.170b)$$

$$G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \quad \boldsymbol{x} \in \partial\mathcal{R}_{\text{surface}} \quad (69.170c)$$

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \quad \boldsymbol{x} \in \partial\mathcal{R}_{\text{bottom}}. \quad (69.170d)$$

Boundary value problem for the boundary propagator

Following the more detailed presentation in Section 9.5.13 for the diffusion equation, we are led to the following boundary value problem satisfied by the boundary propagator

$$\partial_t[\rho\, G^{\text{bp}}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)] + \nabla_{\boldsymbol{x}} \cdot [\rho\, \boldsymbol{v}^{\dagger}\, G^{\text{bp}}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) - \rho\, \boldsymbol{K} \cdot \nabla_{\boldsymbol{x}} G^{\text{bp}}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)] = 0, \quad \boldsymbol{x} \in \mathcal{R} \quad (69.171a)$$

$$G^{\text{bp}}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0, \quad \boldsymbol{x} \notin \partial\mathcal{R}, t \leq t_0 \quad (69.171b)$$

$$G^{\text{bp}}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \delta(t-t_0)\, \delta^{(2)}(\boldsymbol{x}-\boldsymbol{x}_0), \quad \boldsymbol{x},\boldsymbol{x}_0 \in \partial\mathcal{R}. \quad (69.171c)$$

The boundary propagator acts as the mediator between boundary data, σ, and interior points, with the transfer of information realized through both advection and diffusion. A focus on the boundary propagator rather than the Green's function allows us to dispense with the need to compute the normal gradient of the Green's function at the boundary, with that calculation rather awkward in practice. Also recall our discussion in Section 9.7.5, where we argued that the

boundary propagator can be considered the impulse response function for spatially distributed sources. Here, the mediation of the Dirac boundary sources is performed by advection plus diffusion, whereas in Section 9.7 we only considered linear damping and diffusion.

Normalization of the boundary propagator

As seen in Sections 68.3 and 68.4, diffusion acts to smooth all structure in the tracer field. Hence, if the boundary data is a uniform constant, $\sigma = \sigma_{\text{const}}$, then given sufficient time the tracer concentration will equal to this constant, $C = \sigma_{\text{const}}$. This steady state result is independent of details for the velocity field and for the diffusivity tensor, with details of advection and the diffusivity acting only to modify the time scale for the equilibration. Assuming we wait long enough, or equivalently that the initial condition occurs infinitely far in the past, then the tracer concentration solution (69.168) leads to the normalization of the boundary propagator

$$\lim_{t_{\text{init}} \to -\infty} \int_{t_{\text{init}}}^{t} \left[\oint_{\partial \mathcal{R}} G^{\text{bp}}(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0) \, \mathrm{d}\mathcal{S}_0 \right] \mathrm{d}t_0 = 1 \quad \text{for } \boldsymbol{x} \in \mathcal{R}. \tag{69.172}$$

This normalization holds for all field points, $\boldsymbol{x}$, within the region. Even though this condition was derived by assuming the special case of constant boundary data, it holds in general since the Green's function, and by extension the boundary propagator, are independent of the boundary data prescribed for the tracer concentration.

69.9.10 Comments

The Green's function method is a powerful and elegant means to study passive ocean tracers, with *Haine et al.* (2025) reviewing the theory and practice. However, the method is also technically challenging for realistic applications, in part due to doubling of the space-time dimensions to hold the Green's function, $G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0)$, in memory. As a result, realistic applications make approximations to reduce the dimensionality, such as to assume steady state or to focus only on boundary propagators. Hence, there has yet to be a calculation of the full Green's function for a realistic ocean, with that calculation awaiting bigger computers and/or novel methods to side-step the nontrivial memory requirements.

69.10 Exercises

EXERCISE 69.1: ONE-DIMENSIONAL ADVECTION
Consider the advection equation in one space dimension without boundaries

$$(\partial_t + u \, \partial_x) \, C = 0 \tag{69.173a}$$
$$C(x, z, t = 0) = C_0 \, \cos(k \, x) \tag{69.173b}$$
$$u(z, t) = \alpha \, z \cos(\omega \, t). \tag{69.173c}$$

The specified zonal velocity is non-divergent, oscillatory in time, and vertically sheared

$$\partial_z u = \alpha \cos(\omega \, t), \tag{69.174}$$

with ω the angular frequency of the temporal oscillations. What is the tracer concentration at times $t > 0$? Hint: make use of the exact solution given by equation (69.5).

EXERCISE 69.2: SKEW FLUX FOR OCEAN MESOSCALE EDDIES
Consider a middle-latitude mesoscale ocean eddy respecting geostrophic balance (see Section 31.4) on an f-plane (constant Coriolis parameter) and incompressibility. In this case, the horizontal eddy-induced velocity at the ocean surface is non-divergent

$$\boldsymbol{u}^* = \nabla \times \hat{\boldsymbol{z}}\, \psi. \tag{69.175}$$

In this equation, the geostrophic streamfunction is given by

$$\psi = -\hat{\boldsymbol{z}}\, g\, \eta / f, \tag{69.176}$$

with f the Coriolis parameter, g the gravitational acceleration, and η the sea level undulation associated with the eddy. Since the fluid is incompressible, the mass transport equals to the volume transport times a constant reference density, ρ_o.

(a) Determine the skew diffusion tensor (69.30).

(b) Determine the skew tracer flux (69.43a).

EXERCISE 69.3: INTEGRATION BETWEEN TWO CLOSED TRACER CONTOURS
This exercise introduces some ideas of use for determining processes affecting the transport of matter across a tracer contour. Note that in general, the tracer concentration is a function of time. However, the present suite of questions concerns the instantaneous geometry of the tracer field, so that time dependence is not considered.

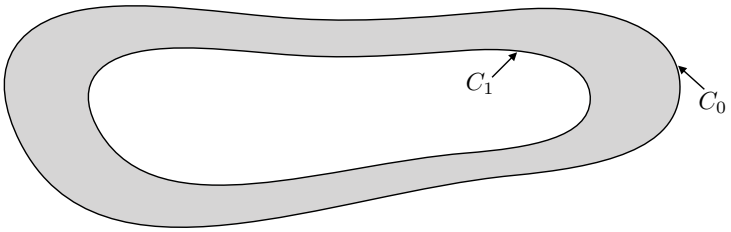

FIGURE 69.4: Illustrating the area contained between two closed tracer contours, $C_0 \leq C(x, y, t) \leq C_1$. Exercise 69.3 develops some mathematical expressions for integration within this area, with the resulting expressions of use for the analyses of tracer transport.

(a) Consider a closed two-dimensional region bounded by two contours of tracer concentration, $C_0 \leq C(x, y, t) \leq C_1$, such as shown in Figure 69.4. Derive the following expression for the area enclosed by the two contours

$$\mathcal{A} = \int_{C_0}^{C_1} \mathrm{d}C \oint \frac{\mathrm{d}l}{|\nabla C|}. \tag{69.177}$$

In this expression, $\mathrm{d}l$ is the line element for a path taken in a counter-clockwise direction along a contour of constant C. We also assume the tracer concentration is not uniform in the region of interest so that $\nabla C \neq 0$.

(b) As a corollary, show that for

$$\mathcal{A}(C) = \int_{C_0}^{C} \mathrm{d}C' \oint \frac{\mathrm{d}l}{|\nabla C'|} \tag{69.178}$$

we have the identity

$$\frac{\partial \mathcal{A}(C)}{\partial C} = \oint \frac{\mathrm{d}l}{|\nabla C|}. \tag{69.179}$$

In words, this result means that the area between two tracer contours has a partial derivative, with respect to the tracer contour, equal to the line integral on the right hand side. The area per C is smaller in regions where the tracer gradient is larger; i.e., there is less area "concentration" in regions of strong tracer gradient.

(c) Use the above two results to prove the following form of the Fundamental Theorem of Calculus

$$\frac{\partial}{\partial C}\left[\int \Phi(\boldsymbol{x})\,\mathrm{d}\mathcal{A}\right] = \frac{\partial}{\partial C}\left[\int_{C_0}^{C} \mathrm{d}C' \oint \frac{\Phi\,\mathrm{d}l}{|\nabla C'|}\right] = \oint \frac{\Phi\,\mathrm{d}l}{|\nabla C|}, \tag{69.180}$$

with Φ an arbitrary function. This is a remarkable identity with many useful applications such as those discussed in *Marshall et al.* (2006).

EXERCISE 69.4: EVOLUTION OF TRACER CENTER OF MASS IN A STATIC DOMAIN

The exercise introduces us to how the tracer center of mass evolves within a Boussinesq ocean. We define the tracer center of mass as

$$\langle \boldsymbol{x} \rangle^{C} = \frac{\int \boldsymbol{x}\, C\,\mathrm{d}V}{\int C\,\mathrm{d}V}, \tag{69.181}$$

with C the tracer concentration, $\boldsymbol{x}$ the coordinate of a point in the fluid, and integration is over the full fluid domain. For example, with a spherically symmetric tracer cloud, the center of mass position is at the sphere's center. The center of mass position is not necessarily where the largest tracer concentration sits, in the same way that the center of mass of a massive object is not necessarily where the object is most dense. For example, a hollow spherical shell has its center of mass at the center of the sphere, even though there is no mass there.

For this exercise, assume the fluid is within a domain whose static boundaries are either material (no normal component to the boundary flux) or periodic. Hence, the total fluid volume and total tracer content remain constant

$$\mathcal{V} = \int \mathrm{d}V \qquad \text{and} \qquad \mathcal{C} = \int C\,\mathrm{d}V. \tag{69.182}$$

Furthermore, when computing the time derivative acting on the integral, make use of the kinematic results from Section 20.2.3, in which for any integrand φ

$$\frac{\mathrm{d}}{\mathrm{d}t}\int \varphi\,\mathrm{d}V = \int \partial_t \varphi\,\mathrm{d}V, \tag{69.183}$$

which follows since the region boundaries are assumed to be static. Equivalently, since the region under consideration is material (no matter crosses the boundaries), we can make use of Reynold's transport theorem from Section 20.2.4 to write

$$\frac{\mathrm{d}}{\mathrm{d}t}\int \varphi\,\mathrm{d}V = \int \frac{\mathrm{D}\varphi}{\mathrm{D}t}\,\mathrm{d}V. \tag{69.184}$$

(a) Consider a tracer concentration whose tendency at a point in space is affected only by advection

$$\frac{\mathrm{D}C}{\mathrm{D}t} = 0 \Longrightarrow \partial_t C + \nabla\cdot(\boldsymbol{v}\,C) = 0, \tag{69.185}$$

with $\boldsymbol{v}$ a non-divergent velocity, $\nabla\cdot\boldsymbol{v} = 0$. Show that the tracer center of mass position evolves according to the tracer center of mass velocity

$$\frac{\mathrm{d}\langle \boldsymbol{x}\rangle^{C}}{\mathrm{d}t} = \langle \boldsymbol{v}\rangle^{C}, \tag{69.186}$$

where the tracer center of mass velocity is given by

$$\langle \boldsymbol{v} \rangle^C = \frac{\int \boldsymbol{v}\, C \,\mathrm{d}V}{\int C \,\mathrm{d}V} = \frac{1}{\mathcal{C}} \int \boldsymbol{v}\, C \,\mathrm{d}V. \tag{69.187}$$

(b) Consider a tracer concentration whose tendency at a point in space affected only by diffusion

$$\partial_t C = \nabla \cdot (K \cdot \nabla C)\,, \tag{69.188}$$

where $K = K(\boldsymbol{x}, t) > 0$ is a kinematic diffusivity (physical dimensions of squared length per time), and which is assumed to vanish at the domain boundaries. Show that the tracer center of mass drifts up the diffusivity gradient

$$\frac{\mathrm{d}\langle \boldsymbol{x} \rangle^C}{\mathrm{d}t} = \langle \nabla K \rangle^C. \tag{69.189}$$

Hint: use the product rule and drop boundary terms.

(c) Consider an initial tracer concentration that is a function only of latitude,

$$C(x, y, z, t = 0) = C_0(y), \tag{69.190}$$

and assume a smooth spherical domain. Assume the diffusivity, K, is a turbulent diffusivity proportional to the eddy kinetic energy of the flow, so that large diffusivity occurs in regions with large eddy activity; i.e., there is a lot of turbulent mixing where turbulence is active. Introduce an stirring from the eddies that breaks the zonal symmetry. Qualitatively discuss the process whereby this turbulent diffusive mixing causes the tracer center of mass to drift towards the turbulent region.

(d) Generalize the result from part (b) to the case of the diffusion equation

$$\partial_t C = \nabla \cdot (\boldsymbol{K} \cdot \nabla C) = \partial_p (K^{pq}\, \partial_q C), \tag{69.191}$$

where $\boldsymbol{K}$ is a second order symmetric diffusion tensor.

EXERCISE 69.5: EVOLUTION OF TRACER CENTER OF MASS IN MOVING REGION

Consider a finite region of fluid with fixed mass that is moving with the fluid velocity field, $\mathcal{R}(\boldsymbol{v})$. The fluid is assumed to have a tracer whose concentration is affected by an irreversible process so that

$$\frac{\mathrm{D}C}{\mathrm{D}t} = \dot{C} \neq 0. \tag{69.192}$$

For example, $\dot{C}$ may represent a diffusive process, in which case the tracer content within the region changes due to diffusion of tracer across the region boundary.

Determine the evolution equation for the tracer center of mass position

$$\langle \boldsymbol{x} \rangle^C = \frac{\int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{x}\, C\, \rho \,\mathrm{d}V}{\int_{\mathcal{R}(\boldsymbol{v})} C\, \rho \,\mathrm{d}V}. \tag{69.193}$$

Hint: the region under consideration is moving with the fluid and has constant mass. Although the region boundaries are not material, we can make use of Reynold's transport theorem from Section 20.2.6 since the region has a constant mass. Consequently, we can set

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}(\boldsymbol{v})} \psi\, \rho \,\mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})} \frac{\mathrm{D}\psi}{\mathrm{D}t}\, \rho \,\mathrm{d}V. \tag{69.194}$$

EXERCISE 69.6: STEADY TWO DIMENSIONAL ADVECTION-DIFFUSION

Consider the steady state advection-diffusion equation for a scalar field, Q, in a two dimensional non-divergent flow

$$\nabla \cdot (\boldsymbol{u}\, Q) = \nabla \cdot (\boldsymbol{K} \cdot \nabla Q) \quad \text{with} \quad \boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla \psi, \tag{69.195}$$

and $\boldsymbol{K}$ a diffusion tensor. Show that when evaluated along a contour of constant Q we can write

$$-(\hat{\boldsymbol{n}} \cdot \nabla Q)\, (\hat{\boldsymbol{t}} \cdot \nabla \psi) = \nabla \cdot (\boldsymbol{K} \cdot \nabla Q) \tag{69.196}$$

where $\hat{\boldsymbol{t}}$ is the unit tangent along the contour and $\hat{\boldsymbol{n}}$ is a unit vector pointing to the left of the tangent (e.g., see Figure 5.6). Assuming $\hat{\boldsymbol{n}} \cdot \nabla Q \neq 0$, this equation takes on the form

$$\hat{\boldsymbol{t}} \cdot \nabla \psi = -\frac{\nabla \cdot (\boldsymbol{K} \cdot \nabla Q)}{(\hat{\boldsymbol{n}} \cdot \nabla Q)}, \tag{69.197}$$

which provides a means to integrate the streamfunction, ψ, along contours of constant Q.

If Q is the quasi-geostrophic potential vorticity (Chapter 45), then contours of constant Q are known as *geostrophic contours*. Within this context, *Rhines and Holland* (1979) made use of the identity (69.197) in their study of ocean circulation in the presence of eddy diffusion of potential vorticity.

Hint: write the advection operator as a Jacobian and make use of Exercise 5.1.

EXERCISE 69.7: DISTRIBUTION OF ONE TRACER WITH RESPECT TO ANOTHER

Consider two tracers, ψ and B, that satisfy the advection-diffusion equation with the same diffusion tensor

$$\rho \frac{\mathrm{D}\psi}{\mathrm{D}t} = \nabla \cdot (\rho\, \boldsymbol{K} \cdot \nabla \psi) \tag{69.198a}$$

$$\rho \frac{\mathrm{D}B}{\mathrm{D}t} = \nabla \cdot (\rho\, \boldsymbol{K} \cdot \nabla B). \tag{69.198b}$$

Having access to two tracers allows us to diagnose certain properties of the flow, both in geographical/depth space as well as in the space defined by the tracers. We here study how the tracer B is distributed within layers defined by ψ, and how that distribution evolves in time. These considerations are partly motivated by the work of *Ruan and Ferrari* (2021), who assumed B to be buoyancy (with a linear equation of state). Whereas *Ruan and Ferrari* (2021) assumed a Boussinesq ocean with a constant scalar diffusivity, here we generalize to the non-Boussinesq case with a flow-dependent diffusion tensor, $\boldsymbol{K}$, which is a symmetric and positive-definite second order tensor.

(a) Derive the following identity

$$\rho \frac{\mathrm{D}(\psi\, B^{\Gamma})}{\mathrm{D}t} = \nabla \cdot (B^{\Gamma}\, \rho\, \boldsymbol{K} \cdot \nabla \psi - \psi\, \rho\, \boldsymbol{K} \cdot \nabla B^{\Gamma}) + \Gamma\, \psi\, \nabla B^{\Gamma-1} \cdot \rho\, \boldsymbol{K} \cdot \nabla B + 2\, \Gamma\, \psi\, B^{\Gamma-1}\, \rho\, \dot{B}, \tag{69.199}$$

where B^{Γ} is B raised to the integer power Γ, and where we made use of the shorthand

$$\dot{B} = \frac{\mathrm{D}B}{\mathrm{D}t}. \tag{69.200}$$

Show all relevant steps in the derivation of equation (69.199). Hint: as an optional warm-up, derive the special case with $\Gamma = 1$

$$\rho \frac{\mathrm{D}(\psi\, B)}{\mathrm{D}t} = \nabla \cdot (B\, \rho\, \boldsymbol{K} \cdot \nabla \psi - \psi\, \rho\, \boldsymbol{K} \cdot \nabla B) + 2\, \psi\, \rho\, \dot{B} \tag{69.201}$$

and then the case with $\Gamma = 2$

$$\rho \frac{\mathrm{D}(\psi B^2)}{\mathrm{D}t} = \nabla \cdot (B^2 \rho \boldsymbol{K} \cdot \nabla \psi - \psi \rho \boldsymbol{K} \cdot \nabla B^2) + 2 \psi \nabla B \cdot \rho \boldsymbol{K} \cdot \nabla B + 4 \psi B \rho \dot{B}. \quad (69.202)$$

(b) Introduce the ψ-weighted mean of an arbitrary field, Γ, according to

$$\overline{\Gamma} \equiv \frac{\int_{\mathscr{R}} \Gamma \psi \rho \, \mathrm{d}V}{\int_{\mathscr{R}} \psi \rho \, \mathrm{d}V}. \quad (69.203)$$

Furthermore, assume all boundaries to the domain are material, which means that the domain matter content is fixed in time

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathscr{R}} \rho \, \mathrm{d}V = 0 \qquad \text{and} \qquad \frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathscr{R}} \psi \rho \, \mathrm{d}V = 0 \qquad \text{and} \qquad \frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathscr{R}} B \rho \, \mathrm{d}V = 0. \quad (69.204)$$

Make use of equation (69.201) to derive the following identity

$$\frac{\mathrm{d}\overline{B}}{\mathrm{d}t} = 2 \overline{\dot{B}}, \quad (69.205)$$

and offer some discussion.

EXERCISE 69.8: EVOLUTION OF TRACER MOMENTS

In Section 68.4.3 we studied how tracer diffusion affects tracer moments. Here we consider the combined effects of advection and diffusion. We assume the boundaries are insulating (i.e., zero normal boundary flux of tracer) so that $\boldsymbol{J} \cdot \hat{\boldsymbol{n}} = 0$ with $\hat{\boldsymbol{n}}$ the outward normal at the boundary. We also assume there is no matter crossing the boundary, so that $(\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}} = 0$, where $\boldsymbol{v}^{(\mathrm{b})}$ is the velocity of a point stuck to the boundary. Correspondingly, the total fluid mass in the domain remains fixed

$$M = \int \rho \, \mathrm{d}V \quad \text{with} \quad \frac{\mathrm{d}M}{\mathrm{d}t} = 0, \quad (69.206)$$

so that the domain is material since we assume no exchange of mass or tracer across the boundaries. These assumptions allow us to focus on the effects from tracer diffusion and advection within the domain interior.

(a) DOMAIN AVERAGED TRACER CONCENTRATION: The domain averaged tracer concentration is defined by

$$\overline{C} = \frac{\int_{\mathscr{R}} C \rho \, \mathrm{d}V}{M}. \quad (69.207)$$

Show that its time derivative vanishes.

(b) TRACER VARIANCE WITHIN THE DOMAIN: The variance of the tracer concentration is defined by

$$\mathrm{var}(C) \equiv \frac{\int_{\mathscr{R}} (C - \overline{C})^2 \rho \, \mathrm{d}V}{M} = \overline{C^2} - \overline{C}^2 \geq 0. \quad (69.208)$$

The tracer variance measures the deviation of the tracer concentration relative to the domain averaged concentration. Since the domain average tracer concentration remains fixed in time, the time change of the variance is given by

$$\frac{\mathrm{d}[\mathrm{var}(C)]}{\mathrm{d}t} = \frac{\mathrm{d}\overline{C^2}}{\mathrm{d}t}. \quad (69.209)$$

Thus, it is common to refer to $\overline{C^2}$ as the tracer variance, though strictly speaking only

time derivatives of $\overline{C^2}$ and $\text{var}(C)$ are equal as per equation (69.209). Show that

$$\frac{\text{d}[\text{var}(C)]}{\text{d}t} = \frac{\text{d}\overline{C^2}}{\text{d}t} \leq 0, \tag{69.210}$$

with this inequality determined solely by diffusion, whereas advection has no impact on the variance.

(c) DIFFUSION OF ARBITRARY TRACER MOMENTS: Prove that

$$\frac{\text{d}\overline{C^\Gamma}}{\text{d}t} = \Gamma\,(\Gamma - 1) \int C^{\Gamma-2}\, \nabla C \cdot \boldsymbol{J}\, \text{d}V \leq 0. \tag{69.211}$$

For $\Gamma = 0$ we have an expression of mass conservation for the domain, whereas $\Gamma = 1$ is an expression of tracer conservation. The case of $\Gamma = 2$ yields the tracer variance result (69.210).

Hint: This exercise reveals that tracer moments evolve solely through the effects of diffusion, whereas advection does not touch the tracer moments. The goal of this exercise is to emphasize these results by working through the details, which are largely identical to those presented in Section 68.4.3 when studying diffusion alone.

Chapter 70

EDDY AND MEAN TRACER KINEMATICS

Geophysical fluid flows exhibit multiple scales in both space and time. In the analysis of these flows, it is useful to seek a description that decomposes fluid properties into a mean component and a fluctuation relative to the mean. We perform an eddy-mean decomposition when interest concerns the mean field and impacts on the mean by the fluctuating instantaneous flow, with such impacts often termed *rectified* effects. The mean field can be defined in many fashions with subjective choices based on particulars of the flow and the analysis goals. The definition for the mean in turn affects what we refer to as the fluctuation. Quite generally, fluctuations take the form of transient linear waves, nonlinear and/or breaking waves, coherent structures, and/or a chaotic/turbulent soup of eddying features. In this chapter we develop a kinematic framework originally motivated by the analysis of scalar transport induced by small amplitude wave-like eddying features. This framework can also be used for turbulent processes and their parameterizations (e.g., Chapter 71).

We consider two kinematic methods to decompose the flow into a mean and eddy, with elements of these methods pervasive in the geophysical fluids literature. The first method is the *generalized Lagrangian mean (GLM)*, which is a hybrid Eulerian/Lagrangian method that introduces an Eulerian disturbance field to measure the position of a fluid particle relative to its mean position (*Andrews and McIntyre*, 1978a,b; *Bühler*, 2014a; *Gilbert and Vanneste*, 2025). We only access a small portion of the GLM framework, used here to help unpack the kinematics of eddy tracer fluxes following from *Middleton and Loder* (1989). A more thorough treatment that considers the momentum and vorticity equations is outside the scope for this chapter.

The second kinematic method makes use of isopycnal vertical coordinates. The isopycnal approach is quasi-Lagrangian since it fixes the horizontal position (Eulerian) yet allows the vertical to follow an adiabatic fluid parcel (Lagrangian). Furthermore, we show that the isopycnal description is a special case of the GLM, where the GLM displacement field is restricted to the vertical direction. The isopycnal approach is frequently used to describe how ocean mesoscale eddies affect stratification and tracer transport in stably stratified flows. Our presentation follows the methods developed by *McDougall and McIntosh* (2001) and summarized in Chapter 9 of *Griffies* (2004). A directly related approach is considered in Chapter 67 for the stacked shallow water equations, in which we develop the thickness weighted tracer, momentum, and vorticity budgets (see also *Young* (2012) and *Jansen et al.* (2024)).

CHAPTER GUIDE

This chapter relies on an understanding of the tracer equation as derived in Section 20.1 and the maths and physics of the advection-diffusion equation explored in Chapter 69. We focus on non-divergent flows with kinematics presented in Chapter 21 and as applicable to the Boussinesq ocean studied in Chapter 29. Generalizations to non-Boussinesq flows are straightforward, with examples provided by *Griffies and Greatbatch* (2012). The kinematics of isopycnal fluid layers in a perfect fluid (Sections 70.4 and 70.5) are posed using the isopycnal vertical coordinates detailed in Chapter 63 and further pursued in Chapter 65. This discussion is served by experience with the shallow water thickness weighted averaging from Chapter 67.

Throughout this chapter we assume Cartesian tensors in the horizontal directions, which simplifies the necessary mathematical tools. This assumption is sufficient for the isopycnal averaging in Sections 70.4 and 70.5. Indeed, this assumption is sufficient for any generalized vertical coordinate discussed in Part XII of this book. However, to extend the full GLM theory to arbitrary horizontal coordinates requires more sophisticated mathematical tools, such as those reviewed by *Gilbert and Vanneste* (2025).

70.1 Reynolds decomposition

At any point in space and time, we can perform an *Eulerian average* operation to decompose a field into a mean, $\overline{\Psi}(\boldsymbol{x}, t)$, and a departure from the mean, $\Psi'(\boldsymbol{x}, t)$

$$\Psi(\boldsymbol{x}, t) = \overline{\Psi}(\boldsymbol{x}, t) + \Psi'(\boldsymbol{x}, t). \tag{70.1}$$

The departure from the mean is generally termed the "eddy" or the "fluctuation". The following offers a non-exhaustive list of mean operators computed at a fixed point in space (i.e., Eulerian mean operators).

- TIME MEAN: If the mean operator is based on a long time average, then the mean fields are assumed to be time independent: $\overline{\Psi}(\boldsymbol{x}, t) = \overline{\Psi}(\boldsymbol{x})$. This is a common operator when interest is focused on the long term mean fluid properties. Additionally, it is often the mean operator of choice with realistic climate modeling.
- PHASE AVERAGE: Rather than a time mean, we may choose to average over the phase (or period) of a wave. This choice is particularly relevant when the fluctuating field involves quasi-linear waves such as studied in Part X of this book.
- ZONAL MEAN: If the mean operator is based on an average along a particular coordinate direction (e.g., zonal average), then the mean field is independent of the "averaged out" direction.
- COARSE GRAINING: If the mean operator is based on an average over a spatial and temporal region, such as the mesoscale, then such coarse-graining averages out smaller scales. A systematic means for doing so is detailed in *Buzzicotti et al.* (2023).
- ENSEMBLE AVERAGE: Rather than a space or time mean operation, we may consider the mean or average computed over an ensemble of many flow realizations. For many purposes this is the most analytically convenient mean operator, though it is often difficult to realize in practice.

If a mean operator satisfies the following properties then it is said to provide a *Reynolds decomposition*

$$\overline{\Psi'} = 0 \tag{70.2a}$$

$$\overline{\overline{\Psi}} = \overline{\Psi} \tag{70.2b}$$

$$\overline{A\,\overline{\Psi}} = A\,\overline{\Psi} \qquad \text{for } A \text{ a constant.} \tag{70.2c}$$

Equation (70.2a) says that the mean of an eddy fluctuation vanishes. The equality (70.2b) says that the mean of a mean field returns the mean field. The final equality, (70.2c), says that a constant commutes with the mean operator. Notably, some or all of these properties are not satisfied by certain operators used for eddy-mean decompositions. However, in the following we assume they are satisfied.

A Reynolds average acting on a linear equation means that both the mean and fluctuating quantity satisfy the linear equation. In particular, consider the non-divergence condition for a Boussinesq ocean flow, $\nabla \cdot \boldsymbol{v} = 0$. Taking the mean of this equation renders

$$\nabla \cdot \boldsymbol{v} = 0 \Longrightarrow \nabla \cdot \overline{\boldsymbol{v}} = 0, \tag{70.3}$$

so that the mean velocity is non-divergent. So since both the full velocity and mean velocity are non-divergent, then so is the fluctuating velocity

$$\nabla \cdot (\overline{\boldsymbol{v}} + \boldsymbol{v}') = \nabla \cdot \boldsymbol{v}' = 0. \tag{70.4}$$

70.2 GLM kinematics for scalar fields

We here consider basic elements of generalized Lagrangian mean (GLM) theory. GLM is a hybrid between Lagrangian and Eulerian descriptions of fluid motions, so that it might be more appropriate to refer to it as the "hybrid Lagrangian-Eulerian mean theory". The GLM and the Eulerian mean for a fluid property are generally distinct, with their difference referred to as the *Stokes mean*

$$\text{generalized Lagrangian mean} = \text{Eulerian mean} + \text{Stokes mean}. \tag{70.5}$$

This name is motivated from the *Stokes drift* introduced in Section 52.11, which is the difference between the Lagrangian and Eulerian means. Note that the literature sometimes refers to the Stokes mean as the "Stokes correction". We avoid that terminology in order to avoid the spurious notion that one type of mean operator is more correct than the other. Instead, a mean operator is subjectively chosen based on its suitability to a particular question.

70.2.1 Motivation

Consider a materially constant scalar field

$$\frac{\mathrm{D}\Psi}{\mathrm{D}t} = \frac{\partial \Psi}{\partial t} + \boldsymbol{v} \cdot \nabla \Psi = 0. \tag{70.6}$$

The scalar, Ψ, is constant following fluid particles whose trajectories are integral curves of the fluid velocity, $\boldsymbol{v}$. The goal is to develop a mean operator that averages over fluctuations in the trajectories while preserving the material constancy nature of the instantaneous equation. This goal is not trivial.

Eulerian mean

An Eulerian mean operator considered in Section 70.1 leads to the mean field equation, here written either in advective form or flux form

$$\frac{\partial \overline{\Psi}}{\partial t} + \overline{\boldsymbol{v}} \cdot \nabla \overline{\Psi} = -\overline{\boldsymbol{v}' \cdot \nabla \Psi'} \qquad \text{advective form} \tag{70.7a}$$

$$\frac{\partial \overline{\Psi}}{\partial t} + \nabla \cdot (\overline{\boldsymbol{v}}\, \overline{\Psi}) = -\nabla \cdot (\overline{\boldsymbol{v}'\, \Psi'}) \qquad \text{flux form}. \tag{70.7b}$$

The equations are equivalent since both the Eulerian mean velocity and the fluctuating velocity are non-divergent, as shown in Section 70.1. Whereas Ψ is materially constant when following the instantaneous flow field, $\boldsymbol{v}$, the Eulerian mean, $\overline{\Psi}$, is not materially constant when following the Eulerian mean velocity, $\overline{\boldsymbol{v}}$, due to the source term, $-\overline{\boldsymbol{v}' \cdot \nabla \Psi'}$, provided by the eddy correlation. Furthermore, when given information only about the mean fields, then we must develop a closure for the unresolved correlation. Accurate and physically motivatived closures are not simple to derive.

Lagrangian mean

An alternative approach is to remain in the Lagrangian frame, where we work with the scalar property evaluated along a fluid particle trajectory as in Section 18.3.3[1]

$$\Psi^{\mathrm{L}}(\boldsymbol{a}, T) = \text{property } \Psi \text{ following the fluid particle trajectory } \boldsymbol{X}(\boldsymbol{a}, T), \tag{70.8}$$

where $\boldsymbol{a}$ is the material label coordinate, and T is the time measured in the co-moving fluid particle frame. Since we are not considering relativistic motions, $T = t$, and yet it is useful to make the distinction for purposes of time derivatives. As such, the material constancy equation (70.6) becomes

$$\frac{\partial \Psi^{\mathrm{L}}(\boldsymbol{a}, T)}{\partial T} = 0. \tag{70.9}$$

Consider a mean operator computed as an average over a region of material space. For example, if $\boldsymbol{a}$ is the initial fluid particle position, then an average coordinate, $\overline{\boldsymbol{a}}$, and corresponding averaged field, $\overline{\Psi}^{\mathrm{L}}$, render a coarse-graining over the initial positions. Since each member of the Lagrangian average satisfies equation (70.9), so too does the Lagrangian mean

$$\frac{\partial \overline{\Psi}^{\mathrm{L}}(\overline{\boldsymbol{a}}, T)}{\partial T} = 0. \tag{70.10}$$

Although this equation retains the simplicity of the unaveraged version, it still requires information about trajectories. Trajectories are computed based on the flow map (i.e., the velocity field), with trajectories not always convenient when describing chaotic or turbulent fluids. GLM offers an alternative that aims to meld elements of the Eulerian (e.g., computability) to the Lagrangian (e.g., material constancy).

Generalized Lagrangian mean

The GLM approach produces a field that remains constant following the GLM velocity

$$\frac{\partial \overline{\Psi}^{(\mathrm{GLM})}}{\partial t} + \overline{\boldsymbol{v}}^{(\mathrm{GLM})} \cdot \nabla \overline{\Psi}^{(\mathrm{GLM})} = 0. \tag{70.11}$$

Hence, GLM maintains the desirable properties of the Lagrangian mean. However, it does so using Eulerian methods that prove to be more practical for many cases. Notably, even if the Eulerian velocity is non-divergent, as for a Boussinesq ocean, the GLM velocity is divergent. Although we do not derive the GLM equation (70.11), in the following we motivate the GLM average from the analysis of small amplitude eddying motions.

70.2.2 Length scales and the small parameter

We consider two length scales associated with an eddy or wave fluctuation. One characterizes the size of the eddy whose length scale we write as λ. If the eddy is a monochromatic wave, then λ is its wave length. The other length scale characterizes the size of particle displacements, $|\boldsymbol{\xi}|$. In the following, we assume the particle displacements are small relative to λ

$$|\boldsymbol{\xi}| \ll \lambda \qquad \text{small amplitude waves.} \tag{70.12}$$

[1]We here use the notation $\boldsymbol{X}(\boldsymbol{a}, T)$ for the trajectory of fluid particles, whereas in Chapter 18 we generally used the motion field, $\boldsymbol{\varphi}(\boldsymbol{a}, T)$. As discussed in Section 18.2.1, the two are the same when fixing a particular particle label, $\boldsymbol{a}$.

We thus introduce the small non-dimensional ratio of length scales for the following analysis

$$\alpha = |\boldsymbol{\xi}|/\lambda \ll 1. \tag{70.13}$$

70.2.3 Decomposing the particle trajectory

Recall the discussion of fluid particle trajectories given in Chapter 17. In this description, the trajectory of a particle is determined by integrating the relation between the particle trajectory and the particle velocity

$$\left[\frac{\partial \boldsymbol{X}(\boldsymbol{a},T)}{\partial T}\right]_{\boldsymbol{a}} = \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a},T)] \Longrightarrow \boldsymbol{X}(\boldsymbol{a},T) = \boldsymbol{X}(\boldsymbol{a},0) + \int_0^T \boldsymbol{v}[\boldsymbol{X}(\boldsymbol{a},T')]\,\mathrm{d}T', \tag{70.14}$$

so that the trajectory measures the position of a particle relative to a chosen origin. The material coordinate, $\boldsymbol{a}$, distinguishes the continuum of fluid particles, thus making the trajectory a field in material space-time.

The GLM develops a hybrid Eulerian-Lagrangian method and it is motivated by linear or quasi-linear disturbances. Keeping this motivation in mind, we consider each point in space, $\boldsymbol{x}$, to be the mean position of a unique fluid particle. In turn, we introduce an Eulerian field, $\boldsymbol{\xi}(\boldsymbol{x},t)$, that measures the position of a fluid particle relative to its mean position.[2] Correspondingly, the Eulerian mean of the disturbance field vanishes

$$\overline{\boldsymbol{\xi}(\boldsymbol{x},t)} = 0. \tag{70.15}$$

Note that the Eulerian mean operator can be any of the operators (or others) satisfying the Reynold's decomposition property discussed in Section 70.1

Specification of $\boldsymbol{\xi}(\boldsymbol{x},t)$ for large amplitude disturbances (i.e., nonlinear waves) requires the full machinery of GLM, which is beyond our scope. Instead, to expose the rudiments we here assume small amplitude disturbances such as shown in Figure 70.1, for which the particle displacement amplitude is much smaller than the wavelength of the disturbance as given by the inequality (70.13). In this case the disturbance field is constructed by time integration of the eddy velocity field

$$\left[\frac{\partial \boldsymbol{\xi}(\boldsymbol{x},t)}{\partial t}\right]_{\boldsymbol{x}} = \boldsymbol{v}'(\boldsymbol{x},t) \Longrightarrow \boldsymbol{\xi}(\boldsymbol{x},t) = \int^t \boldsymbol{v}'(\boldsymbol{x},t')\,\mathrm{d}t'. \tag{70.16}$$

With this specification for the disturbance field, we see that if the eddy velocity is non-divergent then so is the disturbance field

$$\nabla\cdot\boldsymbol{v}' = 0 \Longrightarrow \nabla\cdot\boldsymbol{\xi} = 0. \tag{70.17}$$

The definition (70.16) for the disturbance field, $\boldsymbol{\xi}(\boldsymbol{x},t)$, is directly analogous to the particle trajectory position, $\boldsymbol{X}(\boldsymbol{a},T)$, given by equation (70.14). However, there are important distinctions. Namely, the disturbance, $\boldsymbol{\xi}(\boldsymbol{x},t)$, is an Eulerian field that measures the position of a fluid particle relative to its mean position, with each Eulerian position, $\boldsymbol{x}$, corresponding to the mean position for a distinct fluid particle. In contrast, the particle position, $\boldsymbol{X}(\boldsymbol{a},T)$, is a Lagrangian field that is attached to each fluid particle and measures the position of that particle relative to a chosen origin.

[2] We introduced a one-dimensional disturbance field in Section 51.3 when taking a Lagrangian perspective to derive the equations for acoustic waves. Hence, the GLM disturbance field, $\boldsymbol{\xi}(\boldsymbol{x},t)$, provides a three-dimensional generalization of that approach.

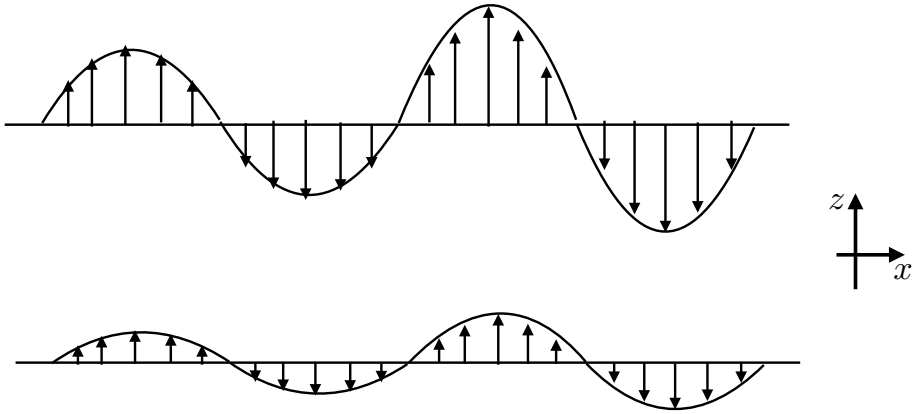

FIGURE 70.1: Illustrating the displacement of fluid particles at two selective vertical positions due to a linear transverse wave disturbance. The particle positions, $\boldsymbol{x}^{(\xi)}(\boldsymbol{x},t) = \boldsymbol{x} + \boldsymbol{\xi}(\boldsymbol{x},t)$, here have a disturbance field of the form $\boldsymbol{\xi}(\boldsymbol{x},t) = \hat{\boldsymbol{z}}\,\xi_0(x,z)\sin(k\,x - \omega\,t)$, with $\xi_0(x,z)$ a spatially dependent wave amplitude, $\lambda = 2\pi/k$ the wavelength, $\boldsymbol{k} = \hat{\boldsymbol{x}}\,k$ the wavevector, $\omega = c\,k$ the angular frequency, and c the phase speed. Small amplitude waves satisfy $|\xi_0| \ll \lambda$. Note that this wave does not produce a Stokes drift since particle displacements are perpendicular to the wavevector: $\boldsymbol{\xi} \cdot \boldsymbol{k} = 0$ (see Section 70.2.5), whereas Stokes drift requires particle motion to have a nonzero component in the wave direction (see Figures 52.4 and 52.9). Even so, it does generally produced a Stokes mean for an arbitrary field Ψ (Section 70.2.4).

70.2.4 GLM and the Stokes mean

The mean of a fluid property, Ψ, is a function of how the property is sampled when computing the mean. For example, the mean sampled on a fluctuating fluid particle differs from the mean sampled at the particle's mean position. Mathematically, this distinction implies that

$$\underbrace{\overline{\Psi(\boldsymbol{x} + \boldsymbol{\xi}(\boldsymbol{x},t))}}_{\text{GLM}} \neq \underbrace{\overline{\Psi(\boldsymbol{x},t)}}_{\text{Eulerian}}, \tag{70.18}$$

where it is common to make use of the shorthand

$$\boldsymbol{x}^{(\xi)}(\boldsymbol{x},t) \equiv \boldsymbol{x} + \boldsymbol{\xi}(\boldsymbol{x},t) \tag{70.19}$$

for the instantaneous position of the fluid particle. The average,

$$\overline{\Psi}^{(\text{GLM})}(\boldsymbol{x},t) \equiv \overline{\Psi(\boldsymbol{x} + \boldsymbol{\xi}(\boldsymbol{x},t),t)} = \overline{\Psi(\boldsymbol{x}^{(\xi)},t)}, \tag{70.20}$$

defines the generalized Lagrangian mean for the fluid property, Ψ. That is, the GLM is computed by evaluating the property, Ψ, at the position of a fluid particle, $\boldsymbol{x}^{(\xi)}(\boldsymbol{x},t) = \boldsymbol{x} + \boldsymbol{\xi}(\boldsymbol{x},t)$, and then performing an Eulerian average. We emphasize that $\boldsymbol{x}$ is both an arbitrary Eulerian field point *and* the mean position of a fluid particle, $\overline{\boldsymbol{x}^{(\xi)}} = \boldsymbol{x}$. In contrast, the Eulerian mean is determined by evaluating Ψ at a fixed Eulerian point in space

$$\overline{\Psi}^{(\text{E})}(\boldsymbol{x},t) \equiv \overline{\Psi(\boldsymbol{x},t)}, \tag{70.21}$$

where there is no consideration of instantaneous particle positions. Given this identity, we sometimes drop the (E) superscript on the Eulerian mean to reduce clutter.

Following our discussion at the start of Section 70.2, we define the Stokes mean as the difference between the GLM and Eulerian mean

$$\overline{\Psi}^{(\text{S})}(\boldsymbol{x},t) = \overline{\Psi}^{(\text{GLM})}(\boldsymbol{x},t) - \overline{\Psi}(\boldsymbol{x},t). \tag{70.22}$$

The Stokes mean arises from inhomogenities in Ψ, which in turn lead to differences in its mean

depending on how that field is sampled, whether sampled on a fluid particle, $\boldsymbol{x}^{(\xi)}(\boldsymbol{x},t)$, or sampled at the mean position of the fluid particle, $\boldsymbol{x}$.

We mathematically expose the origin of the Stokes mean by performing a Taylor series expansion around the mean particle position

$$\Psi(\boldsymbol{x}+\boldsymbol{\xi},t) = \Psi(\boldsymbol{x},t) + \boldsymbol{\xi}\cdot\nabla\Psi(\boldsymbol{x},t) + \frac{1}{2}\,\xi^m\,\xi^n\partial_m\partial_n\Psi(\boldsymbol{x},t) + \mathcal{O}(\alpha^3). \tag{70.23}$$

The non-dimensional ratio, $\alpha = |\boldsymbol{\xi}|/\lambda \ll 1$, was introduced in equation (70.13). It measures the ratio of the amplitude for particle displacements to the wavelength, λ, of fluctuations in the field Ψ. Taking the mean of equation (70.23) then leads to an expression for the Stokes mean

$$\overline{\Psi}^{(\mathrm{S})}(\boldsymbol{x},t) = \overline{\Psi}^{(\mathrm{GLM})}(\boldsymbol{x},t) - \overline{\Psi}(\boldsymbol{x},t) \tag{70.24a}$$

$$= \overline{\boldsymbol{\xi}\cdot\nabla\Psi} + \frac{1}{2}\,\overline{\xi^m\,\xi^n\partial_m\partial_n\Psi} + \mathcal{O}(\alpha^3). \tag{70.24b}$$

$$= \overline{\boldsymbol{\xi}\cdot\nabla\Psi'} + \frac{1}{2}\,\overline{\xi^m\,\xi^n}\,\partial_m\partial_n\overline{\Psi} + \mathcal{O}(\alpha^3), \tag{70.24c}$$

where we introduced the Eulerian fluctuation,

$$\Psi'(\boldsymbol{x},t) = \Psi(\boldsymbol{x},t) - \overline{\Psi}(\boldsymbol{x},t), \tag{70.25}$$

and all terms on the right hand side of equation (70.24c) are evaluated at $(\boldsymbol{x},t)$. Observe that the Stokes mean (70.24c) is nonzero only starting at $\mathcal{O}(\alpha^2)$. When Ψ represents the velocity field, we refer to the Stokes mean as the *Stokes drift* (Section 52.11), in which

$$\boldsymbol{v}^{(\mathrm{S})} = \overline{(\boldsymbol{\xi}\cdot\nabla)\,\boldsymbol{v}'} + \frac{1}{2}\,\overline{\xi^m\,\xi^n}\,\partial_m\partial_n\overline{\boldsymbol{v}} + \mathcal{O}(\alpha^3). \tag{70.26}$$

70.2.5 An example wave

We exemplify the previous discussion by considering the small amplitude wave

$$\boldsymbol{\xi} = -\omega^{-1}\,\boldsymbol{U}(\boldsymbol{x})\sin(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t) \tag{70.27a}$$

$$\boldsymbol{v}' = \partial_t\boldsymbol{\xi} = \boldsymbol{U}(\boldsymbol{x})\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t) \tag{70.27b}$$

$$\nabla v'^p = \nabla U^p\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t) - \boldsymbol{k}\,U^p\sin(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t) \tag{70.27c}$$

$$\nabla\cdot\boldsymbol{v}' = (\nabla\cdot\boldsymbol{U})\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t) - \boldsymbol{k}\cdot\boldsymbol{U}\sin(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t), \tag{70.27d}$$

where $\boldsymbol{U}$ is the velocity amplitude that is generally a function of space, $\boldsymbol{k}$ is the wavevector, and $2\,\pi/\omega$ is the wave period. The wave renders an oscillatory motion to fluid particles, with the disturbance field specifying the instantaneous position of fluid particles whose mean position is $\boldsymbol{x}$. The disturbance field and velocity field both have a zero mean when time integrated over a wave period

$$\frac{1}{2\,\pi/\omega}\int_0^{2\,\pi/\omega}\boldsymbol{\xi}(\boldsymbol{x},t)\,\mathrm{d}t = 0 \tag{70.28a}$$

$$\frac{1}{2\,\pi/\omega}\int_0^{2\,\pi/\omega}\boldsymbol{v}'(\boldsymbol{x},t)\,\mathrm{d}t = 0. \tag{70.28b}$$

To maintain a non-divergent eddy velocity at arbitrary times requires

$$\nabla\cdot\boldsymbol{v}' = 0 \Longrightarrow \nabla\cdot\boldsymbol{U} = \boldsymbol{U}\cdot\boldsymbol{k} = 0. \tag{70.29}$$

As studied in Part X of this book, $\boldsymbol{U} \cdot \boldsymbol{k} = 0$ means that the wave is transverse, so that particle displacements arising from the wave are orthogonal to the wavevector (e.g., Figure 70.1)

Stokes drift

Specializing to the velocity field (70.27b), substituting into the Stokes drift expression (70.26), and making use of an average over a wave period yields

$$\overline{(\boldsymbol{\xi} \cdot \nabla) v'^p} = \frac{U^p \, \boldsymbol{U} \cdot \boldsymbol{k}}{2\,\omega} \quad \text{and} \quad \overline{\boldsymbol{v}} = 0. \tag{70.30}$$

The second equality holds since the velocity at a point arises just from the wave field, which has a zero Eulerian mean. Hence, to $\mathcal{O}(\alpha^2)$, the Stokes drift velocity associated with the GLM is given by

$$\boldsymbol{v}^{(\mathrm{S})} = \frac{\boldsymbol{U}\,(\boldsymbol{U} \cdot \boldsymbol{k})}{2\,\omega} + \mathcal{O}(\alpha^2). \tag{70.31}$$

The Stokes drift vanishes at this order of accuracy for transverse waves since $\boldsymbol{U} \cdot \boldsymbol{k} = 0$.

As a check on the formalism, consider a one-dimensional longitudinal wave, in which the Stokes drift is given by

$$\overline{v}^{(\mathrm{S})} = \frac{U^2}{2\,c} + \mathcal{O}(\alpha^2), \tag{70.32}$$

where $c = \omega/k$ is the wave speed. This result agrees with that derived using Lagrangian trajectories in Section 52.11 (see Exercise 52.7). Use of the GLM displacement field offers a somewhat more streamlined method for computing Stokes drift.

Stokes mean for an arbitrary field

The Stokes mean for an arbitrary field is given by

$$\overline{\Psi}^{(\mathrm{S})}(\boldsymbol{x}, t) = -\omega^{-1}\, \boldsymbol{U} \cdot \overline{\nabla \Psi' \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega t)} + \mathcal{O}(\alpha^2) \tag{70.33a}$$

$$= -\omega^{-1}\, \overline{\nabla \cdot (\boldsymbol{U}\, \Psi') \sin(\boldsymbol{k} \cdot \boldsymbol{x} - \omega t)} + \mathcal{O}(\alpha^2), \tag{70.33b}$$

where the second equality made use of the non-divergent nature of the wave field (70.29). To second order in wave amplitude, the Stokes mean is determined by the projection of the gradient of the Eulerian fluctuation, $\nabla \Psi'$, onto the wave amplitude, $\boldsymbol{U}$. For example, consider a transverse wave such as that shown in Figure 70.1. Even though the Stokes drift vanishes to order $\mathcal{O}(\alpha^2)$, the Stokes mean, $\overline{\Psi}^{(\mathrm{S})}(\boldsymbol{x}, t)$, can be nonzero so long as there is a nonzero vertical gradient in the Eulerian fluctuation.

70.2.6 GLM with a materially constant scalar

Consider a materially constant scalar field, such as a tracer concentration in the absence of mixing and sources

$$\frac{\mathrm{D}C}{\mathrm{D}t} = 0. \tag{70.34}$$

How the GLM for C is related to the instantaneous C

The GLM for C equals to the value of C on a fluid particle

$$\overline{C(\boldsymbol{x} + \boldsymbol{\xi}, t)} = \overline{C}^{(\mathrm{GLM})}(\boldsymbol{x}, t) = C(\boldsymbol{x} + \boldsymbol{\xi}, t). \tag{70.35}$$

This is a subtle identity that packs in a lot of information. It says that when evaluated at the mean fluid particle position, $\boldsymbol{x}$, the GLM tracer concentration, $\overline{C}^{(\mathrm{GLM})}(\boldsymbol{x}, t)$, equals to the concentration evaluated on a fluid particle, $C(\boldsymbol{x} + \boldsymbol{\xi}, t)$. One way to understand this identity is to assume the averaging operator is an ensemble mean, so that the GLM is an ensemble mean following fluid particles. Since C is constant on fluid particles, each ensemble member has the same value for C, in which case the GLM for C clearly equals the value of C for each ensemble member. We make particular use of the identity (70.35) when considering isopycnal kinematics in Sections 70.4 and 70.5.

Relating the particle disturbance field to Eulerian properties of C

There is a frequently used consequence of the identity (70.35) involving the Eulerian fluctuation

$$C'(\boldsymbol{x}, t) = C(\boldsymbol{x}, t) - \overline{C}(\boldsymbol{x}, t) \tag{70.36}$$

and the Eulerian mean

$$C^{(\mathrm{E})}(\boldsymbol{x}, t) = \overline{C}(\boldsymbol{x}, t). \tag{70.37}$$

To derive it, recall the Taylor series expansion (70.23) truncated here to first order accuracy

$$C(\boldsymbol{x} + \boldsymbol{\xi}, t) = C(\boldsymbol{x}, t) + \boldsymbol{\xi} \cdot \nabla \overline{C}(\boldsymbol{x}, t) + \mathcal{O}(\alpha^2). \tag{70.38}$$

Taking the Eulerian mean of both sides renders

$$\overline{C(\boldsymbol{x} + \boldsymbol{\xi}, t)} = \overline{C}(\boldsymbol{x}, t) + \mathcal{O}(\alpha^2), \tag{70.39}$$

which follows since $\overline{\xi^p} = 0$ for each component of the displacement field. The identity (70.39) says that the GLM equals to the Eulerian mean to order $\mathcal{O}(\alpha^2)$, which is a result consistent with the Stokes mean being an order $\mathcal{O}(\alpha^2)$ quantity as revealed by equation (70.24c). From equation (70.35) we know that $C(\boldsymbol{x} + \boldsymbol{\xi}, t) = \overline{C(\boldsymbol{x} + \boldsymbol{\xi}, t)}$, so that we can subtract equations (70.38) and (70.39) to find

$$C'(\boldsymbol{x}, t) = -\boldsymbol{\xi} \cdot \nabla \overline{C}(\boldsymbol{x}, t) + \mathcal{O}(\alpha^2). \tag{70.40}$$

Hence, to first order accuracy, the Eulerian fluctuation equals to minus the disturbance field projected onto the gradient of the mean field; i.e., the Eulerian fluctuation in the tracer is first order in the disturbance. We make use of this result when discussing the kinematics of eddy tracer fluxes in Section 70.3. Furthermore, for the isopycnal kinematics in Sections 70.4 and 70.5, we focus on vertical particle displacements, $\boldsymbol{\xi} = \xi\, \hat{\boldsymbol{z}}$, in which case the Eulerian fluctuation is given by

$$C'(z, t) = -\xi\, \partial_z \overline{C}(z, t) + \mathcal{O}(\alpha^2). \tag{70.41}$$

70.2.7 Further study

GLM was introduced in the seminal papers by *Andrews and McIntyre* (1978a,b). These papers offer a wealth of intellectual rewards after much study. GLM is also detailed in the monograph on waves and mean flows by *Bühler* (2014a). *Gilbert and Vanneste* (2025) provide an elegant and powerful mathematical framework for GLM that allows for its use for arbitrary manifolds.

70.3 Kinematics of eddy tracer fluxes

As introduced in Section 70.2.1, consider the Eulerian eddy-mean decomposition for a materially constant tracer in an non-divergent flow. The advection equation for this tracer is given by

$$\partial_t C + \nabla \cdot (\boldsymbol{v}\, C) = 0, \tag{70.42}$$

and its Eulerian mean is

$$\partial_t \overline{C} + \nabla \cdot (\overline{\boldsymbol{v}}\, \overline{C}) = -\nabla \cdot (\overline{\boldsymbol{v}'\, C'}). \tag{70.43}$$

The eddy advective flux, $\boldsymbol{v}'\, C'$, is the product of the eddy velocity and eddy tracer concentration. Its mean provides the correlation or mean eddy flux, $\overline{\boldsymbol{v}'\, C'}$. The convergence of this mean eddy flux provides a source to the advection equation for the Eulerian mean tracer concentration.

In this section we make use of the particle disturbance field of Section 70.2 to unpack the kinematics of eddy tracer fluxes induced by small amplitude waves. As we see, the particle disturbance field is a useful conceptual tool to frame the kinematics of tracer eddy fluxes.

70.3.1 Particle displacements and eddy tracer fluxes

Following Section 70.2, we here introduce a particle disturbance vector corresponding to small amplitude eddy fluctuations

$$\partial_t \boldsymbol{\xi}(\boldsymbol{x}, t) = \boldsymbol{v}'(\boldsymbol{x}, t) + \mathcal{O}(\alpha^2) \tag{70.44a}$$

$$\overline{\boldsymbol{\xi}} = 0. \tag{70.44b}$$

Correspondingly, each spatial point, $\boldsymbol{x}$, is the mean position of a fluid particle whose instantaneous position is $\boldsymbol{x} + \boldsymbol{\xi}(\boldsymbol{x}, t)$. Following the results from Section 70.2.6, to leading order we can write the Eulerian fluctuation in terms of the particle displacement (equation (70.40))

$$C'(\boldsymbol{x}, t) = -\boldsymbol{\xi} \cdot \nabla \overline{C}(\boldsymbol{x}, t) + \mathcal{O}(\alpha^2). \tag{70.45}$$

Notice that if the particle displacement is oriented along a mean tracer iso-surface, then $\boldsymbol{\xi} \cdot \nabla \overline{C}(\boldsymbol{x}, t) = 0$ and there is no tracer fluctuation, $C' = 0$, to order $\mathcal{O}(\alpha^2)$. More general eddy motions lead to a nonzero tracer fluctuation with the eddy tracer flux taking on the form

$$\boldsymbol{v}'\, C' = -\partial_t \boldsymbol{\xi}\, (\boldsymbol{\xi} \cdot \nabla) \overline{C} + \mathcal{O}(\alpha^2). \tag{70.46}$$

We unpack this expression for the purpose of characterizing kinematic properties of the eddy tracer flux.

70.3.2 Decomposing into symmetric and skew symmetric fluxes

From equation (70.46), the m'th component of the eddy tracer flux is given by

$$v'^m\, C' = -\left[(\partial_t\, \xi^m)\, \xi^n\right] \partial_n \overline{C}. \tag{70.47}$$

To explore the kinematic properties of the tracer flux (70.47), decompose the second order tensor, $(\partial_t\, \xi^m)\, \xi^n$, into its symmetric and anti-symmetric components[3]

$$2\, (\partial_t\, \xi^m)\, \xi^n = [(\partial_t\, \xi^m)\, \xi^n + (\partial_t\, \xi^n)\, \xi^m] + [(\partial_t\, \xi^m)\, \xi^n - (\partial_t\, \xi^n)\, \xi^m] \tag{70.48a}$$

$$= \partial_t (\xi^m\, \xi^n) + [(\partial_t\, \xi^m)\, \xi^n - (\partial_t\, \xi^n)\, \xi^m]\,. \tag{70.48b}$$

[3] See Section 18.8 for a similar decomposition of the velocity gradient tensor.

Introducing the symmetric and anti-symmetric correlation tensors

$$2\,K^{mn} \equiv \overline{\partial_t\,(\xi^m\,\xi^n)} \tag{70.49a}$$

$$2\,A^{mn} \equiv \overline{(\partial_t\,\xi^m)\,\xi^n} - \overline{(\partial_t\,\xi^n)\,\xi^m} \tag{70.49b}$$

allows us to write the mean eddy tracer flux

$$\overline{v'^m\,C'} = -(K^{mn} + A^{mn})\,\partial_n \overline{C} \tag{70.50}$$

and the mean field tracer equation (70.43)

$$\partial_t \overline{C} + \nabla \cdot (\overline{\boldsymbol{v}}\,\overline{C}) = \nabla \cdot \left[(\boldsymbol{K} + \boldsymbol{A}) \cdot \nabla \overline{C}\right]. \tag{70.51}$$

The right hand side of this equation equals to the convergence of the symmetric and skew-symmetric tracer fluxes

$$\nabla \cdot \left[(\boldsymbol{K} + \boldsymbol{A}) \cdot \nabla \overline{C}\right] = -\nabla \cdot (\boldsymbol{F}^{\text{sym}} + \boldsymbol{F}^{\text{skew}}), \tag{70.52}$$

where

$$\boldsymbol{F}^{\text{sym}} = -\boldsymbol{K} \cdot \nabla \overline{C} \tag{70.53a}$$

$$\boldsymbol{F}^{\text{skew}} = -\boldsymbol{A} \cdot \nabla \overline{C} \tag{70.53b}$$

$$\overline{\boldsymbol{v}'\,C'} = \boldsymbol{F}^{\text{sym}} + \boldsymbol{F}^{\text{skew}}. \tag{70.53c}$$

70.3.3 The symmetric tracer flux

In terms of particle displacements, the symmetric flux (70.53a) is given by

$$(F^{\text{sym}})^m = -K^{mn}\,\partial_n \overline{C} = -\frac{1}{2}\,\overline{\partial_t(\xi^m\,\xi^n)}\,\partial_n \overline{C}. \tag{70.54}$$

The symmetric tensor, $\boldsymbol{K}$, vanishes when the average is over the period of a periodic wave, in which the particle displacements undergo reversible periodic excursions (see Section 70.3.9). For waves that decay in amplitude over the averaging period, particle displacements decrease in magnitude thus leading to an upgradient symmetric flux. In contrast, particle displacements increase in magnitude for waves that grow over the averaging period, in which case the flux is downgradient, just as for diffusion. Furthermore, growing nonlinear waves generally break and then develop into turbulence, with turbulence leading to further particle separation and dispersive tracer mixing. Dispersive mixing from turbulent motions is generally parameterized by downgradient diffusion, and we have more to say about diffusive parameterizations of lateral dispersion in Section 71.4.

70.3.4 The skew, advective, and rotational tracer fluxes

Following our discussion in Section 69.5, we write the skew flux as

$$(F^{\text{skew}})^m = -A^{mn}\,\partial_n \overline{C} = -\epsilon^{mnp}\,\Psi_p\,\partial_n \overline{C} = -\left(\nabla \overline{C} \times \boldsymbol{\Psi}\right)^m, \tag{70.55}$$

where we introduced the vector streamfunction (dimensions squared length per time)[4]

$$\boldsymbol{\Psi} = \frac{1}{2}\,\overline{\partial_t \boldsymbol{\xi} \times \boldsymbol{\xi}} = \frac{1}{2}\,\overline{\boldsymbol{v}' \times \boldsymbol{\xi}}. \tag{70.56}$$

[4] *Middleton and Loder* (1989) and *Garrett* (2006) introduce a skew-diffusivity, $\boldsymbol{D}$, which is opposite in sign to the vector streamfunction: $\boldsymbol{\Psi} = -\boldsymbol{D}$.

The vector streamfunction is half the angular momentum per mass of a fluid particle undergoing eddying motion, with the angular momentum computed relative to the mean particle position. The vector streamfunction is nonzero only if the eddy has a preferred sense of rotation, in which case the wave field is said to be *polarized*. That is, polarization results if the fluctuating velocity, $\boldsymbol{v}'$, is correlated to a fluid particle displacement, $\boldsymbol{\xi}$, in an orthogonal direction, thus giving rise to a nonzero angular momentum.

The skew flux can be written

$$\begin{aligned} \boldsymbol{F}^{\text{skew}} &= -\nabla \overline{C} \times \boldsymbol{\Psi} && \text{(70.57a)} \\ &= (\nabla \times \boldsymbol{\Psi})\, \overline{C} - \nabla \times (\overline{C}\, \boldsymbol{\Psi}) && \text{(70.57b)} \\ &= \boldsymbol{U}^{\text{A}}\, \overline{C} - \nabla \times (\overline{C}\, \boldsymbol{\Psi}) && \text{(70.57c)} \\ &= \boldsymbol{F}^{\text{adv}} - \boldsymbol{F}^{\text{rot}}, && \text{(70.57d)} \end{aligned}$$

so that the skew flux equals to an advective flux minus a rotational flux. We here introduced the non-divergent velocity

$$\boldsymbol{U}^{\text{A}} = \nabla \times \boldsymbol{\Psi} \tag{70.58}$$

and the non-divergent rotational flux

$$\boldsymbol{F}^{\text{rot}} = \nabla \times (\overline{C}\, \boldsymbol{\Psi}). \tag{70.59}$$

Since $\nabla \cdot \boldsymbol{F}^{\text{rot}} = 0$, we see that the divergence of the skew flux equals to the divergence of the advective flux

$$\nabla \cdot \boldsymbol{F}^{\text{skew}} = \nabla \cdot (\boldsymbol{F}^{\text{adv}} - \boldsymbol{F}^{\text{rot}}) = \nabla \cdot \boldsymbol{F}^{\text{adv}}. \tag{70.60}$$

Consequently, the rotational flux, $\boldsymbol{F}^{\text{rot}}$, has no impact on evolution of the mean tracer concentration.

70.3.5 What does a point measurement estimate?

From equation (70.53c), we see that a point measurement of the correlation, $\overline{\boldsymbol{v}'\, C'}$, provides an estimate of the symmetric tracer flux plus the skew tracer flux

$$\overline{\boldsymbol{v}'\, C'} = \boldsymbol{F}^{\text{sym}} + \boldsymbol{F}^{\text{skew}} = -(\boldsymbol{K} + \boldsymbol{A}) \cdot \nabla \overline{C}. \tag{70.61}$$

Furthermore, for a periodic wave field, where the symmetric tensor vanishes, the correlation, $\overline{\boldsymbol{v}'\, C'}$, provides a direct estimate of the skew flux, $-\nabla \overline{C} \times \boldsymbol{\Psi}$. This latter result might seem puzzling on first encounter, since one could imagine $\overline{\boldsymbol{v}'\, C'}$ instead provides an estimate for the advective flux, $\overline{C}\, \boldsymbol{U}^{\text{A}}$. But that presumption is wrong, as indicated by the decomposition (70.61). We emphasize this point by summarizing the various relations

$$\begin{aligned} \overline{\boldsymbol{v}'\, C'} &= \boldsymbol{F}^{\text{sym}} + \boldsymbol{F}^{\text{skew}} && \text{(70.62a)} \\ &= -\boldsymbol{K} \cdot \nabla \overline{C} - \nabla \overline{C} \times \boldsymbol{\Psi} && \text{(70.62b)} \\ &= -\boldsymbol{K} \cdot \nabla \overline{C} - \nabla \times (\overline{C}\, \boldsymbol{\Psi}) + \overline{C}\, \nabla \times \boldsymbol{\Psi} && \text{(70.62c)} \\ &= \boldsymbol{F}^{\text{sym}} - \boldsymbol{F}^{\text{rot}} + \boldsymbol{F}^{\text{adv}}. && \text{(70.62d)} \end{aligned}$$

The rotational flux is generally nontrivial for polarized waves or turbulent eddies. Hence, the rotational flux provides a sizable contribution to any measurement of $\overline{\boldsymbol{v}'\, C'}$ either from a field measurement or numerical simulation. Hence, for some purposes it can be more convenient to work directly with the skew flux rather than the advective flux.

70.3.6 Area integrated tracer flux

We further our understanding of the rotational contribution by considering the mean of the tracer flux integrated over a static area $\mathcal{S}$

$$\mathcal{T} = \overline{\int_{\mathcal{S}} \boldsymbol{v}\, C \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}} = \int_{\mathcal{S}} \overline{\boldsymbol{v}\, C} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\mathcal{S}} [\overline{\boldsymbol{v}}\, \overline{C} + \overline{\boldsymbol{v}'\, C'}] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{70.63}$$

Introducing the diffusive, advective, and rotational flux as in equation (70.62d) renders

$$\mathcal{T} = \int_{\mathcal{S}} [\overline{\boldsymbol{v}}\, \overline{C} + \boldsymbol{U}^{\mathsf{A}}\, \overline{C} - \nabla \times (\overline{C}\, \boldsymbol{\Psi}) - \boldsymbol{K} \cdot \nabla \overline{C}] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{70.64}$$

Use of Stokes' Theorem transforms the rotational term to a line integral around the boundary of the area

$$\mathcal{T} = \int_{\mathcal{S}} [\overline{\boldsymbol{v}}\, \overline{C} + \boldsymbol{U}^{\mathsf{A}}\, \overline{C} - \boldsymbol{K} \cdot \nabla \overline{C}] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}S - \oint_{\partial \mathcal{S}} \overline{C}\, \boldsymbol{\Psi} \cdot \mathrm{d}\boldsymbol{l}. \tag{70.65}$$

Following Section 2b of *Middleton and Loder* (1989), we interpret the boundary term as a Stokes contribution associated with the correlation of particle motion and perturbation velocity along the boundary

$$\oint_{\partial \mathcal{S}} \overline{C}\, \boldsymbol{\Psi} \cdot \mathrm{d}\boldsymbol{l} = \frac{1}{2} \oint_{\partial \mathcal{S}} \overline{C}\, (\overline{\boldsymbol{v}' \times \boldsymbol{\xi}}) \cdot \mathrm{d}\boldsymbol{l}. \tag{70.66}$$

We further this interpretation when considering the transport beneath a fluctuating isopycnal surface in Section 70.5.4.

70.3.7 Massaging the mean field tracer equation

We here write the mean tracer equation (70.51) in various forms that can be found throughout the literature. For this purpose, write the right hand side of equation (70.51) in the form

$$\nabla \cdot \left[(\boldsymbol{K} + \boldsymbol{A}) \cdot \nabla \overline{C} \right] = \partial_m \left[(K^{mn} + A^{mn})\, \partial_n \overline{C} \right] \tag{70.67a}$$

$$= \partial_m \left(K^{mn} + A^{mn} \right) \partial_n \overline{C} + (K^{mn} + A^{mn})\, \partial_m \partial_n \overline{C} \tag{70.67b}$$

$$= \partial_m \left(K^{mn} + A^{mn} \right) \partial_n \overline{C} + K^{mn}\, \partial_m \partial_n \overline{C}. \tag{70.67c}$$

The final equality follows from the identity

$$A^{mn}\, \partial_m \partial_n \overline{C} = 0, \tag{70.68}$$

which results from the contraction of the anti-symmetric tensor, A^{mn}, with the symmetric derivative operator $\partial_m \partial_n$. The second term, $K^{mn}\, \partial_m \partial_n \overline{C}$, is a diffusion operator *if* the symmetric tensor $\boldsymbol{K}$ is also positive-definite. The first term in equation (70.67c) can be interpreted as an advection operator through the action of a non-divergent plus a divergent advection velocity

$$\partial_m \left(K^{mn} + A^{mn} \right) \partial_n \overline{C} \equiv -(\boldsymbol{U}^{\mathsf{K}} + \boldsymbol{U}^{\mathsf{A}}) \cdot \nabla \overline{C}, \tag{70.69}$$

where we defined[5]

$$\boldsymbol{U}^{\mathsf{K}} \equiv -\nabla \cdot \boldsymbol{K} \Longrightarrow \nabla \cdot \boldsymbol{U}^{\mathsf{K}} = -\partial_n \partial_m K^{mn} \neq 0 \tag{70.70a}$$

$$\boldsymbol{U}^{\mathsf{A}} \equiv -\nabla \cdot \boldsymbol{A} \Longrightarrow \nabla \cdot \boldsymbol{U}^{\mathsf{A}} = -\partial_n \partial_m A^{mn} = 0. \tag{70.70b}$$

Bringing the above results together allows us to write the mean field tracer equation (70.51)

[5] Note that *Middleton and Loder* (1989) define $\boldsymbol{U}^{\mathsf{K}} = \nabla \cdot \boldsymbol{K}$, which is the opposite sign to that used here in equation (70.70a), whereas they define $\boldsymbol{U}^{\Psi} = -\nabla \cdot \boldsymbol{A}$ as in equation (70.70b).

in the following equivalent forms

$$\partial_t \overline{C} + (\overline{\boldsymbol{v}} + \boldsymbol{U}^{\mathsf{A}} + \boldsymbol{U}^{\mathsf{K}}) \cdot \nabla \overline{C} = K^{mn}\, \partial_m \partial_n \overline{C} \qquad \text{advective form} \tag{70.71a}$$

$$\partial_t \overline{C} + \nabla \cdot [(\overline{\boldsymbol{v}} + \boldsymbol{U}^{\mathsf{A}})\, \overline{C}] = \nabla \cdot (\boldsymbol{K} \cdot \nabla \overline{C}) \qquad \text{flux form} \tag{70.71b}$$

$$\partial_t \overline{C} + \nabla \cdot [(\overline{\boldsymbol{v}} + \boldsymbol{U}^{\mathsf{A}})\, \overline{C} + \boldsymbol{F}^{\mathsf{sym}}] = 0, \qquad \text{alternate flux form} \tag{70.71c}$$

where we made use of the identities

$$\nabla \cdot \overline{\boldsymbol{v}} = 0 \quad \text{and} \quad \nabla \cdot \boldsymbol{U}^{\mathsf{A}} = 0 \quad \text{and} \quad \nabla \cdot \boldsymbol{U}^{\mathsf{K}} \neq 0. \tag{70.72}$$

70.3.8 Connection to Stokes drift

From equation (70.26) we have the leading order expression for the Stokes drift

$$\boldsymbol{v}^{(\mathsf{S})} = \overline{\xi^n\, \partial_n\, \partial_t\, \boldsymbol{\xi}} + \mathcal{O}(\alpha^2). \tag{70.73}$$

As noted in equation (70.17), with $\partial_t \boldsymbol{\xi} = \boldsymbol{v}'$ and with $\nabla \cdot \boldsymbol{v}' = 0$, the corresponding particle displacements are non-divergent, $\nabla \cdot \boldsymbol{v}' = 0 \Rightarrow \nabla \cdot \boldsymbol{\xi} = 0$. Consequently, to second order accuracy, the Stokes drift velocity can be written

$$(v^{(\mathsf{S})})^p = \overline{\xi^n\, \partial_n\, \partial_t\, \xi^p} \tag{70.74a}$$

$$= \partial_n\, [\overline{(\partial_t\, \xi^p)\, \xi^n}] \tag{70.74b}$$

$$= \partial_n\, (K^{pn} + A^{pn}) \tag{70.74c}$$

$$= \partial_n\, (K^{np} - A^{np}) \tag{70.74d}$$

$$= -(U^{\mathsf{K}})^p + (U^{\mathsf{A}})^p. \tag{70.74e}$$

For the case of periodic fluid particle motion, the Stokes drift velocity equals to the non-divergent skew velocity

$$\boldsymbol{v}^{(\mathsf{S})} = \boldsymbol{U}^{\mathsf{A}} \Longrightarrow \nabla \cdot \boldsymbol{v}^{(\mathsf{S})} = 0 \qquad \text{periodic motion.} \tag{70.75}$$

More generally, for non-periodic motion, the divergent velocity is non-zero so that the Stokes velocity is also divergent

$$\boldsymbol{v}^{(\mathsf{S})} = \boldsymbol{U}^{\mathsf{A}} - \boldsymbol{U}^{\mathsf{K}} \Longrightarrow \nabla \cdot \boldsymbol{v}^{(\mathsf{S})} = -\nabla \cdot \boldsymbol{U}^{\mathsf{K}} \neq 0 \qquad \text{non-periodic motion.} \tag{70.76}$$

70.3.9 A polarized periodic example

We illustrate some of the previous analysis by considering a particle displacement vector comprised of periodic and polarized motion in the horizontal plane

$$\boldsymbol{\xi}(\boldsymbol{x}, t) = \Gamma\, [\hat{\boldsymbol{x}}\, \cos(\omega\, t) + \hat{\boldsymbol{y}}\, \sin(\omega\, t)] \tag{70.77a}$$

$$\partial_t \boldsymbol{\xi}(\boldsymbol{x}, t) = \omega\, \Gamma\, [-\hat{\boldsymbol{x}}\, \sin(\omega\, t) + \hat{\boldsymbol{y}}\, \cos(\omega\, t)], \tag{70.77b}$$

where $\Gamma > 0$ a time-independent amplitude and $2\pi/\omega > 0$ is the period. The fluid particles exhibit counter-clockwise circular and periodic motion in the horizontal plane with squared radius

$$\boldsymbol{\xi} \cdot \boldsymbol{\xi} = \Gamma^2. \tag{70.78}$$

Define the mean operator be a phase average

$$\overline{\phi} = \frac{1}{2\pi/\omega} \int_0^{2\pi/\omega} \phi(t)\, \mathrm{d}t, \tag{70.79}$$

which is a suitable averaging operator for examining the impacts of oscillatory motion on mean fields. For a spatially constant amplitude, we find below that the mean tracer concentration, $\overline{C}$, remains unchanged. The absence of a rectified change to $\overline{C}$ reflects the assumed periodic nature of the fluid particle motion.

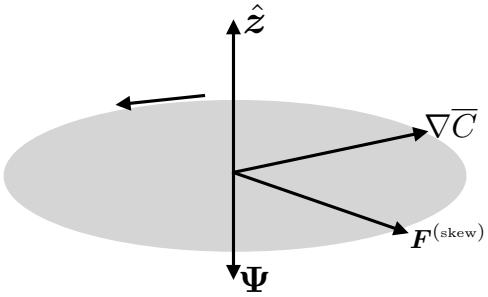

FIGURE 70.2: Sketch of the skew tracer flux associated with the polarized displacement vector (70.77a). The fluid particles are moving in the horizontal plane along a circle with a constant radius, Γ. The vector streamfunction (70.82) points in the negative $\hat{\boldsymbol{z}}$ direction. The mean concentration gradient, $\nabla\overline{C}$, generally points outside of the horizontal plane. However, it is only the horizontal components that contribute since the displacement vector is in the horizontal plane, thus resulting in a horizontal skew tracer flux. The advective velocity vanishes since the amplitude, Γ, is assumed to be spatially constant. Hence, the skew flux is purely rotational, which means there is no rectified effects on the mean tracer concentration.

Symmetric mixing tensor

In the presence of the oscillatory particle displacement (70.77a), the symmetric mixing tensor (70.49a) is given by

$$2\,K^{mn} = \frac{\Gamma^2}{2\pi/\omega}\int_0^{2\pi/\omega} \mathrm{d}t\,\frac{\partial}{\partial t}\begin{bmatrix} \cos^2(\omega\,t) & \cos(\omega\,t)\,\sin(\omega\,t) \\ \cos(\omega\,t)\,\sin(\omega\,t) & \sin^2(\omega\,t)\end{bmatrix} = 0, \tag{70.80}$$

which vanishes identically since the particles exhibit periodic motion.

Skew symmetric stirring tensor

The skew-symmetric tensor (70.49b) has non-zero components due to the polarization

$$2\,A^{12} = -A^{21} = \overline{(\partial_t\,\xi^1)\,\xi^2} - \overline{(\partial_t\,\xi^2)\,\xi^1} = -\Gamma^2\,\omega\,\overline{\sin^2(\omega\,t) + \cos^2(\omega\ ,t)} = -\Gamma^2\,\omega. \tag{70.81}$$

The corresponding vector streamfunction (70.56) is vertical

$$\boldsymbol{\Psi} = -\frac{\Gamma^2\,\omega}{2}\,\hat{\boldsymbol{z}}, \tag{70.82}$$

and the skew flux is horizontal

$$\boldsymbol{F}^{\text{skew}} = -\frac{\Gamma^2\,\omega}{2}\,(\hat{\boldsymbol{z}}\times\nabla\overline{C}). \tag{70.83}$$

Finally, the advective velocity is given by

$$\nabla\times\boldsymbol{\Psi} = -\omega\,\Gamma\,\nabla\Gamma\times\hat{\boldsymbol{z}}. \tag{70.84}$$

The advective velocity vanishes when the wave amplitude, Γ, is a constant, in which case the advective tracer flux is zero although the skew flux is non-zero. Indeed, with a constant wave amplitude, the skew tracer flux has a zero divergence so that it is a purely rotational flux. Hence,

for a constant wave amplitude, neither the skew flux nor the advective flux affect the evolution of $\overline{C}$. Figure 70.2 offers a schematic of the skew flux induced by the periodic rotating particle motion in the horizontal plane.

70.3.10 Further study

Much of this section follows *Plumb* (1979), *Middleton and Loder* (1989), and *Garrett* (2006), each of whom considered elements of tracer dispersion by waves and nonlinear eddies. *Middleton and Loder* (1989) work through a few oceanographically motivated examples that offer further understanding of skew fluxes. Additional treatments can be found in the review article of *Moffatt* (1983), who considers flow in a rotating reference frame as well as magneto-hydrodynamic flows.

70.4 Kinematics of volume transport in isopycnal layers

In this section we consider the reversible stirring of fluid parcels by turbulent flow in a perfect (i.e., no mixing or sources) stratified Boussinesq fluid. As the fluid parcels are stirred, they preserve their volume while changing their shape and stretching into finer scale features. Stirring by ocean mesoscale/baroclinic eddies offers the canonical example of such stirring. Eventually, small-scale processes, such as those summarized in Section 71.1.1, irreversibly mix properties. We are here focused just on the stirring part of this process.

Over space and time scales larger than the mesoscale, the stirring by ocean mesoscale eddies can be considered chaotic, which in turn motivates a stochastic perspective in which an ensemble of eddies is considered. The goal is to describe the ensemble mean properties of the perfect fluid, with a focus in this section on the kinematics of parcel rearrangement. Hence, eddy correlations in the present section appear between the thickness of a fluid layer and the velocity. We introduce tracers in Section 70.5, at which point we also consider eddy correlations between velocity and tracer as in Section 70.3.

The material in this section is rather detailed. However, its mastery comes readily by keeping in mind the more general (and somewhat simpler) presentation of GLM offered in Section 70.2. We are motivated to provide full details in this section since the kinematics of isopycnal ensembles appears throughout the study of wave-mean flow interactions in adiabatic geophysical fluid mechanics, such as in the study of ocean mesoscale eddies.

70.4.1 Isopycnal mean

Each fluid parcel in a stably stratified perfect Boussinesq ocean preserves its potential density. We are interested in following the vertical motion of potential density layer interfaces as waves and turbulent processes transport layer thickness from one region to another. In contrast, we are not concerned with following the lateral position of a fluid parcel within a layer. Here we introduce the isopycnal mean, which is based on describing ensembles of perfect fluid parcels using isopycnal coordinates. In Sections 70.4.2 and 70.4.3, we relate this isopycnal approach to the GLM restricted to the vertical direction.

Defining the isopycnal ensemble

An overbar with a potential density label, $\overline{(\,)}^{(\varrho)}$, denotes a mean over an ensemble of fluid parcels, each having the same potential density, ϱ, the same horizontal position, (x, y), and the same time, t. Isopycnals undulate in space and time, which means that each ensemble member has a vertical position that is generally distinct from the ensemble mean vertical position, z. Furthermore, when the context is clear, it is useful to drop the dependence on (x, y, t) to highlight the dependence on potential density and/or the vertical position.

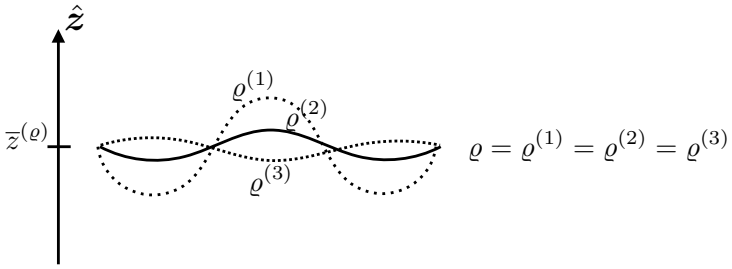

FIGURE 70.3: Schematic of the ensemble mean vertical position, $\overline{z}^{\varrho}(x, y, \varrho, t)$, for a particular potential density surface ϱ, here illustrated with a three member ensemble whose potential density is ϱ. In general, different members of an isopycnal ensemble live on different geopotentials. Therefore, when considering ensemble members with the same potential density, the ensemble mean vertical position is the average over the different members. For the case of a three member ensemble, as shown here, the averaged vertical position is $3\,\overline{z}^{\varrho}(x, y, \varrho, t) = z^{(1)}(x, y, \varrho, t) + z^{(2)}(x, y, \varrho, t) + z^{(3)}(x, y, \varrho, t)$.

Isopycnal ensemble mean

The isopycnal ensemble mean makes use of potential density as a vertical coordinate (Chapters 63 and 65), with the mean field denoted by

$$\overline{\Psi}^{(\varrho)}(x, y, \varrho, t) \equiv \text{ensemble mean using isopycnal vertical coordinates.} \tag{70.85}$$

This average is straightforward to compute when using isopycnal coordinates, thus producing an isopycnal mean that is a function of the potential density, ϱ. Figure 70.3 depicts this average.

70.4.2 Modified mean is the vertical GLM

As a complement to the isopycnal approach in Section 70.4.1, we here introduce the vertical GLM following isopycnals, which is also known as the *modified mean*.

The vertical GLM following isopycnal surfaces

The discussion in Section 70.2 considered a three dimensional particle displacement vector $\boldsymbol{\xi}(\boldsymbol{x}, t)$. In contrast, we are here interested just in the vertical displacement of an isopycnal layer interface

$$\boldsymbol{\xi}(x, y, \varrho, t) = \hat{\boldsymbol{z}}\, \xi(x, y, \varrho, t). \tag{70.86}$$

The displacement field, $\xi(x, y, \varrho, t)$, measures the vertical position of a potential density interface, ϱ, relative to its ensemble mean vertical position. For any particular ensemble member with potential density, ϱ, we write its vertical position as (dropping x, y, t dependence for brevity)

$$z(\varrho) = \overline{z}^{(\varrho)} + \xi(\varrho), \tag{70.87}$$

where

$$\overline{z}^{(\varrho)} = \overline{z(\varrho)}^{(\varrho)} \tag{70.88}$$

is the vertical position for the isopycnal ensemble mean, and the displacement field has a zero ensemble mean

$$\overline{\xi(\varrho)}^{(\varrho)} = 0. \tag{70.89}$$

Given the above definitions for the vertical position, we define the *vertical GLM* for an arbitrary function

$$\widetilde{\Psi}(x, y, \overline{z}^{(\varrho)}, t) \equiv \overline{\Psi(x, y, \overline{z}^{(\varrho)} + \xi(x, y, \varrho, t), t)}^{(\varrho)}. \tag{70.90}$$

As defined, the vertical GLM, $\widetilde{\Psi}$, is a function of the ensemble mean vertical position, $\overline{z}^{(\varrho)}$ (left hand side), and it is determined by an ensemble mean of Ψ sampled at the vertical position of each ensemble member, $\overline{z}^{(\varrho)} + \xi(\varrho)$. *McDougall and McIntosh* (2001) refer to the vertical GLM defined by equation (70.90) as the *modified mean*.

Relating the modified mean to the isopycnal mean

Following the general result (70.35), we know that the modified mean potential density, $\widetilde{\varrho}(x, y, \overline{z}^{(\varrho)}, t)$, equals to the potential density of each ensemble member so that

$$\widetilde{\varrho}(x, y, \overline{z}^{(\varrho)}, t) = \varrho(x, y, \overline{z}^{(\varrho)} + \xi(x, y, \varrho, t), t). \tag{70.91}$$

This relation means that the modified mean potential density is the functional inverse of the isopycnal ensemble mean vertical position. Consequently, the isopycnal ensemble mean of a function, $\overline{\Psi}^{(\varrho)}$ (equation (70.85)), when evaluated at the modified mean potential density, $\widetilde{\varrho}$, equals to the modified mean $\widetilde{\Psi}$ when evaluated at the vertical position of the mean density

$$\overline{\Psi}^{(\varrho)}(x, y, \widetilde{\varrho}, t) = \widetilde{\Psi}(x, y, \overline{z}^{(\varrho)}, t). \tag{70.92}$$

This is a very important identity that will be used in the following.

70.4.3 Transformed residual mean (TRM)

When working with isopycnal layers, it is very useful to use specific thickness weighting to account for the net amount of material within a layer, or to measure the net transport in the layer.[6] For this purpose we make use of the *specific thickness* from Section 64.2 as given by[7]

$$\hbar = \partial z / \partial \varrho = 1 / (\partial \varrho / \partial z), \tag{70.93}$$

and thus make use of thickness weighted fields, $\hbar\, \Psi$, and the corresponding thickness weighted isopycnal ensemble mean

$$\widehat{\Psi}(\varrho) = \frac{\overline{\hbar\, \Psi}^{(\varrho)}}{\overline{\hbar}^{(\varrho)}}. \tag{70.94}$$

The identity (70.91) then renders

$$\overline{\Psi}^{\#}(x, y, \overline{z}^{(\varrho)}, t) \equiv \widehat{\Psi}(x, y, \widetilde{\varrho}, t), \tag{70.95}$$

where $\overline{\Psi}^{\#}$ is the *transformed residual mean* (TRM) evaluated at the isopycnal ensemble mean vertical position. This is yet another important identity that will be used in the following.

Depth integrated TRM transport

The horizontal TRM velocity is a particularly key TRM field

$$\widehat{\boldsymbol{u}}(x, y, \widetilde{\varrho}, t) = \overline{\boldsymbol{u}}^{\#}(x, y, \overline{z}^{(\varrho)}, t). \tag{70.96}$$

[6] We pursue a vertical discrete version of this *thickness weighted averaging* approach for the stacked shallow water model in Chapter 67.

[7] As discussed in Section 63.9.1, specific thickness is the Jacobian of transformation between geopotential coordinates, (x, y, z, t), and isopycnal coordinates, (x, y, ϱ, t). For stably stratified ideal fluids, $\hbar$ is one-signed, hence making the coordinate transformation well defined. It is also related to the buoyancy frequency through (Section 30.6.1) $N^2 = -(g/\rho_o)\,(\partial \varrho / \partial z) = -g/(\rho_o\, \hbar)$.

Following the discussion of the vertical gauge in Section 69.5.1 (see in particular equation (69.41)), we are led to define the depth integrated TRM transport

$$\overline{\boldsymbol{U}}^{\#}(\overline{z}^{(\varrho)}) = \int_{-H}^{\overline{z}^{(\varrho)}} \overline{\boldsymbol{u}}^{\#}(z)\,\mathrm{d}z = \int_{\varrho(-H)}^{\widetilde{\varrho}(\overline{z}^{(\varrho)})} \widehat{\boldsymbol{u}}(\gamma)\,\overline{h}^{(\gamma)}\,\mathrm{d}\gamma, \tag{70.97}$$

with the second equality following from a change of coordinates from geopotential to isopycnal. We can go further with this expression by writing

$$\begin{aligned}
\overline{\boldsymbol{U}}^{\#}(\overline{z}^{(\varrho)}) &= \int_{\varrho(-H)}^{\widetilde{\varrho}(\overline{z}^{(\varrho)})} \widehat{\boldsymbol{u}}(\gamma)\,\overline{h}^{(\gamma)}\,\mathrm{d}\gamma && \text{from equation (70.97)} && \text{(70.98a)}\\
&= \int_{\varrho(-H)}^{\widetilde{\varrho}(\overline{z}^{(\varrho)})} \overline{\boldsymbol{u}\,h}^{(\gamma)}\,\mathrm{d}\gamma && \text{from equation (70.94)} && \text{(70.98b)}\\
&= \int_{\varrho(-H)}^{\varrho(\overline{z}^{(\varrho)}+\xi)} \overline{\boldsymbol{u}\,h}^{(\gamma)}\,\mathrm{d}\gamma && \text{from equation (70.91).} && \text{(70.98c)}
\end{aligned}$$

The final equality makes it clear that the TRM transport, $\overline{\boldsymbol{U}}^{\#}(\overline{z}^{(\varrho)})$, is the ensemble mean volume transport for fluid denser than $\varrho(\overline{z}^{(\varrho)}+\xi) = \widetilde{\varrho}(\overline{z}^{(\varrho)})$. This transport can also be written using geopotential coordinates

$$\overline{\boldsymbol{U}}^{\#}(\overline{z}^{(\varrho)}) = \overline{\int_{-H}^{\overline{z}^{(\varrho)}+\xi} \boldsymbol{u}\,\mathrm{d}z}. \tag{70.99}$$

The transport from each ensemble member is determined by integrating from the bottom to the vertical position, $\overline{z}^{(\varrho)}+\xi$, and then the TRM transport is determined by computing the ensemble mean for this transport.

Quasi-Stokes transport

The TRM transport (70.99) can be decomposed into an Eulerian mean plus the correlation of a fluctuation

$$\overline{\boldsymbol{U}}^{\#}(\overline{z}^{(\varrho)}) \equiv \overline{\boldsymbol{U}}(\overline{z}^{(\varrho)}) + \overline{\boldsymbol{U}}^{\mathsf{qs}}(\overline{z}^{(\varrho)}). \tag{70.100}$$

The first term,

$$\overline{\boldsymbol{U}}(\overline{z}^{(\varrho)}) = \int_{-H}^{\overline{z}^{(\varrho)}} \boldsymbol{u}\,\mathrm{d}z \tag{70.101}$$

is the ensemble mean transport between the bottom and the ensemble mean vertical position, $\overline{z}^{(\varrho)}$. We interpret this transport as an Eulerian mean since the depth ranges are fixed. In contrast, the *quasi-Stokes* transport

$$\overline{\boldsymbol{U}}^{\mathsf{qs}}(\overline{z}^{(\varrho)}) \equiv \overline{\int_{\overline{z}^{(\varrho)}}^{\overline{z}^{(\varrho)}+\xi} \boldsymbol{u}\,\mathrm{d}z} \tag{70.102}$$

measures the ensemble mean transport between the mean vertical position of an isopycnal, $\overline{z}^{(\varrho)}$, and that of each ensemble member, $\overline{z}^{(\varrho)} + \xi(\varrho)$. We refer to transport as "quasi-Stokes" given that it is the difference between an isopycnal (i.e., quasi-Lagrangian) mean and an Eulerian mean (see Section 70.2)

$$\overline{\boldsymbol{U}}^{\mathsf{qs}} = \overline{\boldsymbol{U}}^{\#} - \overline{\boldsymbol{U}}. \tag{70.103}$$

As for the traditional Stokes drift discussed in Sections 52.11, and 70.2.5, which arises from a correlation between larger velocity when a wave crest is present, so too does the quasi-Stokes transport arise from a correlation between a larger velocity and a larger undulation in isopycnal thickness.

Three-component TRM velocity

Following from the vertical gauge expression (69.40), we introduce the TRM vector streamfunction

$$\overline{\boldsymbol{\Psi}}^{\#} = \overline{\boldsymbol{U}}^{\#} \times \hat{\boldsymbol{z}}, \tag{70.104}$$

and the corresponding three-dimensional non-divergent TRM velocity

$$\overline{\boldsymbol{v}}^{\#} = \nabla \times \overline{\boldsymbol{\Psi}}^{\#}. \tag{70.105}$$

The vertical component,

$$\overline{w}^{\#} = \hat{\boldsymbol{z}} \cdot (\nabla \times \overline{\boldsymbol{\Psi}}^{\#}), \tag{70.106}$$

has no corresponding component in an isopycnal description, which only requires the horizontal thickness weighted transport, $\widehat{\boldsymbol{u}}$. However, the TRM vector streamfunction only requires the horizontal TRM transport, $\overline{\boldsymbol{U}}^{\#}$, so the two descriptions in effect make use of the same number of degrees of freedom.

70.4.4 Volume conservation and the thickness equation

Consider two perspectives on volume conservation: one based on isopycnal coordinates and the other based on geopotential coordinates.

Isopycnal coordinates

In isopycnal vertical coordinates, the volume of a fluid element is written

$$\delta V = \delta x \, \delta y \, \delta z = \delta x \, \delta y \, \delta \varrho \, \hbar, \tag{70.107}$$

where we introduced the specific thickness, $\hbar$, from equation (70.93). Geometrically, the product $|\hbar \, \delta \varrho|$ represents the vertical distance, or *thickness*, between two infinitesimally close density interfaces, ϱ and $\varrho + \delta \varrho$ (see Figure 64.2). Material conservation of both volume and potential density implies conservation of the product of specific thickness and horizontal area, $\delta x \, \delta y \, \hbar$, which leads to the thickness equation (Section 66.2.3)

$$\frac{\partial \hbar}{\partial t} + \nabla_{\varrho} \cdot (\hbar \, \boldsymbol{u}) = 0, \tag{70.108}$$

with $\boldsymbol{u}$ the horizontal velocity field, the time derivative is computed with ϱ held fixed, and

$$\nabla_{\varrho} = \nabla_{\hbar} + \boldsymbol{S} \, \partial_z \tag{70.109}$$

is the horizontal derivative operator with ϱ held fixed, and

$$\boldsymbol{S} = \nabla_{\varrho} z \tag{70.110}$$

is the horizontal slope of the potential density surface.

Geopotential coordinates

An Eulerian z-coordinate description of volume stirring within isopycnal layers is rendered via a combination of volume conservation, $\nabla \cdot \boldsymbol{v} = 0$, and material conservation of potential density, $\mathrm{D}\varrho/\mathrm{D}t = 0$. When written as skewsion rather than advection, the natural gauge is the vertical gauge introduced in Section 69.5.1, since this gauge only requires the same horizontal velocity field, $\boldsymbol{u}$, used with the isopycnal coordinate description. This gauge has an associated potential density skew flux, $\boldsymbol{F}^{\text{skew}} = -\nabla\varrho \times \boldsymbol{\Psi}$, which leads to the evolution

$$\partial_t \varrho = \nabla \cdot (\nabla\varrho \times \boldsymbol{\Psi}), \tag{70.111}$$

where all derivatives are here taken with fixed Eulerian (geopotential) coordinates, (x, y, z), and the ∇ operator is three-dimensional.

70.4.5 Ensemble mean kinematics in isopycnal coordinates

Consider an ensemble of stably stratified (so that the layer specific thickness, $\hbar$, is single-signed and nonvanishing) perfect Boussinesq fluid parcels with the same infinitesimal volume, $\delta V = \delta x\, \delta y\, \delta z = \delta x\, \delta y\, \hbar\, \delta\varrho$, and same potential density, ϱ. Lacking any other marker, such as a tracer concentration, the ensemble members are distinguished from one another by values of their horizontal area, $\delta A = \delta x\, \delta y$, and their specific thickness, $\hbar$, that is, their geometric attributes. The ensemble members are assumed to be stirred by different stochastic realizations of the fluid flow. Since each flow realization alters the geometric properties of the parcels, a mean field description focuses on the mean of these geometric properties.

In isopycnal coordinates, (x, y, ϱ, t), the thickness equation (70.108) is satisfied by each ensemble member

$$\partial_t \hbar + \nabla_{\!\varrho} \cdot (\hbar\, \boldsymbol{u}) = 0. \tag{70.112}$$

The ensemble mean computed over these fluid parcels, each with potential density ϱ, satisfies

$$\partial_t\, \overline{\hbar}^{(\varrho)} + \nabla_{\!\varrho} \cdot \left(\overline{\hbar}^{(\varrho)}\, \overline{\boldsymbol{u}}^{(\varrho)} + \overline{\hbar'\, \boldsymbol{u}'}^{(\varrho)} \right) = 0, \tag{70.113}$$

where primed variables represent deviations from the isopycnal mean. It follows that the mean specific thickness, $\overline{\hbar}^{(\varrho)}$, of parcels with potential density, ϱ, satisfies the conservation equation

$$\partial_t\, \overline{\hbar}^{(\varrho)} + \nabla_{\!\varrho} \cdot (\overline{\hbar}^{(\varrho)}\, \widehat{\boldsymbol{u}}) = 0. \tag{70.114}$$

In this equation we introduced the thickness weighted isopycnal ensemble mean horizontal velocity

$$\widehat{\boldsymbol{u}} = \frac{\overline{\hbar\, \boldsymbol{u}}^{(\varrho)}}{\overline{\hbar}^{(\varrho)}} = \overline{\boldsymbol{u}}^{(\varrho)} + \frac{\overline{\hbar'\, \boldsymbol{u}'}^{(\varrho)}}{\overline{\hbar}^{(\varrho)}} \equiv \overline{\boldsymbol{u}}^{(\varrho)} + \boldsymbol{u}^{\text{bolus}}, \tag{70.115}$$

along with the isopycnal ensemble mean horizontal velocity, $\overline{\boldsymbol{u}}^{(\varrho)}$, and the horizontal *bolus velocity*, $\boldsymbol{u}^{\text{bolus}}$, originally introduced by *Rhines* (1982). The bolus velocity for an isopycnal layer corresponds to the transport

$$\overline{\hbar}^{(\varrho)}\, \boldsymbol{u}^{\text{bolus}} = \overline{\hbar}^{(\varrho)}\, (\widehat{\boldsymbol{u}} - \overline{\boldsymbol{u}}^{(\varrho)}) = \overline{\hbar'\, \boldsymbol{u}'}^{(\varrho)}, \tag{70.116}$$

which arises from the along-isopycnal correlations between specific thickness and horizontal velocity.

Quite conveniently, the mean conservation equation (70.114) takes the *same* mathematical form as the conservation equation (70.112) satisfied by each ensemble member. The key difference is that the isopycnal ensemble mean thickness, $\overline{\hbar}^{(\varrho)}$, is stirred by the thickness weighted isopycnal

ensemble mean horizontal velocity, $\widehat{\boldsymbol{u}}$, whereas the thickness of each ensemble member is stirred by a randomly different realization of the horizontal velocity, $\boldsymbol{u}$. The simplicity of the mean field description (70.114) is afforded by use of the Lagrangian vertical coordinate, ϱ.

70.4.6 Ensemble mean kinematics in geopotential coordinates

Now consider a geopotential coordinate description of the isopycnal ensemble. For this purpose, we interpret a vertical position, z, as the ensemble mean vertical position, $\overline{z}^{(\varrho)}$. Consequently, mean fields defined at the fixed vertical position correspond to either modified mean fields when not thickness weighted (equation (70.90)), or TRM fields when thickness weighted (equation (70.95)).

Evolution of modified mean density

Following the skewsion formulation from Section 69.5, at the ensemble mean vertical position, $z = \overline{z}^{\rho}$, the streamfunction $\overline{\boldsymbol{\Psi}}^{\#}$ defines an effective skew flux of the modified mean potential density given by

$$\overline{\boldsymbol{F}}^{\#} = -\nabla\widetilde{\varrho} \times \overline{\boldsymbol{\Psi}}^{\#}. \tag{70.117}$$

Using the identity $\overline{\boldsymbol{\Psi}}^{\#} = \overline{\boldsymbol{U}}^{\#} \times \hat{\boldsymbol{z}}$, we can write this skew flux as

$$\overline{\boldsymbol{F}}^{\#} = -\overline{\boldsymbol{U}}^{\#}\, \partial_z \widetilde{\varrho} + \hat{\boldsymbol{z}}\, \overline{\boldsymbol{U}}^{\#} \cdot \nabla_{\mathrm{h}} \widetilde{\varrho} \tag{70.118a}$$

$$= -(\overline{\boldsymbol{U}}^{\#} + \hat{\boldsymbol{z}}\, \boldsymbol{S} \cdot \overline{\boldsymbol{U}}^{\#})\, \partial_z \widetilde{\varrho}, \tag{70.118b}$$

where

$$\boldsymbol{S} = -\frac{\nabla_{\mathrm{h}} \widetilde{\varrho}}{\partial_z \widetilde{\varrho}} \tag{70.119}$$

is the slope of the modified mean density field originally introduced via equation (70.110), and $\nabla_{\mathrm{h}} = (\partial_x, \partial_y, 0)$ is the horizontal gradient operator taken with constant geopotential, $z = \overline{z}^{(\varrho)}$. The convergence of the effective skew flux leads to a stirring of the modified mean density $\widetilde{\varrho}$ at the mean vertical position, $z = \overline{z}^{(\varrho)}$,

$$\partial_t \widetilde{\varrho} = \nabla \cdot (\nabla\widetilde{\varrho} \times \overline{\boldsymbol{\Psi}}^{\#}). \tag{70.120}$$

This equation represents a geopotential coordinate specification of the evolution of the modified mean density due to stirring by the mean eddies. It corresponds directly to the evolution equation (70.111) satisfied at vertical position, z, by a single member of the ensemble.

70.4.7 Approximate ensemble mean kinematics in geopotential coordinates

Equation (70.120) represents an exact z-coordinate description of the stirring of modified mean potential density. However, when working in geopotential coordinates, all that is available is Eulerian information. Hence, the Lagrangian information used to realize this exact description must be approximated.

Estimating the quasi-Stokes transport

The approximation requires an estimate of the quasi-Stokes transport, $\overline{\boldsymbol{U}}^{\mathrm{qs}}$, defined by equation (70.102). We addressed a similar estimation in Section 70.2.4 when discussing the Stokes mean.

Here, we expand the TRM transport in a Taylor series about the vertical position, $z = \overline{z}^{(\varrho)}$

$$\overline{\boldsymbol{U}}^{\#}(z) = \overline{\int_{-H}^{z+\xi} \boldsymbol{u}(s)\, \mathrm{d}s} \tag{70.121a}$$

$$= \overline{\boldsymbol{U}}(z) + \overline{\boldsymbol{u}\,\xi}^{(z)} + \frac{1}{2}\,\overline{\partial_z \boldsymbol{u}\,\xi\,\xi}^{(z)} + \mathcal{O}(\alpha^3), \tag{70.121b}$$

where neglected terms are third order in deviation quantities. Note that all ensemble means are taken at fixed vertical position, which accords with taking a Taylor series about the ensemble mean vertical position, $z = \overline{z}^{(\varrho)}$.

The ensemble means in equation (70.121b) are interpreted as follows. The first term is the Eulerian mean horizontal transport passing beneath the ensemble mean vertical position, $z = \overline{z}^{(\varrho)}$. The second term, $\overline{\boldsymbol{u}\,\xi}$, is the horizontal velocity evaluated at the ensemble mean vertical position and multiplied by the deviation, ξ, of the potential density surface from its mean vertical position, all averaged at fixed vertical position. An Eulerian split of the horizontal velocity, $\boldsymbol{u}$, into its Eulerian mean, $\overline{\boldsymbol{u}}^{(z)}$, and deviation, $\boldsymbol{u}'$, leads to the correlation

$$\overline{\boldsymbol{u}\,\xi}^{(z)} = \overline{\boldsymbol{u}'\,\xi}^{(z)}. \tag{70.122}$$

For the second order term, similar considerations lead to

$$\overline{\partial_z \boldsymbol{u}\,\xi\,\xi}^{(z)} \approx \partial_z \overline{\boldsymbol{u}}^{(z)}\, \overline{\xi\,\xi}^{(z)}, \tag{70.123}$$

where neglected terms are third order and higher. Combining these relations leads to the second order accurate expression

$$\overline{\boldsymbol{U}}^{\#} \approx \overline{\boldsymbol{U}} + \overline{\boldsymbol{u}'\,\xi}^{(z)} + \frac{1}{2}\,\overline{\xi\,\xi}^{(z)}\, \partial_z \overline{\boldsymbol{u}}^{(z)}. \tag{70.124}$$

The disturbance field

Following the discussion in Section 70.2.6, we here determine the disturbance field, ξ, in terms of fields at constant vertical position. For this purpose, use the identity (70.91) to give

$$\widetilde{\varrho}(z) = \varrho(z+\xi) \tag{70.125a}$$

$$= \varrho(z) + \partial_z \varrho(z)\, \xi + \frac{1}{2}\, \partial_{zz} \varrho(z)\, \xi^2 + \mathcal{O}(\alpha^3). \tag{70.125b}$$

Subtracting the Eulerian mean of equation (70.125b) from the unaveraged equation (70.125b), and noting that $\widetilde{\varrho}$ is already a mean field, leads to the second order accurate expression for the deviation

$$\xi = -\varrho'(z)/\partial_z \overline{\varrho}^{(z)} + \mathcal{O}(\alpha^2), \tag{70.126}$$

where

$$\varrho(z) = \overline{\varrho}^{(z)} + \varrho'(z). \tag{70.127}$$

To within the same order, the deviation can be written

$$\xi = -\varrho'(z)/\partial_z \widetilde{\varrho}(z) + \mathcal{O}(\alpha^2). \tag{70.128}$$

Approximate quasi-Stokes transport

Substituting the deviation (70.128) into the approximate expression (70.121b) for the TRM transport yields an approximate expression for the quasi-Stokes transport

$$\overline{\boldsymbol{U}}^{\text{qs}} = -\frac{\overline{\boldsymbol{u}'\,\varrho'}^{(z)}}{\partial_z \widetilde{\varrho}} + \frac{\overline{\phi}^{(z)}\,\partial_z \overline{\boldsymbol{u}}^{(z)}}{(\partial_z \widetilde{\varrho})^2} + \mathcal{O}(\alpha^3), \tag{70.129}$$

where

$$\overline{\phi}^{(z)} = \frac{1}{2}\,\overline{\varrho'\,\varrho'}^{(z)} \tag{70.130}$$

is the mean potential density variance. *McDougall and McIntosh* (2001) noted that the *Gent et al.* (1995) scheme offers a parameterization of the two correlations on the right hand side of equation (70.129). We have more to say regarding this parameterization in Section 71.1.

Substituting the deviation (70.128) into the approximate expression (70.125b) yields, to within terms of third order, the relation

$$\widetilde{\varrho} = \overline{\varrho}^{(z)} - \partial_z \left[\frac{\overline{\phi}^{(z)}}{\partial_z \overline{\varrho}^{(z)}} \right] + \mathcal{O}(\alpha^3). \tag{70.131}$$

As for the Stokes transport, the modified mean density and Eulerian mean density, when evaluated at the same vertical position, differ by terms that are second order in eddy amplitude.

70.4.8 Further study

This section is largely based on approaches used by *DeSzoeke and Bennett* (1993), *McIntosh and McDougall* (1996), *Kushner and Held* (1999), and *McDougall and McIntosh* (2001) as summarized in Section 9.3 of *Griffies* (2004). Many other papers have applied this formalism to a variety of analyses, with examples including *Nurser and Lee* (2004a), *Nurser and Lee* (2004b), *Young* (2012), *Wolfe* (2014), and *Jansen et al.* (2024).

70.5 Mean tracer equation

We now include a tracer field to the ideal Boussinesq fluid element and determine a mean field description for the tracer. The transport of tracer by eddies has both a reversible stirring component and an irreversible mixing component. The stirring arises from both the thickness correlation to velocity as well as the velocity correlated with tracer.

70.5.1 Thickness weighted average[8]

In equation (70.115) we introduced a specific thickness weighted average (or mean) operator, which is quite useful when considering the mean tracer equation. In general, for any field, Ψ, associated with a potential density layer, ϱ, we define the decomposition into thickness weighted average and deviation

$$\Psi(\varrho) = \widehat{\Psi}(\varrho) + \Psi''(\varrho) \tag{70.132a}$$

$$= \frac{\overline{h\,\Psi}^{(\varrho)}}{\overline{h}^{(\varrho)}} + \Psi''. \tag{70.132b}$$

[8]We also considered thickness weighted averaging for the shallow water equations in Chapter 67. The same identities hold here for the continuously stratified fluid.

It follows by definition that the thickness weighted average of Ψ'' vanishes,

$$\overline{\hbar\, \Psi''}^{(\varrho)} = 0. \tag{70.133}$$

70.5.2 Isopycnal mean thickness weighted tracer equation

When attaching a tracer to fluid elements, each member of the ensemble satisfies the isopycnal tracer equation

$$\partial_t C + \boldsymbol{u} \cdot \nabla_{\!\varrho} C = 0. \tag{70.134}$$

Combining the tracer and thickness equations leads to the thickness weighted tracer equation

$$\partial_t(\hbar\, C) + \nabla_{\!\varrho} \cdot (\hbar\, \boldsymbol{u}\, C) = 0. \tag{70.135}$$

Hence, in isopycnal coordinates and in the absence of irreversible processes, the evolution of thickness weighted tracer occurs via the isopycnally oriented convergence of the two-dimensional thickness weighted horizontal advective flux, $\hbar\, \boldsymbol{u}\, C$.

To address the problem of describing the ensemble mean tracer equation in isopycnal coordinates, decompose the tracer and velocity field into their thickness weighted average and deviation

$$\partial_t[\hbar\, (\widehat{C} + C'')] + \nabla_{\!\varrho} \cdot [\hbar\, (\widehat{\boldsymbol{u}} + \boldsymbol{u}'')\, (\widehat{C} + C'')] = 0. \tag{70.136}$$

Taking an ensemble average over fluid elements with the same potential density, and using equation (70.133), yield the mean thickness weighted tracer equation

$$\partial_t(\overline{h}^{(\varrho)}\, \widehat{C}) + \nabla_{\!\varrho} \cdot (\overline{h}^{(\varrho)}\, \widehat{C}\, \widehat{\boldsymbol{u}}) = -\nabla_{\!\varrho} \cdot (\overline{h\, C''\, \boldsymbol{u}''}^{(\varrho)}). \tag{70.137}$$

Now introduce the correlation,

$$\overline{\hbar\, C''\, \boldsymbol{u}''}^{(\varrho)} = \overline{\hbar}^{(\varrho)}\, \widehat{C''\, \boldsymbol{u}''}, \tag{70.138}$$

(see equation (70.132b)), and recall that the mean thickness $\overline{\hbar}^{(\varrho)}$ satisfies the mean thickness equation (70.114). These two points lead to the evolution equation for the mean thickness weighted tracer concentration

$$(\partial_t + \widehat{\boldsymbol{u}} \cdot \nabla_{\!\varrho})\, \widehat{C} = -\frac{1}{\overline{\hbar}^{(\varrho)}}\, \nabla_{\!\varrho} \cdot (\overline{\hbar}^{(\varrho)}\, \widehat{C''\, \boldsymbol{u}''}). \tag{70.139}$$

70.5.3 Subgrid scale tracer transport tensor

The correlation between tracer and velocity found on the right-hand side of the mean thickness weighted tracer equation (70.139) is typically written in terms of a subgrid scale tracer transport tensor

$$\widehat{C''\, \boldsymbol{u}''} = -\mathbb{J} \cdot \nabla_{\!\varrho} \widehat{C}. \tag{70.140}$$

This definition leads to the evolution equation

$$(\partial_t + \widehat{\boldsymbol{u}} \cdot \nabla_{\!\varrho})\, \widehat{C} = \frac{1}{\overline{h}^{(\varrho)}}\, \nabla_{\!\varrho} \cdot (\overline{h}^{(\varrho)}\, \mathbb{J} \cdot \nabla_{\!\varrho} \widehat{C}). \tag{70.141}$$

The subgrid scale operator on the right hand side has the same general form as the diffusion operator written in isopycnal coordinates as derived in Section 63.15. However, in addition to symmetric diffusion processes, this operator includes skewed fluxes that lead to skew diffusion as discussed in Section 70.3.2. Whereas the diffusive aspect is commonly parameterized as dianeutral diffusion and neutral diffusion (Section 71.1), there is no parameterization for the

skewed correlations for use in ocean models. We comment further on this situation in Section 71.3.9.

70.5.4 Mean tracer transport beneath a density surface

It is useful to further elucidate the relevance of mean thickness weighted fields. For this purpose, consider the mean horizontal tracer transport occurring beneath a particular potential density surface $\varrho = \widetilde{\varrho}$,

$$\overline{\boldsymbol{C}}^{\#}(\overline{z}^{(\varrho)}) = \overline{\int_{-H}^{\overline{z}^{\varrho}+\xi} C\,\boldsymbol{u}\,\mathrm{d}z}. \tag{70.142}$$

Setting tracer concentration to unity recovers the expression (70.99) for the TRM transport. Changing coordinates and making use of the subgrid scale tracer tensor renders

$$\begin{aligned}
\overline{\boldsymbol{C}}^{\#}(\overline{z}^{(\varrho)}) &= \int_{\varrho(-H)}^{\widetilde{\varrho}(\overline{z}^{(\varrho)})} \overline{C\,\boldsymbol{u}\,h}^{(\varrho)}\,\mathrm{d}\varrho && (70.143a)\\
&= \int_{\varrho(-H)}^{\widetilde{\varrho}(\overline{z}^{(\varrho)})} (\widehat{C}\,\widehat{\boldsymbol{u}} + \widehat{C''\,\boldsymbol{u}''})\,\overline{h}^{(\varrho)}\,\mathrm{d}\varrho && (70.143b)\\
&= \int_{\varrho(-H)}^{\widetilde{\varrho}(\overline{z}^{(\varrho)})} (\widehat{C}\,\widehat{\boldsymbol{u}} - \mathbb{J}\cdot\nabla_{\!\!\varrho}\widehat{C})\,\overline{h}^{(\varrho)}\,\mathrm{d}\varrho && (70.143c)\\
&= \int_{-H}^{\overline{z}^{(\varrho)}} (\widehat{C}\,\widehat{\boldsymbol{u}} - \mathbb{J}\cdot\nabla_{\!\!\varrho}\widehat{C})\,\mathrm{d}z. && (70.143d)
\end{aligned}$$

Hence, the mean thickness weighted fields naturally appear when considering such physically interesting quantities as the mean horizontal transport of a tracer beneath the modified mean potential density surface.

70.5.5 Summary of the tracer parameterization problem

Traditionally, the isopycnal parameterization problem for the evolution of the mean thickness weighted tracer requires a parameterization of the bolus velocity $\boldsymbol{u}^{\text{bolus}}$, which again is related to the thickness weighted horizontal velocity via

$$\widehat{\boldsymbol{u}}((\varrho)) = \frac{\overline{h\,\boldsymbol{u}}^{(\varrho)}}{\overline{h}^{(\varrho)}} = \overline{\boldsymbol{u}}^{(\varrho)} + \frac{\overline{h'\,\boldsymbol{u}'}^{(\varrho)}}{\overline{h}^{(\varrho)}} = \overline{\boldsymbol{u}}^{(\varrho)} + \boldsymbol{u}^{\text{bolus}}. \tag{70.144}$$

In addition to the bolus velocity, it is necessary to parameterize the subgrid scale tracer transport tensor

$$\widehat{C''\,\boldsymbol{u}''} = -\mathbb{J}\cdot\nabla_{\!\!\varrho}\widehat{C}, \tag{70.145}$$

which generally has symmetric (diffusive) and antisymmetric (stirring) components (Section 70.3).

For a geopotential coordinate description, equation (70.95) is used to relate thickness weighted mean fields, defined as a function of ϱ, and TRM fields, defined as a function of the mean vertical position of ϱ, to write for the tracer field

$$\widehat{C}(x, y, \widetilde{\varrho}, t) = \overline{C}^{\#}(x, y, \overline{z}^{(\varrho)}, t). \tag{70.146}$$

Equation (70.146), and the developed formalism, leads to the mean field tracer equation in geopotential coordinates

$$\partial_t \overline{C}^{\#} = \nabla\cdot(\nabla\overline{C}^{\#} \times \overline{\boldsymbol{\Psi}}^{\#}) + R(\overline{C}^{\#}), \tag{70.147}$$

where $R(\overline{C}^{\#})$ is the geopotential coordinate form of the mixing/stirring operator on the right-hand side of equation (70.141). Details for the transformation of the mixing/stirring opertor from isopycnal to geopotential coordinates are provided in Section 63.15.

70.5.6 Comments

Much in this section follows from *Smith* (1999), *McDougall and McIntosh* (2001), *Young* (2012), and *Jansen et al.* (2024), each of which focused on the hydrostatic primitive equations assuming a vertically stable buoyancy stratification. The paper by *Young* (2012) is the first to formulate the ensemble mean primitive equations (continuity, tracer, momentum, vorticity, and energy equations) in a form where only the thickness weighted (residual mean) velocity appears. Hence, the formulation of *Young* (2012) eliminates the need to parameterize the bolus velocity or the quasi-Stokes transport since neither appear as separately identified terms. The paper by *Jansen et al.* (2024) further pursues the ideas from *Young* (2012) within the context of generalized vertical coordinate ocean models (see Part XII of this book), and they identify some inconsistencies in how certain ocean models are implementing the eddy parameterizations. The topic of formulating the equations of motion remains an active topic of research for purposes of facilitating subgrid scale closure.

Chapter 71

ELEMENTS OF PARAMETERIZED OCEAN TRACER TRANSPORT

In the presence of turbulent flows, tracer variance directly cascades to the small scales. This *downscale cascade* is facilitated by reversible stirring from balanced and unbalanced fluctuations (e.g., mesoscale eddies, submesoscale eddies, breaking gravity and lee waves, turbulent boundary layer processes). The cascade to progressively smaller scales eventually reaches the *Batchelor scale* (order millimetres; e.g., Section 11.5.1 of *Vallis* (2017)). At this scale, tracer gradients are sufficiently large in magnitude that molecular diffusion can readily act to dissipate tracer variance through irreversible diffusive mixing. Tracer transport at scales larger than the Batchelor scale is dominated by nearly reversible stirring, whereas transport at and below the Batchelor scale is dominated by irreversible mixing from molecular diffusion. This phenomenology provides a constraint on the form of the tracer equation to be used for coarse grained numerical models, where the model grid scale is generally much larger than the Batchelor scale.

In this chapter, we study certain of the mathematical and physical properties of parameterized advective and diffusive tracer transport. In general, such parameterizations aim to encapsulate key aspects of physical processes too small to observe and/or to simulate. This *subgrid scale parameterization problem* is far broader and deeper than available from a single chapter. We focus mostly on subgrid scale tracer advection and diffusion operators arising from mesoscale eddy motions, yet even this limited focus involves far more than can be covered here. In particular, we do not discuss theories for how the eddy diffusivities are computed, which generally require studies of the momentum, energy, and vorticity budgets that are not considered here. Furthermore, we only consider parameterizations of the subgrid scale tracer flux, whose convergence provides a subgrid tendency for the coarse-grained tracer equation. Focusing on fluxes supports locality and conservation for the coarse-grained tracer equation, with these properties also shared by the uncoarsened tracer equation.

CHAPTER GUIDE

We studied the physics of tracer diffusion in Chapter 68 and then advection-diffusion in Chapter 69. We also studied the kinematics of tracer transport in Chapter 70. The present chapter relies on that material, with a focus on the maths and physics of advective-diffusive parameterizations of tracer transport. We also make use of neutral directions as detailed in Section 30.5. Mathematically, we rely on Cartesian tensor analysis from Chapters 1 and 2.

The reader is cautioned that the notation in this chapter is somewhat tedious, which arises from the many variants of tracer fluxes considered. Furthermore, there are a variety of unanswered questions about the suitability of certain parameterizations for ocean circulation models, particularly the anisotropic neutral diffusion discussed in Section 71.5 and the anisotropic Gent-McWilliams stirring in Section 71.6. These sections are written in the hope that they offer a framework for numerically implementing and testing these schemes in models.

71.1 Summarizing tracer transport parameterizations

In this section we offer an outline of the tracer transport parameterizations, starting from the small scales and moving to the mesoscale. We mostly focus on ocean applications, though similar arguments hold for the atmosphere as well.

71.1.1 A synopsis of ocean mixing processes

Irreversible mixing in the ocean takes place at the millimeter scale through the action of chaotic molecular motions that act to dissipate property gradients. This mixing is generally represented by downgradient molecular diffusion. The molecular diffusivity of matter (e.g., salt) in seawater is roughly 10^{-9} m^2 s^{-1}, whereas the molecular thermal diffusivity is roughly 100 times larger (it is easier to diffuse enthalpy (heat) than matter, *Gill*, 1982). Reversible stirring by turbulent eddies greatly increases the magnitude of property gradients upon which *molecular diffusion* acts (*Eckart*, 1948; *Nakamura*, 2001; *Müller and Garrett*, 2002), thereby increasing the total amount of irreversible mixing. Motivated by molecular diffusion and *Brownian motion* *Einstein* (1905), and following the pioneering work of *Taylor* (1921), it is common to parameterize mixing induced by turbulent eddy stirring as a diffusive closure with an eddy diffusivity that is far larger than molecular values. Furthermore, the eddy diffusivities are generally the same for all tracers since eddies generally act the same regardless the tracer. Double diffusive processes is the notable counter-example to this equivalence *Schmitt* (1994).

Mixing induced by eddies of length scale $\mathcal{O}(\text{centimeters} - \text{metres})$ is associated with *fine scale mixing* processes such as gravitational instability, shear instability and breaking internal gravity waves (*MacKinnon et al.*, 2013), as well as a suite of boundary layer processes (*Large et al.*, 1994). This mixing is commonly parameterized by a flow dependent isotropic eddy diffusivity. The magnitude of the eddy diffusivity is typically $\mathcal{O}(10^{-3} - 10^{-2}$ m^2 s$^{-1})$ in boundary layers, and $\mathcal{O}(10^{-5}$ m^2 s$^{-1})$ in the quiescent ocean interior (*Polzin et al.*, 1997; *Whalen et al.*, 2012; *Waterhouse et al.*, 2014).

Mesoscale eddies, with size $\mathcal{O}(10 - 100)$ km, preferentially stir tracers along neutral directions (*McDougall*, 1987a,b; *McDougall et al.*, 2014). The mesoscale eddy stirring in turn induces a mixing that is parametrized by downgradient diffusion along neutral directions (Section 71.4). When feeling the geometric constraints of the surface boundary, mesoscale stirring leads to horizontal oriented mixing across outcropped density surfaces (*Treguier et al.*, 1997; *Ferrari et al.*, 2008; *Danabasoglu et al.*, 2008). This mixing is parameterized by downgradient horizontal diffusion. The neutral and horizontal eddy diffusivities associated with mesoscale processes are typically $\mathcal{O}(10^2 - 10^3$ m^2 s$^{-1})$ in the ocean interior and can rise to $\mathcal{O}(10^4$ m^2 s$^{-1})$ in the ocean surface layer (*Abernathey et al.*, 2013; *Klocker and Abernathey*, 2014; *Cole et al.*, 2015).

71.1.2 A rough comparison

What process is more important for setting tracer distributions: neutral diffusion induced by mesoscale eddies or small scale isotropic diffusion induced by breaking gravity waves? Since the neutral diffusivity arises from mesoscale eddy stirring, it is many orders of magnitude larger than the isotropic diffusivity arising from fine scale mixing. However, these two eddy diffusivities act on very different tracer gradients, in which case the net effects on tracer distributions could be more comparable.

To help answer the question, consider a scaling with a constant neutral diffusivity and a constant isotropic diffusivity. Furthermore, assume Cartesian orientation of the diffusion operators (i.e., zero neutral slope) and assume the isotropic diffusion is dominated by vertical diffusion (see Section 71.2). We are thus comparing the following two diffusion processes

$$\text{horizontal diffusion} = \kappa_{\text{horz}} \nabla_h^2 C \quad \text{and} \quad \text{vertical diffusion} = \kappa_{\text{vert}} \, \partial_{zz} C. \tag{71.1}$$

Now introduce a vertical length scale, H, and horizontal scale, L, over which the tracer concentration changes by the same amount δC. Doing so leads to the scaled diffusion operators

$$\text{horizontal diffusion} \sim (\kappa_{\text{horz}}/L^2) \, \delta C \quad \text{and} \quad \text{vertical diffusion} \sim (\kappa_{\text{vert}}/H^2) \, \delta C. \tag{71.2}$$

These operators have the same scale when

$$\kappa_{\text{vert}} = (H/L)^2 \, \kappa_{\text{horz}}. \tag{71.3}$$

Choosing $L = 10^5$ m and $H = 10^1$ m leads to

$$\kappa_{\text{vert}} = 10^{-8} \, \kappa_{\text{horz}}. \tag{71.4}$$

Furthermore, if $\kappa_{\text{horz}} = 10^3$ m^2 s^{-1}, then the two operators provide a similar contribution to tracer evolution if $\kappa_{\text{vert}} = 10^{-5}$ m^2 s^{-1}. This is a rather small diffusivity that is generally thought to be on the order of that afforded by the background of breaking gravity waves in the ocean interior (*MacKinnon et al.*, 2013). This scaling is crude since the length scales are dependent on details of the flow regime, as are the eddy diffusivities. Even so, it suggests that the two diffusive processes can indeed contribute to tracer distributions by a similar amount.

71.1.3 Diffusive parameterization of fine scale mixing

Ignoring the cross-diffusion processes introduced in Section 26.10 (see also *IOC et al.* (2010), Section 2.5 of *Olbers et al.* (2012), and *Graham and McDougall* (2013)), the molecular diffusion of Θ and S lead to the material evolution equations

$$\rho \frac{\mathrm{D}\Theta}{\mathrm{D}t} = \nabla \cdot (\rho \, \kappa_\Theta \, \nabla \Theta) \tag{71.5a}$$

$$\rho \frac{\mathrm{D}S}{\mathrm{D}t} = \nabla \cdot (\rho \, \kappa_S \, \nabla S), \tag{71.5b}$$

where $\kappa_\Theta > 0$ and $\kappa_S > 0$ are the molecular kinematic diffusivities for Conservative Temperature, Θ, and salinity, S, respectively. For a measured scale, Δ, larger than the scale where gravity waves break and dissipate kinetic energy (i.e., tens to hundreds of metres), diffusion is commonly used to parameterize the associated irreversible tracer mixing (e.g., *MacKinnon et al.*, 2013). Diffusion is also used to parameterize mixing from other small scale processes, such as turbulent boundary layer processes, double-diffusion, and breaking leewaves. As discussed in Section 4 of *McDougall et al.* (2014), small scale mixing generally takes place in an isotropic manner. Its parameterization thus appears just as for isotropic molecular diffusion given by equation (71.5b), yet with a far larger eddy diffusivity $\kappa_{\text{fine}} \gg \kappa_\Theta, \kappa_S$ that is a function of the flow

$$\rho \frac{\mathrm{D}\Theta}{\mathrm{D}t} = \nabla \cdot (\rho \, \kappa_{\text{fine}} \, \nabla \Theta) \tag{71.6a}$$

$$\rho \frac{\mathrm{D}S}{\mathrm{D}t} = \nabla \cdot (\rho \, \kappa_{\text{fine}} \, \nabla S). \tag{71.6b}$$

The same eddy diffusivity is used for both Θ and S. This assumption follows the general approach for turbulent transport parameterizations (e.g, *Vallis*, 2017), whereby eddies are assumed to act in the same manner on any conserved scalar tracer.

71.1.4 Advective-diffusive parameterization of eddy-induced transport

Stirring from turbulent scales smaller than the grid scale is commonly parameterized by an eddy-induced stirring velocity, $\boldsymbol{v}^*$. For ocean mesoscale eddies, such parameterized stirring generally follows a variant of *Gent and McWilliams* (1990) and *Gent et al.* (1995), with this stirring quite important for setting large-scale ocean tracer distributions. In addition, mixing is promoted by the direct cascade from stirring. This mixing is parameterized by a diffusion operator distinct from that used for the small scale mixing discussed in Section 71.1.3.

Consider a second order subgrid scale eddy transport tensor, $\boldsymbol{E}$, meant to parameterize both subgrid scale eddy stirring and eddy mixing. With this tensor, the evolution of salinity and Conservative Temperature takes the form

$$\rho \frac{\mathrm{D}S}{\mathrm{D}t} = \nabla \cdot (\rho \boldsymbol{E} \cdot \nabla S) \tag{71.7a}$$

$$\rho \frac{\mathrm{D}\Theta}{\mathrm{D}t} = \nabla \cdot (\rho \boldsymbol{E} \cdot \nabla \Theta). \tag{71.7b}$$

As for the fine scale diffusion equations (71.6a) and (71.6b), we here use the same transport tensor for both S and Θ as eddies are assumed to act in the same manner on any conserved scalar tracer. As presented in Chapter 69, we decompose the second order transport tensor into the sum of its symmetric and anti-symmetric components

$$\boldsymbol{E} = \boldsymbol{K} + \boldsymbol{A}. \tag{71.8}$$

When the symmetric tensor, $\boldsymbol{K}$, is positive-definite, it gives rise to downgradient diffusion, whereas the anti-symmetric tensor, $\boldsymbol{A}$, gives rise to skew-diffusion or eddy-induced advection.

71.1.5 Mathematical elements of eddy-induced stirring

As detailed in Sections 69.3, 69.4, and 70.3, the anti-symmetric tensor, $\boldsymbol{A}$, contributes to the parameterized transport according to

$$\nabla \cdot (\rho \boldsymbol{A} \cdot \nabla S) = \partial_m (\rho A^{mn} \partial_n S) \tag{71.9a}$$

$$= \partial_m (\rho A^{mn}) \partial_n S + \rho A^{mn} \partial_m \partial_n S \tag{71.9b}$$

$$= -\rho v^{*n} \partial_n S, \tag{71.9c}$$

where A^{mn} are the components to the anti-symmetric transport tensor $\boldsymbol{A}$. Additionally, we noted that

$$\rho A^{mn} \partial_m \partial_n S = 0 \tag{71.10}$$

since A^{mn} is anti-symmetric on the indices m, n whereas $\partial_m \partial_n S$ is symmetric (see Exercise 1.2). Finally, we introduced a density-weighted *eddy-induced velocity*

$$\rho v^{*n} = -\partial_m (\rho A^{mn}) \Longleftrightarrow \rho \boldsymbol{v}^* = -\nabla \cdot (\rho \boldsymbol{A}). \tag{71.11}$$

Importantly, $\rho \boldsymbol{v}^*$ has a zero divergence, again due to anti-symmetry of A^{mn}

$$\nabla \cdot (\rho \boldsymbol{v}^*) = \partial_n (\rho v^{*n}) = -\partial_n \partial_m (\rho A^{mn}) = 0. \tag{71.12}$$

A zero-divergence for $\rho \boldsymbol{v}^*$ means that it contributes no mass sources or sinks to the fluid.[1]

Transport from the anti-symmetric tensor thus provides a means to stir tracers due to unresolved eddy processes. The mathematical form of the stirring can be either through skew-diffusion or through advection (see Section 69.4). Choosing to make use of the advection form allows us to combine the contribution from the anti-symmetric transport tensor with the resolved advection operator, thus resulting in a *residual mean* material transport equation

$$\rho \frac{\mathrm{D}^\dagger S}{\mathrm{D}t} = \nabla \cdot (\rho \boldsymbol{K} \cdot \nabla S) \tag{71.13a}$$

$$\rho \frac{\mathrm{D}^\dagger \Theta}{\mathrm{D}t} = \nabla \cdot (\rho \boldsymbol{K} \cdot \nabla \Theta), \tag{71.13b}$$

where the residual mean material time derivative is given by

$$\frac{\mathrm{D}^\dagger}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}^\dagger \cdot \nabla \tag{71.14}$$

and the *residual mean velocity* is

$$\boldsymbol{v}^\dagger = \boldsymbol{v} + \boldsymbol{v}^*. \tag{71.15}$$

71.1.6 Dianeutral unit vector and the neutral slope

When considering closures for subgrid mixing and stirring arising from mesoscale motions, we orient the parameterized processes according to buoyancy as that reflects the physics of mesoscale motions.[2] We thus follow the discussion in Section 30.5 by working with locally referenced Archimedean buoyancy to determine neutral directions. In particular, at each point in the fluid we orient stirring and mixing through use of the dianeutral unit vector (Section 30.5.3)

$$\hat{\boldsymbol{\gamma}} = \frac{-\alpha \nabla \Theta + \beta \nabla S}{|-\alpha \nabla \Theta + \beta \nabla S|} \quad \text{and} \quad \hat{\boldsymbol{\gamma}} = \hat{\boldsymbol{x}}\, \hat{\gamma}_x + \hat{\boldsymbol{y}}\, \hat{\gamma}_y + \hat{\boldsymbol{z}}\, \hat{\gamma}_z \quad \text{and} \quad \hat{\boldsymbol{\gamma}} \cdot \hat{\boldsymbol{\gamma}} = \hat{\gamma}_x^2 + \hat{\gamma}_y^2 + \hat{\gamma}_z^2 = 1, \tag{71.16}$$

with $\hat{\boldsymbol{\gamma}}$ pointing perpendicular to the neutral tangent plane in a direction towards larger density.[3] Furthermore, when the fluid is stably stratified in the vertical, which is common for the mesoscale and larger, then the squared buoyancy frequency is positive (Section 30.4)

$$N^2 = -g\,(-\alpha\, \partial_z \Theta + \beta\, \partial_z S) > 0. \tag{71.17}$$

We can thus introduce the slope of the neutral tangent plane relative to the (x, y) horizontal plane

$$\boldsymbol{S} = -\left[\frac{-\alpha\, \nabla_{\mathrm{h}} \Theta + \beta\, \nabla_{\mathrm{h}} S}{-\alpha\, \partial_z \Theta + \beta\, \partial_z S}\right] = \frac{g\,(-\alpha\, \nabla_{\mathrm{h}} \Theta + \beta\, \nabla_{\mathrm{h}} S)}{N^2} = \hat{\boldsymbol{x}}\, S_x + \hat{\boldsymbol{y}}\, S_y. \tag{71.18}$$

For such stably stratified fluids, the dianeutral direction can be written in terms of the neutral slope

$$\hat{\boldsymbol{\gamma}} = \frac{\boldsymbol{S} - \hat{\boldsymbol{z}}}{(1 + \boldsymbol{S}^2)^{1/2}}. \tag{71.19}$$

[1] For a Boussinesq fluid, the density factor is replaced by the constant reference density, ρ_o, so that $\nabla \cdot \boldsymbol{v}^* = 0$ in the Boussinesq fluid. See section 7 of *Griffies and Greatbatch* (2012) for more details of the Boussinesq and non-Boussinesq forms for the parameterized eddy-induced transport.

[2] We offer further discussion of this point at the start of Section 71.4.

[3] Equation (4) in *McDougall et al.* (2014) makes use of the opposite convention so that their dianeutral direction points towards decreasing density. We instead follow the water mass transformation convention as in equation (73.38), so that $\hat{\boldsymbol{\gamma}}$ points in the direction of increasing density.

In this form we see that the dianeutral direction is vertically downward when the slopes vanish (i.e., horizontal neutral directions), which accords with this direction generally pointing toward increasing density.

71.2 Expressions of small scale diffusion

We here follow Section 4 from *McDougall et al.* (2014) to highlight distinctions between isotropic diffusion, dianeutral diffusion,[4] and vertical diffusion. Although commonly considered interchangeable in the literature as parameterizations of small scale mixing, there are conceptual distinctions that we identify here. Note that the distinctions between these three diffusions are quantitatively small when neutral slopes are modest and when $\kappa_{\text{ntr}} \gg \kappa_{\text{fine}}$.

71.2.1 Isotropic diffusion

As discussed in Section 71.1.3, we generally parameterize fine scale mixing processes via an isotropic diffusion process using a diffusivity $\kappa_{\text{fine}} > 0$, diffusion tensor

$$\boldsymbol{K}^{\text{iso}} = \kappa_{\text{fine}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \tag{71.20}$$

and corresponding diffusion flux

$$\boldsymbol{J}^{\text{iso}} = -\rho\, \boldsymbol{K}^{\text{iso}} \cdot \nabla C. \tag{71.21}$$

As illustrated in Figure 71.1, under the effects from isotropic diffusion, a region of tracer is diffused the same in all three directions so that, for example, a spherical tracer distribution remains spherical.

71.2.2 Vertical diffusion

Because vertical density gradients are generally much larger than lateral gradients, it is common to approximate the small scale isotropic diffusion tensor with a vertical diffusion tensor

$$\boldsymbol{K}^{\text{vert}} = \kappa_{\text{fine}} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \tag{71.22}$$

with a corresponding vertical diffusive flux

$$\boldsymbol{J}^{\text{vert}} = -\rho\, \kappa_{\text{fine}}\, (\nabla C \cdot \hat{\boldsymbol{z}})\, \hat{\boldsymbol{z}} = -\rho\, \boldsymbol{K}^{\text{iso}} \cdot \nabla C = -\rho\, \kappa_{\text{fine}}\, \partial_z C\, \hat{\boldsymbol{z}}. \tag{71.23}$$

In this manner, vertical mixing of a tracer patch occurs only in the vertical direction (see Figure 71.1).

71.2.3 Dianeutral diffusion

Dianeutral diffusion orients tracer fluxes according to the dianeutral direction (71.16)

$$\boldsymbol{J}^{\text{dia}} = -\rho\, \kappa_{\text{fine}}\, (\nabla C \cdot \hat{\boldsymbol{\gamma}})\, \hat{\boldsymbol{\gamma}} = -\rho\, \boldsymbol{K}^{\text{dia}} \cdot \nabla C, \tag{71.24}$$

[4] Dianeutral diffusion is commonly also referred to as *diapycnal diffusion*, with diapycnal diffusion referring to diffusion across constant potential density surfaces. We distinguish dianeutral from diapycnal in this chapter since neutral directions are defined by locally referenced potential density, and as such neutral directions generally differ from isopycnals. Further discussion is provided in Section 30.5 as well as *McDougall* (1987a).

where the dianeutral diffusion tensor is given by

$$\boldsymbol{K}^{\text{dia}} = \kappa_{\text{fine}} \begin{bmatrix} \hat{\gamma}_x^2 & \hat{\gamma}_x \hat{\gamma}_y & \hat{\gamma}_x \hat{\gamma}_z \\ \hat{\gamma}_x \hat{\gamma}_y & \hat{\gamma}_y^2 & \hat{\gamma}_y \hat{\gamma}_z \\ \hat{\gamma}_x \hat{\gamma}_z & \hat{\gamma}_y \hat{\gamma}_z & \hat{\gamma}_z^2 \end{bmatrix} . \tag{71.25}$$

Assuming a vertically stable stratification, we can make use of the relation (71.19) to write $\hat{\boldsymbol{\gamma}}$ in terms of the slope, $\boldsymbol{S}$, thus rendering

$$(\nabla C \cdot \hat{\boldsymbol{\gamma}})\, \hat{\boldsymbol{\gamma}} = \frac{(\boldsymbol{S} - \hat{\boldsymbol{z}}) \cdot \nabla C}{1 + \boldsymbol{S}^2} (\boldsymbol{S} - \hat{\boldsymbol{z}}) = \frac{1}{1 + \boldsymbol{S}^2} \begin{bmatrix} S_x^2 & S_x S_y & -S_x \\ S_x S_y & S_y^2 & -S_y \\ -S_x & -S_y & 1 \end{bmatrix} \begin{bmatrix} \partial_x C \\ \partial_y C \\ \partial_z C \end{bmatrix} , \tag{71.26}$$

so that the dianeutral diffusion tensor now takes on the form

$$\boldsymbol{K}^{\text{dia}} = \frac{\kappa_{\text{fine}}}{1 + \boldsymbol{S}^2} \begin{bmatrix} S_x^2 & S_x S_y & -S_x \\ S_x S_y & S_y^2 & -S_y \\ -S_x & -S_y & 1 \end{bmatrix} . \tag{71.27}$$

As illustrated in Figure 71.1, dianeutral diffusion elongates a tracer patch in the direction normal to the neutral tangent plane.

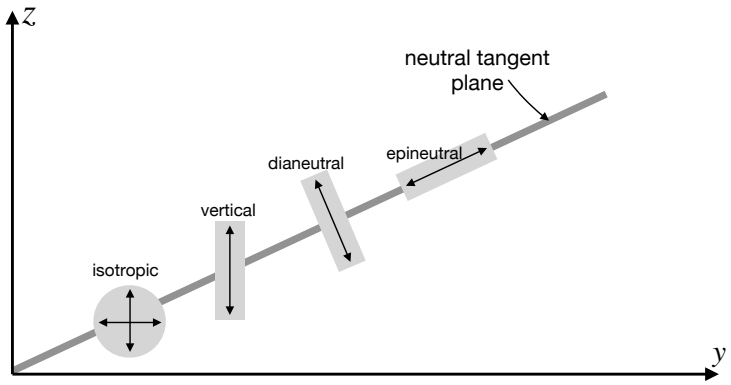

FIGURE 71.1: Illustrating the effects from various forms of diffusion on a tracer patch. When diffused with an isotropic diffusion tensor (equation (71.20)), a spherical patch remains spherical. When diffused with a vertical diffusion tensor (equation (71.22)), a tracer patch elongates in the vertical direction. When diffused with a dianeutral diffusion tensor (equation (71.27)), a tracer patch elongates in the direction normal to the slanted neutral tangent plane. Finally, when diffused with a neutral diffusion tensor, such as the Redi tensor (71.74) or the small slope tensor (71.75), a tracer patch elongates along the neutral tangent plane; i.e., in the *epineutral* direction. This figure is adapted from Figure 4 of *McDougall et al.* (2014).

71.3 Gent-McWilliams eddy-induced advection

As mentioned in Section 70.5.3, there are two processes that contribute to eddy-induced advection/stirring. One involves the correlations between eddy fluctuations in the velocity and tracer fields. In Section 70.3, we considered the kinematics of correlations induced by small amplitude eddying motions, where we found that the eddy-induced motion of fluid particles leads to both a symmetric (mixing) and anti-symmetric (stirring) dispersion of tracer concentrations. There is currently no method proposed for parameterizing this form of eddy-induced stirring when it arises from subgrid scale processes, thus leaving unanswered its importance to large-scale tracer distributions.

The second process leading to eddy-induced stirring arises from correlations between fluctuations in isopycnal layer thickness and horizontal velocity. As detailed in Section 70.4, this

second effect leads to a movement of volume between isopycnal layers, or equivalently we can conceive of it as the quasi-Stokes transport of volume arising from transient eddy motion. This eddy-induced volume transport affects an eddy-induced tracer transport within isopycnal layers. Transient mesoscale eddies are the canonical dynanical process leading to this form of transport. For simulations that do not resolve transient mesoscale eddies, we commonly parameterize the subgrid scale stirring through variants of the *Gent et al.* (1995) scheme. Mathematical elements of this scheme are detailed in this section.

Most presentations of the *Gent et al.* (1995) scheme assume a Boussinesq fluid, though with Section 7 of *Griffies and Greatbatch* (2012) an exception. We here present the non-Boussinesq form, though in places make the Boussinesq approximation since doing so simplifies the presentation without losing anything fundamental.[5]

71.3.1 Details of the parameterization

Gent et al. (1995) parameterize the three-dimensional non-divergent eddy-induced mass flux (recall Section 69.4.3) according to

$$\rho \boldsymbol{v}^* = \nabla \times (\rho \boldsymbol{\Psi}^*) \quad \text{with} \quad \boldsymbol{\Psi}^* = \hat{\boldsymbol{z}} \times \kappa_{\text{gm}} \boldsymbol{S}, \tag{71.28}$$

where $\boldsymbol{S}$ is the neutral slope given by equation (71.18), and $\kappa_{\text{gm}} > 0$ is a kinematic eddy diffusivity with dimensions of velocity times a length. Performing the curl on the streamfunction leads to the horizontal and vertical components to the eddy-induced mass flux

$$\rho \boldsymbol{u}^* = -\partial_z (\kappa_{\text{gm}} \rho \boldsymbol{S}) \quad \text{and} \quad \rho w^* = \nabla_{\text{h}} \cdot (\kappa_{\text{gm}} \rho \boldsymbol{S}), \tag{71.29}$$

along with the skew diffusive tensor

$$A^{\text{gm}} = \kappa_{\text{gm}} \begin{bmatrix} 0 & 0 & -S_x \\ 0 & 0 & -S_y \\ S_x & S_y & 0 \end{bmatrix}. \tag{71.30}$$

Following the discussion in Section 69.4.4, we can identify the advective tracer flux, skew tracer flux, and rotational tracer flux corresponding to the Gent-McWilliams parameterization

$$\boldsymbol{J}^{\text{adv}} = \boldsymbol{J}^{\text{skew}} + \boldsymbol{J}^{\text{rot}} \tag{71.31}$$

where

$$\boldsymbol{J}^{\text{adv}} = C \rho \boldsymbol{v}^* = C \rho [-\partial_z (\kappa_{\text{gm}} \rho \boldsymbol{S}) + \hat{\boldsymbol{z}} \nabla_{\text{h}} \cdot (\kappa_{\text{gm}} \rho \boldsymbol{S})] \tag{71.32a}$$

$$\boldsymbol{J}^{\text{skew}} = -\nabla C \times \rho \boldsymbol{\Psi}^* = \rho \kappa_{\text{gm}} [\boldsymbol{S} \partial_z C - \hat{\boldsymbol{z}} (\boldsymbol{S} \cdot \nabla C)] \tag{71.32b}$$

$$\boldsymbol{J}^{\text{rot}} = \nabla \times (\rho C \boldsymbol{\Psi}^*). \tag{71.32c}$$

71.3.2 Effects on buoyancy

We now consider a Boussinesq fluid with a linear equation of state in order to focus on the impact of the Gent-McWilliams parameterization on buoyancy, which we measure with potential density, ϱ. In this case the parameterized skew flux of potential density due to the quasi-Stokes transport is given by

$$\rho_{\text{o}}^{-1} \boldsymbol{J}^{\text{skew}} = -\kappa_{\text{gm}} [\nabla_{\text{h}} \varrho - \hat{\boldsymbol{z}} \boldsymbol{S}^2 \partial_z \varrho] = -\kappa_{\text{gm}} [\nabla_{\text{h}} \varrho + \hat{\boldsymbol{z}} (\rho_{\text{o}}/g) (\boldsymbol{S} N)^2], \tag{71.33}$$

[5] In brief, for a Boussinesq fluid, the *in situ* density factor found throughout this section is set to the constant Boussinesq reference density, ρ_{o}.

with the squared neutral slope and squared buoyancy frequency written

$$\boldsymbol{S}^2 = \boldsymbol{S} \cdot \boldsymbol{S} \quad \text{and} \quad N^2 = -\frac{g}{\rho_o} \frac{\partial \varrho}{\partial z}. \tag{71.34}$$

The parameterization yields a horizontal downgradient diffusive flux of potential density along with a vertical upgradient diffusive flux. As illustrated by Figure 71.2, so long as the stratification is stable ($N^2 > 0$), which is assumed by the parameterization, the vertical component to the potential density skew flux is vertically downward, which corresponds to a vertically upward buoyancy skew flux. As we see in Section 71.3.3, this orientation ensures that the parameterization reduces available potential energy. Additionally, *Gent et al.* (1995) prescribe a diffusivity that vanishes at the ocean surface and ocean bottom. *McIntosh and McDougall* (1996) and *McDougall and McIntosh* (2001) present more discussion of the boundary conditions, which can be understood by considering the exact form of the quasi-Stokes transport defined by equation (70.102). Furthermore, we consider a boundary value problem approach in Section 71.3.8 that also pays particular attention to the boundary conditions.

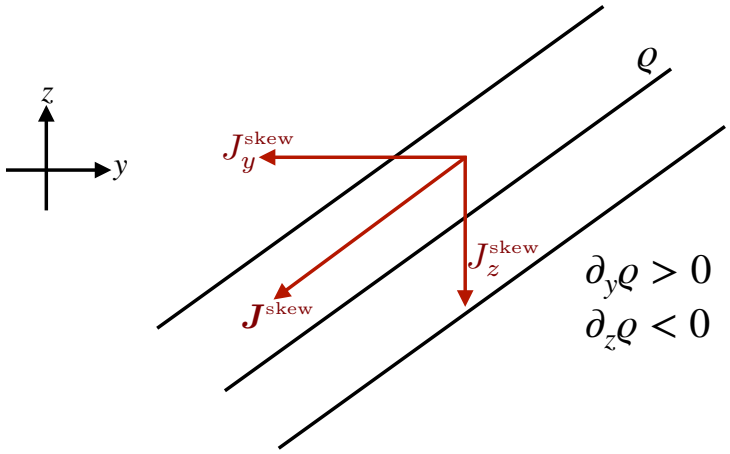

FIGURE 71.2: Orientation of the skew flux of potential density, ϱ, arising from the *Gent et al.* (1995) parameterization and as described by *Griffies* (1998). The sloped black lines are constant ϱ isosurfaces (isopycnals). The horizontal skew flux of potential density is downgradient (directed from high density to low density), whereas the vertical skew flux component is upgradient (directed from low density to high density). The net effect is a skew flux that is oriented parallel to isopycnals.

Figure 71.3 brings elements of the parameterization together by illustrating the *Gent-McWilliams effect* for a meridional potential density front in the southern hemisphere. The mean geostrophic thermal wind flow is eastward, as in the Antarctic Circumpolar Current, whereas a parameterized *secondary circulation* acts to weaken the front, with the secondary circulation proportional to the strength of the front as measured by the isopycnal slope. That is, the parameterization assumes that the mean effects from geostrophic eddies, whose kinetic energy is supported by the potential energy in the front, lead to a weakening of the potential density slope so that the front relaxes toward the horizontal.

71.3.3 Local adiabatic dissipation of available potential energy

We here consider the effects from the *Gent et al.* (1995) scheme on the available potential energy, continuing to assume a Boussinesq fluid with a linear equation of state. We express the behavior using both skew fluxes and advective fluxes. Since we are assuming the parameterization is adiabatic, the change in potential energy is identical to the change in available potential energy.

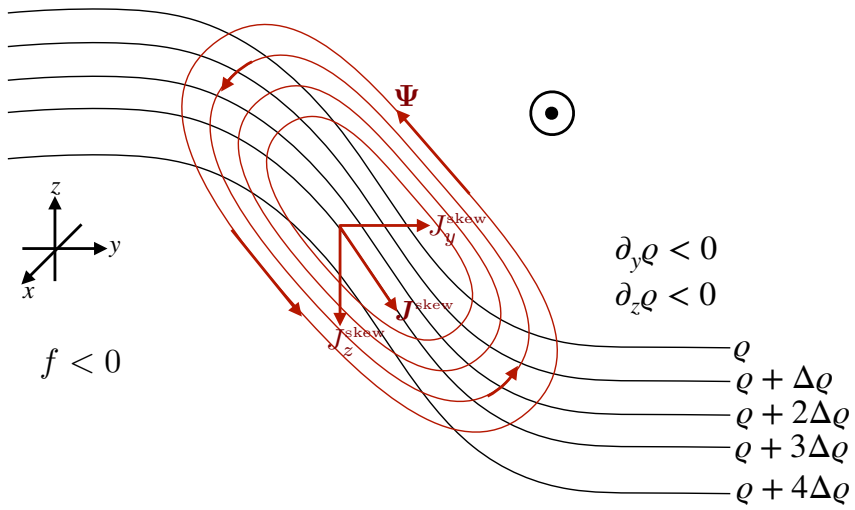

FIGURE 71.3: The Gent-McWilliams effect for a meridional potential density front in the Southern Hemisphere, where dense water rises to the south so that $\partial_y \varrho < 0$. The mean geostrophic thermal wind flow is eastward (out of the page), as in the Antarctic Circumpolar Current. With a stable stratification, whereby $\partial_z \varrho < 0$, the Gent-McWilliams streamfuction given by equation (71.28) leads to a counter-clockwise circulation (red isolines). The dual perspective offered by the Gent-McWilliams skew flux for potential density, given by equation (71.33), reveals a northward (downgradient) meridional skew flux component along with a downward (upgradient) vertical component (red vectors). The result from either the streamfunction perspective or the skew flux perspective is a potential density tendency that relaxes the front towards the horizontal so to reduce the isopycnal slope.

Skew flux approach

Let us approach the parameterization problem from the perspective of satisfying two general properties: (I) the subgrid scale operator adiabatically stirs while maintaining the same amount of fluid within isopycnal layers, (II) the subgrid operator locally dissipates potential energy through an abiabatic rearrangement of the potential density surfaces, with the dissipation vanishing when there is zero baroclinicity. That is, the scheme dissipates available potential energy. What is the form of the stirring operator implied by these two assumptions?

Adiabatic stirring of potential density can be realized via the convergence of a skew flux oriented parallel to potential density surfaces

$$\rho_o^{-1} \boldsymbol{J}^{\text{skew}} = -\nabla \varrho \times \boldsymbol{\Psi}^*, \tag{71.35}$$

where at this point we have yet to specify $\boldsymbol{\Psi}^*$. To see what the local dissipation of available potential energy imposes, consider the gravitational potential energy

$$P = g \int \varrho \, z \, \mathrm{d}V, \tag{71.36}$$

where, again, we assume the *in situ* density equals to the potential density as per a linear equation of state (Section 30.3.5). Assuming all boundaries are material and static allows us to focus on the time tendency of potential energy associated with the unknown flux

$$\frac{\mathrm{d}P}{\mathrm{d}t} = g \int z \, \frac{\partial \varrho}{\partial t} \, \mathrm{d}V = -\frac{g}{\rho_o} \int (z \, \nabla \cdot \boldsymbol{J}^{\text{skew}}) \, \mathrm{d}V = -\frac{g}{\rho_o} \int (z \, \partial_z J^z) \, \mathrm{d}V = \frac{g}{\rho_o} \int J^z \, \mathrm{d}V, \tag{71.37}$$

where J^z is the vertical flux component. We drop boundary effects by assuming the subgrid scale flux vanishes on all boundaries. To provide a *local* available potential energy sink requires

$$J^z \leq 0, \tag{71.38}$$

where zero occurs when the isopycnals are flat. It is sufficient to construct the vertical flux component using only the potential density field itself. For a stably stratified fluid in which $\partial_z \varrho < 0$, the following form provides a local available potential energy sink

$$\rho_o^{-1} J^z = \kappa_{gm} \boldsymbol{S}^2 \partial_z \varrho = -(\kappa_{gm} \rho_o / g) (\boldsymbol{S} N)^2 \leq 0. \tag{71.39}$$

The corresponding horizontal flux is given by a downgradient diffusive flux

$$\boldsymbol{J}^h = -\rho_o \kappa_{gm} \nabla_h \varrho. \tag{71.40}$$

We have thus recovered the skew flux (71.33) as proposed by *Gent et al.* (1995). Note that *Aiki et al.* (2004) proceed in a similar manner yet do not assume locality of the available potential energy sink, thus deriving a more general subgrid scale operator.

Advective flux approach

The impacts on potential energy should be the same when representing the parameterization as an advective flux. To verify this result, return to equation (71.37) and make use of the vertical component of the advective flux rather than the skew flux

$$\frac{dP}{dt} = g \int \varrho \, w^* \, dV \tag{71.41a}$$

$$= g \int \varrho \, \nabla_h \cdot (\kappa_{gm} \boldsymbol{S}) \, dV \tag{71.41b}$$

$$= g \int \nabla_h \cdot (\varrho \, \kappa_{gm} \boldsymbol{S}) \, dV - g \int \nabla_h \varrho \cdot \kappa_{gm} \boldsymbol{S} \, dV \tag{71.41c}$$

$$= -\rho_o \int \kappa_{gm} (\boldsymbol{S} N)^2 \, dV, \tag{71.41d}$$

which is the same result as for the skew flux.

71.3.4 Meridional overturning mass transport

It is often of interest to compute the mass transport across a portion of the ocean. In particular, meridional-depth or meridional-potential density streamfunctions allow one to visualize and quantify the zonally integrated transport occurring in a closed basin or over the full globe. The quasi-Stokes transport provides a transport in addition to that from the resolved scale Eulerian mean transport, and the parameterization of *Gent et al.* (1995) leads to a straightforward computation of the quasi-Stokes contribution. For this purpose, write the net meridional mass transport of fluid across a basin and passing beneath a particular depth in the form (the minus sign is conventional)

$$\mathcal{T}(y,z,t) = -\int dx \int_{-H}^{z} \rho \, (v + v^*) \, dz \tag{71.42a}$$

$$= -\int dx \int_{-H}^{z} \rho \, v \, dz + \int dx \int_{-H}^{z} \partial_z (\kappa_{gm} \rho \, S_y) \, dz \tag{71.42b}$$

$$= -\int dx \int_{-H}^{z} \rho \, v \, dz + \int \kappa_{gm} \rho \, S_y \, dx \tag{71.42c}$$

$$\equiv \mathcal{T}^{\text{eulerian}}(y,z,t) + \mathcal{T}^{\text{gm}}(y,z,t). \tag{71.42d}$$

For the penultimate step we set the parameterized quasi-Stokes transport to zero at the ocean bottom. We thus see that the parameterized quasi-Stokes transport adds a contribution that

scales linearly with basin size, isopyncal slope, and diffusivity,

$$\mathcal{T}^{\text{qs}} \sim \rho_o \, L \, |\boldsymbol{S}| \, \kappa_{\text{gm}}. \tag{71.43}$$

As an example, let $\rho = 1035$ kg m^{-3}, $\kappa_{\text{gm}} = 10^3$ m^2 s^{-1}, $|\boldsymbol{S}| = 10^{-3}$, and $L = 10^7$ m, which yields $\mathcal{T}^{\text{qs}} \approx 10 \times 10^9$ kg s^{-1}. This additional transport is a nontrivial addition to that from the resolved scale velocity field.

71.3.5 Connection to form stress

We now connect the *Gent et al.* (1995) closure, normally implemented in the tracer equation, to vertical transfer of momentum through form stress. For this purpose, recall the general discussion of form stress in Section 28.1 and the more detailed discussions in Sections 31.7 and 36.4. In those discussions, we identify form stress as the horizontal pressure force acting on a sloped surface, with our present concern with surfaces of constant isopycnals as discussed in Sections 31.7 and 36.4.

Young (2012) provides a general means for making the connection between *Gent et al.* (1995) and form stress for a continuously stratified fluid. *Loose et al.* (2023) and *Jansen et al.* (2024) provide further theoretical and numerical analysis of this approach. For our more schematic purposes, we follow the treatment in *Greatbatch and Lamb* (1990), *Gent et al.* (1995) (their Section 4), *Ferreira and Marshall* (2006) (their Section 2), and *Zhao and Vallis* (2008) (their Section 2.2). For this purpose, assume the fluid is in Boussinesq planetary geostrophic balance (detailed in Section 31.5) whereby the horizontal momentum satisfies

$$\rho_o \, f \, (\hat{\boldsymbol{z}} \times \boldsymbol{u}) = -\nabla_h p + \partial_z \boldsymbol{\tau}, \tag{71.44}$$

with $\boldsymbol{\tau}$ a horizontal subgrid scale stress vector. The Coriolis acceleration balances the acceleration from horizontal pressure gradients plus a vertical transfer of horizontal stress. The horizontal stress term is generally quite small in the ocean interior, where the flow is in geostrophic balance, whereas it is large at the ocean surface where it arises from turbulent air-sea interactions; i.e., wind stress. Furthermore, it can be large at the bottom through turbulent bottom stresses.

To make the connection between *Gent et al.* (1995) and the vertical transfer of horizontal form stress, add $\rho_o \, f \, (\hat{\boldsymbol{z}} \times \boldsymbol{u}^*)$ to both sides of equation (71.44) to obtain

$$\rho_o \, f \, (\hat{\boldsymbol{z}} \times \boldsymbol{u}^\dagger) = -\nabla_h p + \partial_z \boldsymbol{\tau} + \rho_o \, f \, (\hat{\boldsymbol{z}} \times \boldsymbol{u}^*), \tag{71.45}$$

where $\boldsymbol{u}^\dagger = \boldsymbol{u} + \boldsymbol{u}^*$ is the horizontal residual mean velocity. This equation says that the Coriolis acceleration from the horizontal residual mean velocity balances pressure gradients, the vertical divergence of the horizontal frictional stresses, plus the Coriolis acceleration from the eddy-induced velocity. We further unpack the eddy Coriolis acceleration by noting that the planetary geostrophic velocity satisfies the thermal wind relation in the ocean interior (Section 31.6), whereby

$$f \, \partial_z \boldsymbol{u} = -(g/\rho_o) \, \hat{\boldsymbol{z}} \times \nabla \rho = -\hat{\boldsymbol{z}} \times N^2 \boldsymbol{S}. \tag{71.46}$$

We can thus write the Coriolis acceleration from the eddy-induced velocity as

$$f \, (\hat{\boldsymbol{z}} \times \boldsymbol{u}^*) = -f \, [\hat{\boldsymbol{z}} \times \partial_z (\kappa_{\text{gm}} \, \boldsymbol{S})] \tag{71.47a}$$

$$= -\partial_z \, [\hat{\boldsymbol{z}} \times (f \, \kappa_{\text{gm}} \, \boldsymbol{S})] \tag{71.47b}$$

$$= \frac{\partial}{\partial z} \left[\frac{\kappa_{\text{gm}} \, f^2}{N^2} \, \frac{\partial \boldsymbol{u}}{\partial z} \right] \tag{71.47c}$$

$$= \partial_z (\nu_e \, \partial_z \boldsymbol{u}), \tag{71.47d}$$

where the final equality introduced an eddy-induced vertical viscosity

$$\nu_{\mathsf{e}} \equiv \kappa_{\mathsf{gm}} \, (f^2/N^2). \tag{71.48}$$

Making use of this result in the planetary geostrophic equation (71.45) thus leads to

$$\rho_{\mathsf{o}} \, f \, (\hat{\boldsymbol{z}} \times \boldsymbol{u}^{\dagger}) = -\nabla_{\mathsf{h}} p + \partial_z (\boldsymbol{\tau} + \boldsymbol{\tau}_{\mathsf{e}}), \tag{71.49}$$

where

$$\rho_{\mathsf{o}}^{-1} \, \boldsymbol{\tau}_{\mathsf{e}} = \nu_{\mathsf{e}} \, \partial_z \boldsymbol{u} \tag{71.50}$$

defines a horizontal mesoscale eddy stress arising from the thermal wind shears. Equation (71.49) says that the Coriolis acceleration from the horizontal residual mean velocity is in balance with the horizontal pressure gradient plus the vertical transfer of horizontal shears arising from both friction/wind/bottom drag *plus* a contribution from parameterized mesoscale eddies.

We conclude that the *Gent et al.* (1995) parameterization appears in the planetary geostrophic residual mean momentum equation as a vertical transport of horizontal stress determined by a viscosity $\nu_{\mathsf{e}} = \kappa_{\mathsf{gm}} \, (f/N)^2$. Notably, this vertical eddy transfer occurs in the absence of irreversible mixing. We thus interpret it as a parameterization of the vertical transfer of pressure form stress via mesoscale eddies that act between isopycnal layers. That is, the *Gent et al.* (1995) scheme offers a means to parameterize vertical transfer of horizontal form stress arising from undulating mesoscale eddies in the ocean interior. This interpretation is more thoroughly discussed in Section 31.7 (see also *Greatbatch and Lamb* (1990) and *Loose et al.* (2023)).

71.3.6 Connection to isopycnal thickness diffusion

Recall the ensemble mean thickness equation (70.114) for a Boussinesq fluid was derived in Section 70.4.5

$$\partial_t \hbar + \nabla_{\varrho} \cdot (\hbar \, \widehat{\boldsymbol{u}}) = 0, \tag{71.51}$$

where

$$\widehat{\boldsymbol{u}} = \boldsymbol{u} + \boldsymbol{u}^{\mathrm{bolus}} \tag{71.52}$$

is the thickness weighted transport velocity affecting evolution of the ensemble mean thickness $\hbar$. Note that for brevity we here drop the nomenclature $(\ )^{(\varrho)}$ used in Section 70.4.5.

Isopycnal correlations of horizontal velocity and layer thickness define the bolus velocity via

$$\hbar \, \boldsymbol{u}^{\mathsf{bolus}} = \overline{\hbar' \, \boldsymbol{u}'} \tag{71.53}$$

Now consider a downgradient diffusive closure for this correlation

$$\hbar \, \boldsymbol{u}^{\mathsf{bolus}} = \overline{\hbar' \, \boldsymbol{u}'}^{(\varrho)} = -\boldsymbol{K}^{\mathsf{thick}} \cdot \nabla_{\varrho} h, \tag{71.54}$$

with $\boldsymbol{K}^{\mathsf{thick}}$ a symmetric and positive-definite 2×2 diffusion tensor. The mean thickness equation thus takes the form of an advection-diffusion equation in isopycnal coordinates

$$\partial_t \hbar + \nabla_{\varrho} \cdot (\hbar \, \boldsymbol{u}) = \nabla_{\varrho} \cdot (\boldsymbol{K}^{\mathsf{thick}} \cdot \nabla_{\varrho} \hbar). \tag{71.55}$$

We note one special property of the closure (71.54) revealed when considering discrete shallow water layers and assuming the thickness diffusion tensor is depth independent. Vertically summing the eddy transport from the ocean bottom up to a particular layer yields

$$\sum_{n=k_{\mathrm{b}}}^{n=k} \overline{\hbar_n' \, \boldsymbol{u}_n'}^{(\varrho)} = -\sum_{n=k_{\mathrm{b}}}^{n=k} \boldsymbol{K}^{\mathsf{thick}} \cdot \nabla_{\varrho} h_n = -\boldsymbol{K}^{\mathsf{thick}} \cdot \sum_{n=k_{\mathrm{b}}}^{n=k} \nabla_{\varrho} h_n = -\boldsymbol{K}^{\mathsf{thick}} \cdot \nabla_{\varrho} \eta_{k-1/2}, \tag{71.56}$$

where $\eta_{k-1/2}$ is the upper interface of layer k (see Figure 35.6), and where $k_{\rm b}$ is the index for the layer at the ocean bottom. In this case we see that the eddy transport below an isopycnal interface is directly proportional to the slope of that interface.

71.3.7 Connection to Gent-McWilliams parameterization

To make a direct connection between the thickness diffusion closure (71.54) and the *Gent et al.* (1995) closure discussed in Section 71.3.1, note that the specific thickness is the inverse of the vertical derivative of the potential density

$$\hbar = (\partial_z \varrho)^{-1}. \tag{71.57}$$

Correspondingly, using the relation between derivative operators, $\nabla_{\hbar\varrho} = \nabla_{\rm h} + \boldsymbol{S}\,\partial_z$, gives

$$\begin{aligned}
\hbar^{-1}\,\nabla_{\hbar\varrho}\hbar &= -\hbar\,\nabla_{\hbar\varrho}(1/\hbar) && \text{product rule identity} && (71.58a)\\
&= -(\partial_z\varrho)^{-1}\,(\nabla_{\rm h} + \boldsymbol{S}\,\partial_z)\,\partial_z\varrho && \hbar = \partial z/\partial\varrho \text{ and } \nabla_{\hbar\varrho} = \nabla_{\rm h} + \boldsymbol{S}\,\partial_z && (71.58b)\\
&= -\frac{\partial_z(\nabla_{\rm h}\varrho)}{\partial_z\varrho} + \frac{\partial_{zz}\varrho\,\nabla_{\rm h}\varrho}{(\partial_z\varrho)^2} && \text{rearrangement} && (71.58c)\\
&= -\partial_z[\nabla_{\rm h}\varrho/(\partial_z\varrho)] && \text{product rule identity} && (71.58d)\\
&= \partial_z \boldsymbol{S} && \text{isopycnal slope } \boldsymbol{S} = -\nabla_{\rm h}\varrho/(\partial_z\varrho). && (71.58e)
\end{aligned}$$

Consequently, the bolus velocity takes the form

$$\boldsymbol{u}^{\rm bolus} = -\hbar^{-1}\,\boldsymbol{K}^{\rm thick}\cdot\nabla_{\hbar\varrho}\hbar = -\boldsymbol{K}^{\rm thick}\cdot\partial_z\boldsymbol{S}. \tag{71.59}$$

The special case of depth independent diffusivity

For the special case of $\boldsymbol{K}^{\rm thick}$ that is independent of depth and proportional to the 2×2 identity matrix, we recover the identity

$$\boldsymbol{u}^{\rm bolus} = -\partial_z(\kappa_{\rm gm}\,\boldsymbol{S}) = \boldsymbol{u}^*, \tag{71.60}$$

where the horizontal component of the *Gent et al.* (1995) velocity, $\boldsymbol{u}^*$, was identified from equation (71.29). Again, this identity holds only for the special case of a vertically independent diffusivity tensor proportional to the identity.

Further caveats

The relevance of a depth-independent diffusivity has been questioned by many authors, such as *Killworth* (1997), *Treguier et al.* (1997), *Smith and Vallis* (2002), *Smith and Marshall* (2009), and *Abernathey et al.* (2013). We conclude from these studies that a depth independent diffusivity is not the best choice for the *Gent et al.* (1995) parameterization, in which case where one places the vertical derivative is crucial.

The relation between thickness diffusion with the *Gent et al.* (1995) parameterization further breaks down near boundaries. The reason is that the eddy diffusivity vanishes next to boundaries and thus has a depth-dependence. Additionally, as noted by *Holloway* (1997) and *Griffies et al.* (2000), thickness diffusion next to solid earth boundaries leads to an increase in potential energy, with isopycnals creeping up the topographic slope. Such unphysical behavior motivates isopycnal modelers instead to use *interfacial height* diffusion to dissipate noise in the thickness field.

71.3.8 A parameterization based on a boundary value problem

There have been variants of the *Gent et al.* (1995) scheme proposed in the literature, such as those of *Aiki et al.* (2004) and *Ferrari et al.* (2010). As for the *Gent et al.* (1995) scheme, these alternatives dissipate available potential energy without mixing between isopycnal classes. We here briefly discuss the scheme of *Ferrari et al.* (2010), which is used by a variety of ocean climate models largely since it contains a natural means to numerically regularize the eddy-induced streamfunction in regions of weak vertical stratification. These considerations are relevant especially in ocean climate models, where weak or zero vertical stratification is inevitable and so it is necessary to handle such regimes.

For the *Ferrari et al.* (2010) scheme we write the parameterized eddy streamfunction as

$$\boldsymbol{\Psi}^* = \hat{\boldsymbol{z}} \times \boldsymbol{\Upsilon} \Longrightarrow \boldsymbol{u}^* = -\partial_z \boldsymbol{\Upsilon} \quad \text{and} \quad w^* = \nabla_h \cdot \boldsymbol{\Upsilon}, \tag{71.61}$$

with $\boldsymbol{\Upsilon}$ determined by solving the following vertical boundary value problem at each horizontal position[6]

$$(c^2\, \partial_{zz} - N^2)\boldsymbol{\Upsilon} = -N^2\, \boldsymbol{\Upsilon}^{\text{gm}} \quad \text{and} \quad \boldsymbol{\Upsilon}(\eta_b) = \boldsymbol{\Upsilon}(\eta) = 0, \tag{71.62}$$

where (see equation (71.28))

$$\boldsymbol{\Upsilon}^{\text{gm}} = \kappa_{\text{gm}}\, \boldsymbol{S} \quad \text{and} \quad N^2\, \boldsymbol{S} = (g/\rho_o)\, \nabla_h \varrho. \tag{71.63}$$

We recover the *Gent et al.* (1995) scheme when setting the squared speed to zero, $c^2 = 0$, in which case $\boldsymbol{\Upsilon} = \boldsymbol{\Upsilon}^{\text{gm}}$. For $c^2 > 0$, the second order differential operator ensures that $\boldsymbol{\Upsilon}$ smoothly and continuously transitions through regions where the vertical stratification is weak (N^2 is small), and hence where $|\boldsymbol{S}|$ is large. In contrast, the standard regularization approaches, with $c^2 = 0$, are somewhat more *ad hoc* (e.g., see Chapter 15 of *Griffies* (2004)) or very tedious (e.g., *Ferrari et al.* (2008)).

Following the discussion in Section 71.3.3, we deduce the impacts on potential energy (assuming a linear equation of state) via equation (71.37), where we make use of the vertical component of the potential density skew flux

$$\frac{1}{g}\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{1}{\rho_o}\int J^z \,\mathrm{d}V = -\int \hat{\boldsymbol{z}} \cdot (\nabla\varrho \times \boldsymbol{\Psi}^*)\,\mathrm{d}V = -\int \nabla_h \varrho \cdot \boldsymbol{\Upsilon}\,\mathrm{d}V = -\frac{\rho_o}{g}\int N^2\, \boldsymbol{S}\cdot\boldsymbol{\Upsilon}\,\mathrm{d}V. \tag{71.64}$$

The governing differential equation (71.62) leads to

$$\boldsymbol{\Upsilon} \cdot (c^2\, \partial_{zz} - N^2)\boldsymbol{\Upsilon} = -(g/\rho_o)\, \kappa_{\text{gm}}\, \boldsymbol{\Upsilon} \cdot \nabla_h \varrho, \tag{71.65}$$

which rearranges to

$$(g/\rho_o)\, \kappa_{\text{gm}}\, \boldsymbol{\Upsilon} \cdot \nabla_h \varrho = -c^2\, \partial_z(\boldsymbol{\Upsilon} \cdot \partial_z \boldsymbol{\Upsilon}) + c^2\, (\partial_z \boldsymbol{\Upsilon} \cdot \partial_z \boldsymbol{\Upsilon}) + N^2\, \boldsymbol{\Upsilon} \cdot \boldsymbol{\Upsilon}. \tag{71.66}$$

Integrating over a vertical column and making use of the homogeneous Dirichlet boundary conditions from equation (71.62) leads to

$$\frac{g}{\rho_o}\int \kappa_{\text{gm}}\, \boldsymbol{\Upsilon} \cdot \nabla_h \varrho \,\mathrm{d}z = \int (c^2\, \partial_z \boldsymbol{\Upsilon} \cdot \partial_z \boldsymbol{\Upsilon} + N^2\, \boldsymbol{\Upsilon} \cdot \boldsymbol{\Upsilon})\,\mathrm{d}z \geq 0. \tag{71.67}$$

This inequality means that the potential energy of a vertical column is dissipated. However, locally at any point in the column the potential energy might increase due to the sign-indefinite term, $-c^2\, \partial_z(\boldsymbol{\Upsilon} \cdot \partial_z \boldsymbol{\Upsilon})$. Notably, there is no *a priori* reason that mesoscale eddies dissipate potential energy at every point in space. Furthermore, numerical experiments documented

[6] Note that *Ferrari et al.* (2010) used the opposite sign convention on $\boldsymbol{\Upsilon}$ from that used here.

in *Ferrari et al.* (2010) suggest that local potential energy dissipation is not necessary for a numerically stable operator. We conclude that this approach offers a suitable method for ocean climate simulations.

71.3.9 Comments

As noted in Section 70.5.3, there is presently no parameterization of subgrid scale stirring along neutral directions arising from the correlations between tracer and velocity fluctuations. Rather, the only parameterized subgrid scale stirring is associated with quasi-Stokes transport, with *Gent et al.* (1995) providing the canonical approach as summarized in this section. To parameterize the skew fluxes arising from tracer-velocity correlations requires one to study the polarization of the eddies giving rise to these skew fluxes, as per the discussion in Section 70.3.2 and *Middleton and Loder* (1989).

71.4 Neutral diffusion

Neutral diffusion, also referred to as *epineutral diffusion*, parameterizes the mixing induced by mesoscale eddy transport. The parameterization assumes that the neutral diffusive flux of a tracer is oriented along a neutral direction or a *neutral tangent plane*. The neutral diffusive tracer flux, $\boldsymbol{J}$, for an arbitrary tracer, C, is perpendicular to the dianeutral unit vector

$$\boldsymbol{J} \cdot \hat{\boldsymbol{\gamma}} = 0 \implies \boldsymbol{J} \cdot (-\alpha \nabla \Theta + \beta \nabla S) = 0, \tag{71.68}$$

where $\hat{\boldsymbol{\gamma}}$ is defined by equation (71.16).

71.4.1 Motivation for neutral diffusion

Pioneering models of the ocean circulation, such as *Cox and Bryan* (1984), were formulated with the tracer mixing tensor oriented according to the horizontal and vertical directions. These simulations exhibited problems near strong density fronts, such as those found in western boundary currents. In such regions, the horizontally oriented diffusion spuriously fluxed temperature and salinity across isopyncnals, thus degrading the strength of the front and leading to, among other problems, unphysically weak meridional heat transport (*Böning et al.*, 1995). In earlier work based on tracer measurements, *Montgomery* (1938), *Veronis* (1975), and *Rooth* (1982) suggested that ocean properties were preferentially homogenized along local potential density surfaces rather than geopotential surfaces. Such measurements motivated *Solomon* (1971) and *Redi* (1982) to propose rotating the tracer mixing tensor according to neutral directions.

We offer further indirect evidence that mesoscale eddy induced diffusion is preferentially aligned along neutral directions. For that purpose, consider a diffusive flux that is not aligned with neutral directions. In this case, diffusive mixing can cause tracer distributions to cross neutral directions, thus adding to the mixing that is already parameterized from small scale mixing processes from Section 71.2. As discussed in Section 14.1.5 of *Griffies* (2004) as well as Section 1 of *McDougall et al.* (2014), the extra mixing induced by this non-neutral orientation of the mesoscale induced diffusive fluxes is proportional to the squared slope between the proposed new direction and the neutral tangent plane. Estimates based on field measurements for interior ocean mixing constrain the magnitude of the miss-alignment to be less than 10^{-4}. This number is very small, indeed it is zero within error bars of field measurements. Although the measurements are sparse, they do support the use of mesoscale eddy induced diffusive fluxes that are oriented according to neutral directions. We thus make use of this constraint in designing the diffusion tensor in the remainder of this section.

71.4.2 Redi neutral diffusion

One diffusive flux satisfying the property (71.68) is given by

$$\boldsymbol{J}^{\text{redi}} = -\rho\,\kappa_{\text{ntr}}\,[\nabla C - \hat{\boldsymbol{\gamma}}\,(\hat{\boldsymbol{\gamma}}\cdot\nabla C)], \tag{71.69}$$

where $\kappa_{\text{ntr}} > 0$ is the eddy neutral diffusivity (dimensions of squared length per time). In Figure 71.4 we illustrate the diffusive flux arising for a particular configuration of the neutral directions and the tracer concentration.

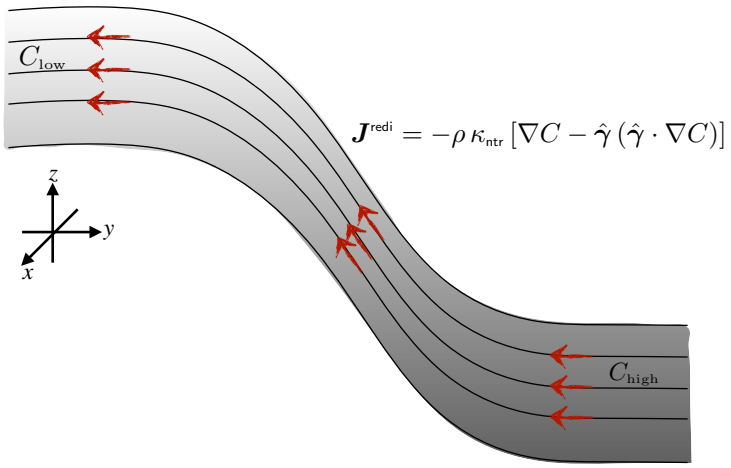

FIGURE 71.4: Schematic of the Redi neutral diffusion flux, $\boldsymbol{J}^{\text{redi}} = -\rho\,\kappa_{\text{ntr}}\,[\nabla C - \hat{\boldsymbol{\gamma}}\,(\hat{\boldsymbol{\gamma}}\cdot\nabla C)]$, from equation (71.69). The sloping lines represent surfaces whose local tangent is in the neutral direction, so that the tracer flux is aligned parallel to the surfaces. We here depict the case with higher tracer concentration on the right side so that the downgradient neutral diffusive flux is to the left and upward.

We confirm that $\boldsymbol{J}^{\text{redi}}$ is oriented down the tracer gradient by noting that

$$\boldsymbol{J}^{\text{redi}}\cdot\nabla C = -\rho\,\kappa_{\text{ntr}}\left[|\nabla C|^2 - (\hat{\boldsymbol{\gamma}}\cdot\nabla C)^2\right] \leq 0. \tag{71.70}$$

We can write the neutral diffusive flux (71.69) in the downgradient flux-gradient relation

$$\boldsymbol{J}^{\text{redi}} = -\rho\,\boldsymbol{K}^{\text{redi}}\cdot\nabla C, \tag{71.71}$$

with the neutral diffusion tensor, $\boldsymbol{K}^{\text{redi}}$, given by

$$\boldsymbol{K}^{\text{redi}} = \kappa_{\text{ntr}}\begin{bmatrix} 1-\hat{\gamma}_x^2 & -\hat{\gamma}_x\,\hat{\gamma}_y & -\hat{\gamma}_x\,\hat{\gamma}_z \\ -\hat{\gamma}_x\,\hat{\gamma}_y & 1-\hat{\gamma}_y^2 & -\hat{\gamma}_y\,\hat{\gamma}_z \\ -\hat{\gamma}_x\,\hat{\gamma}_z & -\hat{\gamma}_y\,\hat{\gamma}_z & 1-\hat{\gamma}_x^2 \end{bmatrix} \Longrightarrow (K^{\text{redi}})^{mn} = \kappa_{\text{ntr}}\,(\delta^{mn} - \hat{\gamma}^m\,\hat{\gamma}^n). \tag{71.72}$$

The corresponding neutral diffusion operator is given by the three-dimensional flux convergence

$$\mathcal{R}^{\text{redi}} = -\nabla\cdot\boldsymbol{J}^{\text{redi}} = \nabla\cdot(\rho\,\boldsymbol{K}^{\text{redi}}\cdot\nabla C). \tag{71.73}$$

When the neutral surfaces are stably stratified in the vertical, so that their slopes are bounded, then the diffusion tensor takes the following form originally suggested by *Redi* (1982), which is written in terms of the neutral slope

$$\boldsymbol{K}^{\text{redi}} = \frac{\kappa_{\text{ntr}}}{1+\boldsymbol{S}^2}\begin{bmatrix} 1+S_y^2 & -S_xS_y & S_x \\ -S_xS_y & 1+S_x^2 & S_y \\ S_x & S_y & \boldsymbol{S}^2 \end{bmatrix}. \tag{71.74}$$

71.4.3 Small slope neutral diffusion

Another form of the neutral diffusion flux is based on assuming a small magnitude for the slope of the neutral tangent plane relative to the horizontal, which is the case for most of the ocean interior even in frontal regions. With this approximation, the small slope neutral diffusion tensor takes the form

$$\boldsymbol{K}^{\text{small}} = \kappa_{\text{ntr}} \begin{bmatrix} 1 & 0 & S_x \\ 0 & 1 & S_y \\ S_x & S_y & \boldsymbol{S}^2 \end{bmatrix}. \tag{71.75}$$

The corresponding small slope neutral diffusive flux is

$$\boldsymbol{J}^{\text{small}} = -\rho\, \kappa_{\text{ntr}} \left[\nabla_{\text{h}\gamma} + \hat{\boldsymbol{z}}\, (\boldsymbol{S} \cdot \nabla_{\text{h}\gamma})\right] C \tag{71.76}$$

where

$$\nabla_{\text{h}\gamma} = \nabla_{\text{h}} + \boldsymbol{S}\, \partial_z \tag{71.77}$$

is the horizontal derivative operator computed on the neutral tangent plane (see equation (63.75)). To show that $\boldsymbol{J}^{\text{small}} \cdot \hat{\boldsymbol{\gamma}} = 0$, we make use of the identity (71.19) so that

$$\boldsymbol{J}^{\text{small}} \cdot \hat{\boldsymbol{\gamma}} = \frac{\boldsymbol{J}^{\text{small}} \cdot \boldsymbol{S} - \boldsymbol{J}^{\text{small}} \cdot \boldsymbol{S}}{(1 + \boldsymbol{S}^2)^{1/2}} = 0. \tag{71.78}$$

Furthermore, we confirm that $\boldsymbol{J}^{\text{small}}$ is oriented down the tracer gradient by noting that

$$\begin{aligned}
\boldsymbol{J}^{\text{small}} \cdot \nabla C &= -\rho\, \kappa_{\text{ntr}} \left[\nabla_{\text{h}\gamma} C \cdot \nabla_{\text{h}} C + (\boldsymbol{S} \cdot \nabla_{\text{h}\gamma} C)\, \partial_z C\right] && \text{(71.79a)} \\
&= -\rho\, \kappa_{\text{ntr}} \left[|\nabla_{\text{h}} C|^2 + 2\, (\boldsymbol{S} \cdot \nabla_{\text{h}} C)\, \partial_z C + |\boldsymbol{S}\, \partial_z C|^2\right] && \text{(71.79b)} \\
&= -\rho\, \kappa_{\text{ntr}} \left|\nabla_{\text{h}} C + \boldsymbol{S}\, \partial_z C\right|^2 && \text{(71.79c)} \\
&= -\rho\, \kappa_{\text{ntr}} \left|\nabla_{\text{h}\gamma} C\right|^2 && \text{(71.79d)} \\
&\le 0. && \text{(71.79e)}
\end{aligned}$$

The small slope approximation was proposed by *Cox* (1987). However, his form for the small slope neutral diffusion flux was incorrect as it did not satisfy $\boldsymbol{J}^{\text{small}} \cdot \hat{\boldsymbol{\gamma}} = 0$. The corrected form given by equation (71.76) was first written by *Gent and McWilliams* (1990). The resulting small slope neutral diffusion operator is commonly used in ocean climate models (*Griffies et al.*, 1998; *Lemarié et al.*, 2012), which results from computing the three-dimensional convergence

$$\mathcal{R}^{\text{small}} = -\nabla \cdot \boldsymbol{J}^{\text{small}} = \nabla_{\text{h}} \cdot (\rho\, \kappa_{\text{ntr}}\, \nabla_{\text{h}\gamma} C) + \partial_z (\rho\, \kappa_{\text{ntr}}\, \boldsymbol{S} \cdot \nabla_{\text{h}\gamma} C). \tag{71.80}$$

71.4.4 Neutral tangent plane neutral diffusion

A third method to compute neutral diffusion is motivated by the form of isopycnal diffusion in isopycnal layered models. Rather than isopycnal layers, we work with layers determined locally by neutral tangent planes. The neutral tangent frame makes use of projected non-orthogonal generalized vertical coordinates detailed in Chapter 63.

Following the derivations given in Section 63.15, the neutral diffusive flux in the neutral tangent frame is given by the horizontal flux

$$\boldsymbol{J}^{\text{ntp}} = -\rho\, \kappa_{\text{ntr}}\, \nabla_{\text{h}\gamma} C. \tag{71.81}$$

This flux is oriented down the tracer gradient as oriented along neutral directions

$$\boldsymbol{J}^{\text{ntp}} \cdot \nabla_{\text{h}\gamma} C = -\rho\, \kappa_{\text{ntr}} \left|\nabla_{\text{h}\gamma} C\right|^2, \tag{71.82}$$

which is the same as equation (71.79d) for the small slope fluxes. However, as a purely horizontal flux, $\boldsymbol{J}^{\text{ntp}}$ is not oriented along neutral directions

$$\boldsymbol{J}^{\text{ntp}} \cdot \hat{\boldsymbol{\gamma}} \neq 0. \tag{71.83}$$

Nevertheless, rather than computing the neutral diffusion operator as a horizontal convergence of this flux, the neutral tangent plane diffusion operator is computed by taking the convergence of $\boldsymbol{J}^{\text{ntp}}$ along the neutral tangent plane as per equation (63.100)

$$\mathcal{R}^{\text{ntp}} = -\frac{1}{h^\gamma} \left[\nabla_{h\gamma} \cdot (h^\gamma \, \boldsymbol{J}^{\text{ntp}}) \right] = \frac{1}{h^\gamma} \left[\nabla_{h\gamma} \cdot (h^\gamma \, \rho \, \kappa_{\text{ntr}} \, \nabla_{h\gamma} C) \right], \tag{71.84}$$

where

$$h^\gamma = \frac{\partial z}{\partial \gamma} \, \mathrm{d}\gamma = - \left[\frac{g}{\rho_o \, N^2} \right] \mathrm{d}\gamma \tag{71.85}$$

measures the thickness of a layer defined by two neutral tangent planes (see equation (63.97)).

As detailed in Section 63.15, $\mathcal{R}^{\text{ntp}}$ is identical to the small slope neutral diffusion operator (71.80)

$$\mathcal{R}^{\text{ntp}} = \mathcal{R}^{\text{small}}. \tag{71.86}$$

In principle, it is a matter of convenience which form of the operator one uses. However, there are certain issues to consider when implementing these operators in a numerical model. Notably, a discrete realization of $\mathcal{R}^{\text{ntp}}$ allows for a diagonal downgradient implementation of neutral diffusion, just as isopycnal diffusion in an isopycnal ocean model. In contrast, a discrete realization of either $\mathcal{R}^{\text{redi}}$ or $\mathcal{R}^{\text{small}}$ cannot guarantee downgradient fluxes due to the off-diagonal nature of its neutral diffusive flux components (*Griffies et al.* (1998), *Beckers et al.* (1998), *Gnanadesikan* (1999), *Beckers et al.* (2000) *Lemarié et al.* (2012), *Shao et al.* (2020)). As a result, discrete realizations of $\mathcal{R}^{\text{redi}}$ or $\mathcal{R}^{\text{small}}$ can produce extrema, which are distinctly not properties of diffusion in the continuum (see Exercise 68.3). Hence, even though the continuum identity holds $\mathcal{R}^{\text{ntp}} = \mathcal{R}^{\text{small}}$, there are important differences that arise upon realizing these operators on a discrete lattice. *Shao et al.* (2020) provide further discussion of these points as part of their numerical realization of neutral diffusion.

71.4.5 Neutrality condition

Given the expression (71.16) for the dianeutral unit vector, $\hat{\boldsymbol{\gamma}}$, it is straightforward to show that the neutral diffusive flux for Conservative Temperature and salinity satisfy the constraints

$$\nabla\Theta \cdot [-\alpha \, \boldsymbol{J}(\Theta) + \beta \, \boldsymbol{J}(S)] = 0 \quad \text{and} \quad \nabla S \cdot [-\alpha \, \boldsymbol{J}(\Theta) + \beta \, \boldsymbol{J}(S)] = 0. \tag{71.87}$$

These constraints are generally satisfied if the diffusive fluxes satisfy the balance

$$\alpha \, \boldsymbol{J}(\Theta) = \beta \, \boldsymbol{J}(S) \Longrightarrow \boldsymbol{K} \cdot \hat{\boldsymbol{\gamma}} = 0. \tag{71.88}$$

We refer to this balance as the *neutrality condition*. It reflects the vanishing of the neutral diffusive flux of locally referenced potential density. It is maintained by the diffusive flux (71.69) of *Redi* (1982), the small slope flux (71.76) of *Gent and McWilliams* (1990), and the neutral tangent frame neutral diffusive flux (71.81). However, it is not maintained by the small slope fluxes from *Cox* (1987). Furthermore, *Griffies et al.* (1998) argued for the importance of maintaining this balance to avoid a nonlinear instability plaguing certain numerical realizations of neutral diffusion such as that from *Cox* (1987).

71.4.6 Symmetry condition

Since the neutral diffusion tensor is symmetric (as are all diffusion tensors), we have

$$\begin{aligned} \boldsymbol{J}(\Theta) \cdot \nabla S &= -\kappa_{\text{ntr}}\, \rho\, K^{mn} \partial_n \Theta\, \partial_m S && \text{(71.89a)} \\ &= -\kappa_{\text{ntr}}\, \rho\, K^{nm}\, \partial_n S\, \partial_m \Theta && \text{(71.89b)} \\ &= -\kappa_{\text{ntr}}\, \rho\, K^{nm}\, \partial_n S\, \partial_m \Theta && \text{(71.89c)} \\ &= \boldsymbol{J}(S) \cdot \nabla \Theta. && \text{(71.89d)} \end{aligned}$$

This symmetry condition holds for for any of the diffusion tensors introduced in this chapter. It is particularly useful in our discussion of cabbeling and thermobaricity in Section 72.3.

71.4.7 GM skewsion plus small slope neutral diffusion

A parameterization of mesoscale eddy stirring and mixing often appears in geopotential coordinate ocean models in the form of GM skewsion (Section 71.3.1) and small slope neutral diffusion (Section 71.4.3). The combined tracer flux takes the form

$$\rho^{-1}\, \boldsymbol{J} = -\kappa_{\text{ntr}}\, \nabla_{\text{h}} C - (\kappa_{\text{ntr}} - \kappa_{\text{gm}})\, \boldsymbol{S}\, \partial_z C - \hat{\boldsymbol{z}}\, [(\kappa_{\text{ntr}} + \kappa_{\text{gm}})\, \boldsymbol{S} \cdot \nabla_{\text{h}} C + \kappa_{\text{ntr}}\, \boldsymbol{S}^2\, \partial_z C], \tag{71.90}$$

which can be written in terms of a subgrid scale transport tensor

$$\rho^{-1} \begin{bmatrix} J^x \\ J^y \\ J^z \end{bmatrix} = - \begin{bmatrix} \kappa_{\text{ntr}} & 0 & (\kappa_{\text{ntr}} - \kappa_{\text{gm}})\, S_x \\ 0 & \kappa_{\text{ntr}} & (\kappa_{\text{ntr}} - \kappa_{\text{gm}})\, S_y \\ (\kappa_{\text{ntr}} + \kappa_{\text{gm}})\, S_x & (\kappa_{\text{ntr}} + \kappa_{\text{gm}})\, S_y & \kappa_{\text{ntr}}\, \boldsymbol{S}^2 \end{bmatrix} \begin{bmatrix} \partial_x C \\ \partial_y C \\ \partial_z C \end{bmatrix}. \tag{71.91}$$

In the 1990s and throughout much of the 2000s, it was common to assume that $\kappa_{\text{ntr}} = \kappa_{\text{gm}}$, in which case the combined mixing tensor is

$$\boldsymbol{K}^{\text{small}} + A^{\text{gm}} = \kappa_{\text{ntr}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 2\, S_x & 2\, S_y & \boldsymbol{S}^2 \end{bmatrix} \quad \text{if } \kappa_{\text{ntr}} = \kappa_{\text{gm}}, \tag{71.92}$$

so that the subgrid scale flux simplifies to

$$\rho^{-1}\, \boldsymbol{J} = -\kappa_{\text{ntr}} \nabla_{\text{h}} C - \hat{\boldsymbol{z}}\, \kappa_{\text{ntr}}\, (2\, \boldsymbol{S} \cdot \nabla_{\text{h}} C + \boldsymbol{S}^2\, \partial_z C) \quad \text{if } \kappa_{\text{ntr}} = \kappa_{\text{gm}}. \tag{71.93}$$

Notably, the 2×2 horizontal mixing tensor is diagonal. Hence, the horizontal tracer flux is the same as that which arises from downgradient horizontal tracer diffusion. The simplicity of the horizontal flux component was alluring to modelers. It was furthermore argued by *Dukowicz and Smith* (1997) to be a fundamental property of mesoscale turbulence. However, as emphasized through the works of *Treguier et al.* (1997), *Ferrari et al.* (2008), *Danabasoglu et al.* (2008), and *Ferrari et al.* (2010), the boundary conditions for neutral diffusion and GM skewsion are distinct, thus breaking their symmetry. Furthermore, studies such as *Smith and Marshall* (2009) and *Abernathey et al.* (2013) clearly point to the distinct vertical structure for the two diffusivities. Such distinctions are expected since the skew diffusivity and neutral diffusivity parameterize physically distinct processes: one parameterizes the quasi-Stokes transport, associated with velocity and layer thickness correlations, whereas the other parameterizes downgradient diffusion along neutral directions, associated with velocity and tracer correlations.

71.4.8 Generalized vertical coordinates

Thus far we have considered neutral diffusion as realized in geopotential coordinates or using neutral tangent plane coordinates. Here, we detail the steps needed to realize neutral diffusion using the generalized vertical coordinates (GVCs) detailed in Chapters 63 and 64. This formulation is relevant for the now common use of generalized vertical coordinates for ocean modeling as reviewed by *Griffies et al.* (2020).

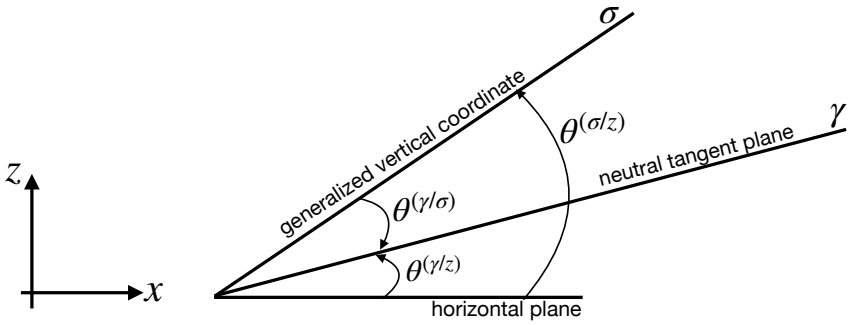

FIGURE 71.5: Slopes of a neutral tangent plane (denoted by γ) relative to both the horizontal plane, $\tan\theta^{(\gamma/z)}$, and relative to a generalized vertical coordinate isoline, $\tan\theta^{(\gamma/\sigma)}$, where σ is a generalized vertical coordinate. We assume positive angles as measure counter-clockwise relative to the horizontal and relative to the σ-isoline, respectively. Hence, for this example, $\theta^{(\gamma/z)} > 0$ yet $\theta^{(\gamma/\sigma)} < 0$. When extending to the two horizontal directions, the slopes generally satisfy $\boldsymbol{S}^{(\sigma/z)} = \boldsymbol{S}^{(\gamma/z)} - \boldsymbol{S}^{(\gamma/\sigma)}$, where $|\boldsymbol{S}^{(\gamma/z)}| = |\tan\theta^{(\gamma/z)}|$ and $|\boldsymbol{S}^{(\gamma/\sigma)}| = |\tan\theta^{(\gamma/\sigma)}|$. Note that this relation between slope vectors also holds for arbitrary orientations of the σ isolines and neutral tangent planes.

Start by recalling the expression (63.99) for a general diffusion operator written in terms of the generalized vertical coordinate, $\sigma = \sigma(x, y, z, t)$

$$\mathcal{R} = -\frac{1}{h^\sigma}\left[\nabla_{h\sigma} \cdot (h^\sigma \, \boldsymbol{J}^h) + \delta_\sigma(z_\sigma \, \nabla\sigma \cdot \boldsymbol{J})\right], \tag{71.94}$$

where $\delta_\sigma \equiv \mathrm{d}\sigma \, \partial_\sigma$ is the dimensionless derivative operator, and the thickness of a σ-layer is

$$h^\sigma = \mathrm{d}z = z_\sigma \, \mathrm{d}\sigma = \frac{\partial z}{\partial \sigma}\, \mathrm{d}\sigma. \tag{71.95}$$

Now assume the flux, $\boldsymbol{J}$, is given by equation (71.76) for small slope neutral diffusion. Transforming to generalized vertical coordinates leads to the horizontal flux component

$$\begin{aligned}
\boldsymbol{J}^{h\text{small}} &= -\rho \, \kappa_{\text{ntr}} \, \nabla_{h\gamma} C && \text{(71.96a)}\\
&= -\rho \, \kappa_{\text{ntr}} \left[\nabla_h + (\nabla_{h\gamma} z)\, \partial_z\right] C && \text{(71.96b)}\\
&= -\rho \, \kappa_{\text{ntr}} \left[\nabla_{h\sigma} + (-\nabla_{h\sigma} z + \nabla_{h\gamma} z)\, \partial_z\right] C && \text{(71.96c)}\\
&= -\rho \, \kappa_{\text{ntr}} \left[\nabla_{h\sigma} + (-\boldsymbol{S}^{(\sigma/z)} + \boldsymbol{S}^{(\gamma/z)})\, \partial_z\right] C && \text{(71.96d)}\\
&= -\rho \, \kappa_{\text{ntr}} \left(\nabla_{h\sigma} + \boldsymbol{S}^{(\gamma/\sigma)}\, \partial_z\right) C, && \text{(71.96e)}
\end{aligned}$$

where the neutral slopes as shown in Figure 71.5 satisfy the identity

$$\boldsymbol{S}^{(\sigma/z)} = \boldsymbol{S}^{(\gamma/z)} - \boldsymbol{S}^{(\gamma/\sigma)}. \tag{71.97}$$

Furthermore, we made use of the identity (63.75) relating the partial derivative operators

$$\nabla_{h\gamma} = \nabla_h + (\nabla_{h\gamma} z)\, \partial_z \quad \text{and} \quad \nabla_h = \nabla_{h\sigma} - (\nabla_{h\sigma} z)\, \partial_z. \tag{71.98}$$

The horizontal flux (71.96e) has the same form as when written using geopotential coordinates,

only now with the derivative operator $\nabla_{h\sigma}$ and the slope $\boldsymbol{S}^{(\gamma/\sigma)}$. Correspondingly, the vertical flux component

$$\boldsymbol{J}^{z\text{small}} = \boldsymbol{J}^{h\text{small}} \cdot \boldsymbol{S}^{(\gamma/z)} \tag{71.99}$$

takes the form

$$z_\sigma \, \nabla\sigma \cdot \boldsymbol{J}^{\text{small}} = -\boldsymbol{S}^{(\sigma/z)} \cdot \boldsymbol{J}^{h\text{small}} + \boldsymbol{J}^{z\text{small}} = \boldsymbol{J}^{h\text{small}} \cdot \boldsymbol{S}^{(\gamma/\sigma)}, \tag{71.100}$$

which in turn yields the diffusion operator (71.94)

$$\mathcal{R} = -\frac{1}{h^\sigma} \left[\nabla_{h\sigma} \cdot (h^\sigma \, \boldsymbol{J}^{h\text{small}}) + \delta_\sigma (\boldsymbol{J}^{h\text{small}} \cdot \boldsymbol{S}^{(\gamma/\sigma)}) \right]. \tag{71.101}$$

In the special case when σ is parallel to the neutral direction so that $\boldsymbol{S}^{(\gamma/\sigma)} = 0$, the diffusion operator (71.101) reduces to the neutral tangent plane version given by equation (71.84).

71.5 Anisotropic neutral diffusion

The neutral diffusion discussed in Section 71.4 is based on isotropic diffusion in the neutral tangent plane. That assumption has been questioned by *Smith and Gent* (2004) and *Fox-Kemper et al.* (2013). We here develop some of the formalism appropriate for studying anisotropic neutral diffusion.

71.5.1 Orthonormal triad of basis vectors

We make use of the following orthonormal unit vectors[7] as depicted in Figure 71.6

$$\hat{\boldsymbol{e}}_{\overline{1}} = \frac{\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}}}{|\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}}|} \tag{71.102a}$$

$$\hat{\boldsymbol{e}}_{\overline{2}} = \frac{\hat{\boldsymbol{\gamma}} \times (\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}})}{|\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}}|} = \frac{\hat{\boldsymbol{d}} - (\hat{\boldsymbol{\gamma}} \cdot \hat{\boldsymbol{d}}) \, \hat{\boldsymbol{\gamma}}}{|\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}}|} \tag{71.102b}$$

$$\hat{\boldsymbol{e}}_{\overline{3}} = \hat{\boldsymbol{\gamma}} \tag{71.102c}$$

where

$$\hat{\boldsymbol{d}} = \hat{\boldsymbol{x}} \, \hat{d}_x + \hat{\boldsymbol{y}} \, \hat{d}_y + \hat{\boldsymbol{z}} \, \hat{d}_z \tag{71.103}$$

is an arbitrary unit vector that is not parallel to $\hat{\boldsymbol{\gamma}}$. The three unit vectors $(\hat{\boldsymbol{e}}_{\overline{1}}, \hat{\boldsymbol{e}}_{\overline{2}}, \hat{\boldsymbol{e}}_{\overline{3}})$ form an orthonormal triad at each point in the fluid so that

$$\hat{\boldsymbol{e}}_{\overline{1}} = \hat{\boldsymbol{e}}_{\overline{2}} \times \hat{\boldsymbol{e}}_{\overline{3}} \quad \text{and} \quad \hat{\boldsymbol{e}}_{\overline{2}} = \hat{\boldsymbol{e}}_{\overline{3}} \times \hat{\boldsymbol{e}}_{\overline{1}} \quad \text{and} \quad \hat{\boldsymbol{e}}_{\overline{3}} = \hat{\boldsymbol{e}}_{\overline{1}} \times \hat{\boldsymbol{e}}_{\overline{2}}. \tag{71.104}$$

These vectors are oriented by the arbitrary direction, $\hat{\boldsymbol{d}}$, and the dianeutral direction, $\hat{\boldsymbol{\gamma}}$. We verify that $\hat{\boldsymbol{e}}_{\overline{2}}$ has unit magnitude by noting that

$$|\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}}|^2 = |\hat{\boldsymbol{\gamma}} \times (\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}})|^2 = 1 - (\hat{\boldsymbol{d}} \cdot \hat{\boldsymbol{\gamma}})^2. \tag{71.105}$$

It is also useful to verify that $\hat{\boldsymbol{e}}_{\overline{3}} = \hat{\boldsymbol{e}}_{\overline{1}} \times \hat{\boldsymbol{e}}_{\overline{2}}$ through the following vector identity (see equation (1.71g))

$$(\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}}) \times [\hat{\boldsymbol{\gamma}} \times (\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}})] = \hat{\boldsymbol{\gamma}} \, |\hat{\boldsymbol{d}} \times \hat{\boldsymbol{\gamma}}|^2. \tag{71.106}$$

[7] The basis vectors (71.102a)-(71.102c) are more suitable for present purposes than the analogous basis vectors defined by equations (14.4)-(14.6) in *Griffies* (2004). In particular, the basis (71.102a)-(71.102c) has a sensible limit when the neutral slopes are horizontal, in which $\hat{\boldsymbol{\gamma}} = -\hat{\boldsymbol{z}}$.

The unit vectors $\hat{\boldsymbol{e}}_{\overline{1}}$ and $\hat{\boldsymbol{e}}_{\overline{2}}$ are both within the neutral tangent plane since they are both orthogonal to $\hat{\boldsymbol{\gamma}}$.

The unit vector $\hat{\boldsymbol{e}}_{\overline{1}}$ is orthogonal to $\hat{\boldsymbol{d}}$ whereas $\hat{\boldsymbol{e}}_{\overline{2}}$ is parallel to $\hat{\boldsymbol{d}}$ if $\hat{\boldsymbol{d}} \cdot \hat{\boldsymbol{\gamma}} = 0$. For example, *Smith and Gent* (2004) proposed setting $\hat{\boldsymbol{d}}$ to be a horizontal vector set according to the local horizontal flow direction, in which case

$$\hat{\boldsymbol{d}} = \frac{u\,\hat{\boldsymbol{x}} + v\,\hat{\boldsymbol{y}}}{(u^2 + v^2)^{1/2}}. \tag{71.107}$$

With $\hat{\boldsymbol{\gamma}}$ nearly vertical for much of the ocean interior, then $\hat{\boldsymbol{e}}_{\overline{2}}$ becomes nearly aligned with $\hat{\boldsymbol{d}}$. For these reasons we refer to $\hat{\boldsymbol{e}}_{\overline{1}}$ as the across-$\hat{\boldsymbol{d}}$ direction and $\hat{\boldsymbol{e}}_{\overline{2}}$ as the along-$\hat{\boldsymbol{d}}$ direction.

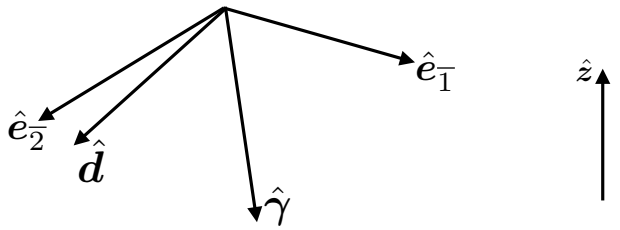

FIGURE 71.6: Depicting the orthonormal triad of basis vectors given by equations (71.102a)-(71.102c). Our convention is such that $\hat{\boldsymbol{\gamma}}$ typically points downward toward increasing density. The unit vector $\hat{\boldsymbol{d}}$ is arbitrary so long as it is not parallel to the dianeutral unit vector, $\hat{\boldsymbol{\gamma}}$. It is horizontal when making use of the *Smith and Gent* (2004) proposal whereby $\hat{\boldsymbol{d}} = \boldsymbol{u}/|\boldsymbol{u}|$, with $\boldsymbol{u} = \hat{\boldsymbol{x}}\,u + \hat{\boldsymbol{y}}\,v$ the horizontal velocity vector. Since $\hat{\boldsymbol{e}}_{\overline{1}}$ is orthogonal to $\hat{\boldsymbol{d}}$, we refer to $\hat{\boldsymbol{e}}_{\overline{1}}$ as the cross-$\hat{\boldsymbol{d}}$ basis vector. Likewise, since $\hat{\boldsymbol{e}}_{\overline{2}}$ is nearly parallel to $\hat{\boldsymbol{d}}$, especially when $\hat{\boldsymbol{d}}$ is close to horizontal and $\hat{\boldsymbol{\gamma}}$ is close to vertical (e.g., Section 71.5.4), then $\hat{\boldsymbol{e}}_{\overline{2}}$ is referred to as the along-$\hat{\boldsymbol{d}}$ basis vector.

71.5.2 Anisotropic neutral diffusion tensor

We consider anisotropy according to the unit vectors $\hat{\boldsymbol{e}}_{\overline{1}}$ and $\hat{\boldsymbol{e}}_{\overline{2}}$. Hence, the diffusion tensor as represented using the locally orthogonal triad $(\hat{\boldsymbol{e}}_{\overline{1}}, \hat{\boldsymbol{e}}_{\overline{2}}, \hat{\boldsymbol{e}}_{\overline{3}})$ is given by

$$\overline{\boldsymbol{K}^{\text{aniso}}} = \begin{bmatrix} \kappa_{\text{cross}} & 0 & 0 \\ 0 & \kappa_{\text{along}} & 0 \\ 0 & 0 & 0 \end{bmatrix}, \tag{71.108}$$

where $\kappa_{\text{cross}} > 0$ and $\kappa_{\text{along}} > 0$ are the generally distinct neutral diffusivities. This tensor takes on the component form

$$(\boldsymbol{K}^{\text{aniso}})^{\overline{mn}} = \kappa_{\text{cross}}\, \hat{e}_{\overline{1}}^{\overline{m}}\, \hat{e}_{\overline{1}}^{\overline{n}} + \kappa_{\text{along}}\, \hat{e}_{\overline{2}}^{\overline{m}}\, \hat{e}_{\overline{2}}^{\overline{n}} \tag{71.109a}$$

$$= \kappa_{\text{cross}}\, (\delta^{\overline{mn}} - \hat{e}_{\overline{2}}^{\overline{m}}\, \hat{e}_{\overline{2}}^{\overline{n}} - \hat{e}_{\overline{3}}^{\overline{m}}\, \hat{e}_{\overline{3}}^{\overline{n}}) + \kappa_{\text{along}}\, (\delta^{\overline{mn}} - \hat{e}_{\overline{1}}^{\overline{m}}\, \hat{e}_{\overline{1}}^{\overline{n}} - \hat{e}_{\overline{3}}^{\overline{m}}\, \hat{e}_{\overline{3}}^{\overline{n}}), \tag{71.109b}$$

where the second expression made use of the following decomposition of the unit tensor in terms of the orthonormal basis vectors

$$\delta^{\overline{mn}} = \hat{e}_{\overline{1}}^{\overline{m}}\, \hat{e}_{\overline{1}}^{\overline{n}} + \hat{e}_{\overline{2}}^{\overline{m}}\, \hat{e}_{\overline{2}}^{\overline{n}} + \hat{e}_{\overline{3}}^{\overline{m}}\, \hat{e}_{\overline{3}}^{\overline{n}}. \tag{71.110}$$

Note that $(\boldsymbol{K}^{\text{aniso}})^{\overline{mn}}$ is invariant under $\hat{\boldsymbol{d}} \to -\hat{\boldsymbol{d}}$. Likewise, it is invariant under a change in the sign of $\hat{\boldsymbol{\gamma}}$. Furthermore, note that we recover the isotropic Redi diffusion tensor (71.72) by setting $\kappa_{\text{cross}} = \kappa_{\text{along}} = \kappa_{\text{ntr}}$ and in which case

$$(K^{\text{aniso}})^{\overline{mn}} = 2\,\kappa_{\text{ntr}}\, (\delta^{\overline{mn}} - \hat{e}_{\overline{3}}^{\overline{m}}\, \hat{e}_{\overline{3}}^{\overline{n}}) - \kappa_{\text{ntr}}\, (\hat{e}_{\overline{1}}^{\overline{m}}\, \hat{e}_{\overline{1}}^{\overline{n}} + \hat{e}_{\overline{2}}^{\overline{m}}\, \hat{e}_{\overline{2}}^{\overline{n}}) \tag{71.111a}$$

$$= \kappa_{\text{ntr}}\, (\delta^{\overline{mn}} - \hat{e}_{\overline{3}}^{\overline{m}}\, \hat{e}_{\overline{3}}^{\overline{n}}) \tag{71.111b}$$

$$= (K^{\text{redi}})^{\overline{mn}} \tag{71.111c}$$

To render a geopotential-Cartesian representation of the anisotropic diffusion tensor, we can make use of the transformation methods for Cartesian tensors developed in Section 1.10. We do so by transforming from the locally orthogonal neutral plane coordinate system, defined by the orthonormal triad (71.102a)-(71.102c), to the geopotential-Cartesian coordinate system, defined by the Cartesian triad

$$\hat{\boldsymbol{e}}_1 = \hat{\boldsymbol{x}} \quad \text{and} \quad \hat{\boldsymbol{e}}_2 = \hat{\boldsymbol{y}} \quad \text{and} \quad \hat{\boldsymbol{e}}_3 = \hat{\boldsymbol{z}}. \tag{71.112}$$

Since we are working with Cartesian tensors, this transformation is a local rotation matrix, $\mathcal{R}$, so that[8]

$$(K^{\text{aniso}})^{mn} = \mathcal{R}^m{}_{\overline{m}} \mathcal{R}^n{}_{\overline{n}} (K^{\text{aniso}})^{\overline{mn}} \Longrightarrow \boldsymbol{K}^{\text{aniso}} = \mathcal{R}\, \overline{\boldsymbol{K}^{\text{aniso}}}\, \mathcal{R}^T, \tag{71.113}$$

where the second equality made use of matrix notation with $\mathcal{R}^T$ the transpose, and where the elements to the rotation matrix are given by the direction cosines following equation (1.87)

$$\mathcal{R} = \begin{bmatrix} \hat{\boldsymbol{e}}^1 \cdot \hat{\boldsymbol{e}}_{\overline{1}} & \hat{\boldsymbol{e}}^1 \cdot \hat{\boldsymbol{e}}_{\overline{2}} & \hat{\boldsymbol{e}}^1 \cdot \hat{\boldsymbol{e}}_{\overline{3}} \\ \hat{\boldsymbol{e}}^2 \cdot \hat{\boldsymbol{e}}_{\overline{1}} & \hat{\boldsymbol{e}}^2 \cdot \hat{\boldsymbol{e}}_{\overline{2}} & \hat{\boldsymbol{e}}^2 \cdot \hat{\boldsymbol{e}}_{\overline{3}} \\ \hat{\boldsymbol{e}}^3 \cdot \hat{\boldsymbol{e}}_{\overline{1}} & \hat{\boldsymbol{e}}^3 \cdot \hat{\boldsymbol{e}}_{\overline{2}} & \hat{\boldsymbol{e}}^3 \cdot \hat{\boldsymbol{e}}_{\overline{3}} \end{bmatrix} = \begin{bmatrix} \hat{\boldsymbol{x}} \cdot \hat{\boldsymbol{e}}_{\overline{1}} & \hat{\boldsymbol{x}} \cdot \hat{\boldsymbol{e}}_{\overline{2}} & \hat{\boldsymbol{x}} \cdot \hat{\boldsymbol{e}}_{\overline{3}} \\ \hat{\boldsymbol{y}} \cdot \hat{\boldsymbol{e}}_{\overline{1}} & \hat{\boldsymbol{y}} \cdot \hat{\boldsymbol{e}}_{\overline{2}} & \hat{\boldsymbol{y}} \cdot \hat{\boldsymbol{e}}_{\overline{3}} \\ \hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{e}}_{\overline{1}} & \hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{e}}_{\overline{2}} & \hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{e}}_{\overline{3}} \end{bmatrix}. \tag{71.114}$$

The machinery outlined here for the transformation is straightforward but tedious (i.e., two matrix multiplies). A more streamlined approach, also used for determining the Cartesian components to the Redi tensor (71.74), is to simply express $(\hat{\boldsymbol{e}}_{\overline{1}}, \hat{\boldsymbol{e}}_{\overline{2}}, \hat{\boldsymbol{e}}_{\overline{3}})$ using geopotential-Cartesian coordinates and then plug directly into equation (71.109b).

71.5.3 Properties of the anisotropic neutral diffusive fluxes

We here verify some standard properties for the anisotropic neutral diffusive flux for tracers

$$\boldsymbol{J}^{\text{aniso}} = -\rho\, \boldsymbol{K}^{\text{aniso}} \cdot \nabla C. \tag{71.115}$$

Downgradient orientation within the neutral tangent plane

By construction, the flux is downgradient along the two orthogonal directions, $\hat{\boldsymbol{e}}_{\overline{1}}$ and $\hat{\boldsymbol{e}}_{\overline{2}}$,

$$\boldsymbol{J}^{\text{aniso}} = -\rho\, \kappa_{\text{cross}}\, \hat{\boldsymbol{e}}_{\overline{1}} (\hat{\boldsymbol{e}}_{\overline{1}} \cdot \nabla C) - \rho\, \kappa_{\text{along}}\, \hat{\boldsymbol{e}}_{\overline{2}} (\hat{\boldsymbol{e}}_{\overline{2}} \cdot \nabla C). \tag{71.116}$$

Furthermore, the flux is within the neutral tangent plane

$$\boldsymbol{J}^{\text{aniso}} \cdot \hat{\boldsymbol{\gamma}} = 0 \tag{71.117}$$

due to orthogonality between the basis vectors

$$\hat{\boldsymbol{e}}_{\overline{1}} \cdot \hat{\boldsymbol{\gamma}} = \hat{\boldsymbol{e}}_{\overline{2}} \cdot \hat{\boldsymbol{\gamma}} = 0. \tag{71.118}$$

Neutrality condition

The neutrality condition (71.88) follows since

$$(-\alpha\, \nabla\Theta + \beta\, \nabla S) \cdot \hat{\boldsymbol{e}}_{\overline{1}} = (-\alpha\, \nabla\Theta + \beta\, \nabla S) \cdot \hat{\boldsymbol{e}}_{\overline{2}} = 0, \tag{71.119}$$

[8] Since we are dealing with Cartesian tensors there is no distinction between raised or lowered tensor indices in equation (71.113). We choose to follow the convention of general tensors in Chapters 3 and 4 simply to help organize elements of the tensor.

so that

$$\alpha\, \boldsymbol{J}^{\text{aniso}}(\Theta) = \beta\, \boldsymbol{J}^{\text{aniso}}(S). \tag{71.120}$$

71.5.4 Small slope anisotropic neutral diffusion

We now consider the special case in which the orientation direction, $\hat{\boldsymbol{d}}$, is strictly horizontal and normalized so that

$$\hat{\boldsymbol{d}} \cdot \hat{\boldsymbol{d}} = \hat{d}_x^2 + \hat{d}_y^2 = 1. \tag{71.121}$$

Additionally, we assume the neutral slope is small so that the neutral directions are nearly horizontal. In this case the basis vectors (71.102a)-(71.102c) take on the following form valid to $\mathcal{O}(|\boldsymbol{S}|)$

$$\hat{\boldsymbol{e}}_{\overline{1}_{\text{small}}} = \hat{\boldsymbol{d}} \times (\boldsymbol{S} - \hat{\boldsymbol{z}}) \tag{71.122a}$$

$$\hat{\boldsymbol{e}}_{\overline{2}} = \hat{\boldsymbol{d}} + \hat{\boldsymbol{z}}\, (\hat{\boldsymbol{d}} \cdot \boldsymbol{S}) \tag{71.122b}$$

$$\hat{\boldsymbol{e}}_{\overline{3}_{\text{small}}} = \boldsymbol{S} - \hat{\boldsymbol{z}}. \tag{71.122c}$$

Note that $\hat{\boldsymbol{e}}_{\overline{3}_{\text{small}}}$ is orthogonal to $\hat{\boldsymbol{e}}_{\overline{1}_{\text{small}}}$ and $\hat{\boldsymbol{e}}_{\overline{2}_{\text{small}}}$, however $\hat{\boldsymbol{e}}_{\overline{1}_{\text{small}}} \cdot \hat{\boldsymbol{e}}_{\overline{2}_{\text{small}}}$ is $\mathcal{O}(\boldsymbol{S} \cdot \boldsymbol{S})$. Likewise, each of these vectors is normalized only to $\mathcal{O}(\boldsymbol{S} \cdot \boldsymbol{S})$.

Making use of the small slope basis vectors in the anisotropic diffusion tensor (71.109a), and expressing them in geopotential-Cartesian coordinates leads to the small slope anisotropic neutral diffusion tensor[9]

$$\boldsymbol{K}^{\text{smallaniso}} = \kappa_{\text{cross}} \begin{bmatrix} 1 & 0 & S_x \\ 0 & 1 & S_y \\ S_x & S_y & \boldsymbol{S} \cdot \boldsymbol{S} \end{bmatrix} + \Delta\kappa_{\text{ntr}} \begin{bmatrix} \hat{d}_x^2 & \hat{d}_x\, \hat{d}_y & (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\, \hat{d}_x \\ \hat{d}_x\, \hat{d}_y & \hat{d}_y^2 & (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\, \hat{d}_y \\ (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\, \hat{d}_x & (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\, \hat{d}_y & (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})^2 \end{bmatrix}, \tag{71.123}$$

where

$$\Delta\kappa_{\text{ntr}} = \kappa_{\text{along}} - \kappa_{\text{cross}}. \tag{71.124}$$

As for the unapproximated anisotropic neutral diffusion tensor (71.109a), its small slope version, $\overline{\boldsymbol{K}}_{\text{small aniso}}$, is invariant if we swap the direction $\hat{\boldsymbol{d}} \to -\hat{\boldsymbol{d}}$. Furthermore, in the form (71.123) we trivially see that $\overline{\boldsymbol{K}}^{\text{smallaniso}} = \overline{\boldsymbol{K}}^{\text{small}}$ (equation (71.75)) in the isotropic limit where $\kappa_{\text{cross}} = \kappa_{\text{along}} = \kappa_{\text{ntr}}$.

The anisotropic small slope neutral diffusive flux is given by

$$\boldsymbol{J}^{h\text{smallaniso}} = -\rho\, \boldsymbol{K}^{\text{smallaniso}} \cdot \nabla C, \tag{71.125}$$

with horizontal and vertical components

$$\boldsymbol{J}^{h\text{smallaniso}} = -\rho\, \kappa_{\text{cross}} \nabla_{\!\gamma} C - \rho\, \Delta\kappa_{\text{ntr}}\, \hat{\boldsymbol{d}}\, (\hat{\boldsymbol{d}} \cdot \nabla_{\!\gamma}) C \tag{71.126a}$$

$$J^{z\text{smallaniso}} = \boldsymbol{S} \cdot \boldsymbol{J}^{h\text{smallaniso}}, \tag{71.126b}$$

where $\nabla_{\!\gamma} = \nabla_{\!\text{h}} + \boldsymbol{S}\, \partial_z$ is the horizontal operator as per equation (71.77). By making use of the expression (71.19), $\hat{\boldsymbol{\gamma}} = (\boldsymbol{S} - \hat{\boldsymbol{z}})\, (1 + \boldsymbol{S}^2)^{-1/2}$, we readily find that

$$\boldsymbol{J}^{h\text{smallaniso}} \cdot \hat{\boldsymbol{\gamma}} = 0. \tag{71.127}$$

Similarly, we can verify that the neutrality condition (Section 71.4.5) is maintained

$$\boldsymbol{K}^{\text{smallaniso}} \cdot \hat{\boldsymbol{\gamma}} = 0 \Longrightarrow \alpha\, \boldsymbol{J}^{h\text{smallaniso}}(\Theta) = \beta\, \boldsymbol{J}^{h\text{smallaniso}}(S). \tag{71.128}$$

[9] Equation (71.123) agrees with equations (10) and (14) from *Smith and Gent* (2004).

Finally, as per the discussion in Section 71.4.4, we can evaluate the small slope anisotropic neutral diffusion operator by following the non-orthogonal neutral tangent approach rather than the three-dimensional Cartesian approach. It is the non-orthogonal neutral tangent approach that is appropriate for vertical Lagrangian ocean models such as detailed in *Griffies et al.* (2020) and *Shao et al.* (2020).

71.6 Anisotropic Gent-McWilliams stirring

In addition to proposing the use of a small slope anisotropic neutral diffusion tensor (equation (71.123)), *Smith and Gent* (2004) proposed a complementary anisotropic version of the Gent-McWilliams stirring. We here detail the parameterization, again assuming the orientation direction, $\hat{\boldsymbol{d}}$, is horizontal

$$\hat{\boldsymbol{d}} = \hat{\boldsymbol{x}}\, \hat{d}_x + \hat{\boldsymbol{y}}\, \hat{d}_y, \tag{71.129}$$

just as assumed when discussing the anisotropic small slope neutral diffusion operator in Section 71.5.4.

71.6.1 Streamfunction and anti-symmetric tensor

The parameterized eddy-induced streamfunction is generalized from that in equation (71.28) to read

$$\boldsymbol{\Psi}^* = \hat{\boldsymbol{z}} \times \kappa_{\text{gmcross}}\, \boldsymbol{S} + \hat{\boldsymbol{z}} \times (\kappa_{\text{gmcross}} - \kappa_{\text{gmalong}})\, (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\, \hat{\boldsymbol{d}}, \tag{71.130}$$

and the corresponding anti-symmetric stirring tensor is

$$A^{\text{gmaniso}} = \kappa_{\text{gmcross}} \begin{bmatrix} 0 & 0 & -S_x \\ 0 & 0 & -S_y \\ S_x & S_y & 0 \end{bmatrix} + \Delta\kappa_{\text{gm}}\, (\hat{\boldsymbol{d}} \cdot \boldsymbol{S}) \begin{bmatrix} 0 & 0 & -\hat{d}_x \\ 0 & 0 & -\hat{d}_y \\ \hat{d}_x & \hat{d}_y & 0 \end{bmatrix}, \tag{71.131}$$

where

$$\Delta\kappa_{\text{gm}} = \kappa_{\text{gmalong}} - \kappa_{\text{gmcross}}. \tag{71.132}$$

As for the small slope anisotropic neutral diffusion tensor (71.123), we write the skew tensor A^{gmaniso} in equation (71.131) in a form that manifestly reduces to the isotropic Gent-McWilliams stirring tensor A^{gm} when $\kappa_{\text{gmalong}} = \kappa_{\text{gmcross}} = \kappa_{\text{gm}}$.

71.6.2 Anisotropic Gent-McWilliams skew tracer flux

The anisotropic Gent-McWilliams skew tracer flux is

$$\boldsymbol{J}_{\text{gm-aniso}} = -\rho\, A^{\text{gmaniso}} \cdot \nabla C \tag{71.133a}$$

$$= \rho\, \kappa_{\text{gmcross}}\, [\boldsymbol{S}\, \partial_z C - \hat{\boldsymbol{z}}\, (\boldsymbol{S} \cdot \nabla_{\text{h}} C)] + \rho\, \Delta\kappa_{\text{gm}}\, (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\, [\hat{\boldsymbol{d}}\, \partial_z C - \hat{\boldsymbol{z}}\, (\hat{\boldsymbol{d}} \cdot \nabla_{\text{h}} C)]. \tag{71.133b}$$

When acting on locally referenced potential density, $C = \gamma$, the flux reduces to

$$\boldsymbol{J}_{\text{gm-aniso}} = \rho\, \kappa_{\text{gmcross}}\, [-\nabla_{\text{h}}\gamma + \hat{\boldsymbol{z}}\, \boldsymbol{S}^2\, \partial_z \gamma] + \rho\, \Delta\kappa_{\text{gm}}\, (\boldsymbol{d} \cdot \boldsymbol{S})\, [\hat{\boldsymbol{d}} + \hat{\boldsymbol{z}}\, (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})]\, \partial_z \gamma. \tag{71.134}$$

As discussed in Section 71.3.3, a negative vertical component to the potential density skew flux ensures that the available potential energy is dissipated,

$$\hat{\boldsymbol{z}} \cdot \boldsymbol{J}_{\text{gm-aniso}} = \rho\, [\kappa_{\text{gmcross}}\, \boldsymbol{S}^2 + \Delta\kappa_{\text{gm}}\, (\boldsymbol{d} \cdot \boldsymbol{S})^2]\, \partial_z \gamma < 0 \Longrightarrow \text{APE dissipated}. \tag{71.135}$$

Stably stratified water means that $\partial_z \gamma < 0$, in which case $\hat{\boldsymbol{z}} \cdot \boldsymbol{J}_{\text{gm-aniso}} < 0$ since

$$\kappa_{\text{gmcross}}\, \boldsymbol{S}^2 + \Delta\kappa_{\text{gm}}\, (\boldsymbol{d} \cdot \boldsymbol{S})^2 = \kappa_{\text{gmcross}}\, [\boldsymbol{S}^2 - (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})^2] + \kappa_{\text{gmalong}}\, (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})^2 > 0. \tag{71.136}$$

71.6.3 Anisotropic GM skewsion plus small slope neutral diffusion

As noted in Section 71.4.7, there are strong reasons to keep the Gent-McWilliams skew flux parameterization distinct from the neutral diffusion parameterization. The central practical reason for the distinction concerns their different treatment of boundary conditions and generally distinct diffusivities. Even so, we here briefly comment on the special case where we ignore these distinctions and set the skew flux diffusivities equal to the neutral diffusivities

$$\kappa_{\text{gmcross}} = \kappa_{\text{cross}} \quad \text{and} \quad \kappa_{\text{gmalong}} = \kappa_{\text{along}}. \tag{71.137}$$

This is the approach assumed by *Smith and Gent* (2004). With the small slope approximation to neutral diffusion, we find the combined anisotropic mixing tensor becomes

$$\boldsymbol{K}^{\text{smallaniso}} + A^{\text{gmaniso}} = \kappa_{\text{cross}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 2\,S_x & 2\,S_y & \boldsymbol{S} \cdot \boldsymbol{S} \end{bmatrix} + \Delta\kappa \begin{bmatrix} \hat{d}_x^2 & \hat{d}_x\,\hat{d}_y & 0 \\ \hat{d}_x\,\hat{d}_y & \hat{d}_y^2 & 0 \\ 2\,(\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\,\hat{d}_x & 2\,(\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\,\hat{d}_y & (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})^2 \end{bmatrix}. \tag{71.138}$$

The vanishing right hand column terms simplifies the horizontal tracer fluxes computed from this tensor. However, again, this formulation lacks is inconsistent with theory that supports the distinct treatments of the skew flux and neutral flux.

71.6.4 A parameterization based on a boundary value problem

We now follow the approach from Section 71.3.8 to develop a boundary value problem version of the anisotropic Gent-McWilliams stirring. For this purpose we consider the vertical boundary value problem

$$(c^2\, \partial_{zz} - N^2)\, \boldsymbol{\Upsilon} = -N^2\, \boldsymbol{\Upsilon}^{\text{gmaniso}} \quad \text{and} \quad \boldsymbol{\Upsilon}(\eta_{\text{b}}) = \boldsymbol{\Upsilon}(\eta) = 0, \tag{71.139}$$

where (see equation (71.130))

$$\boldsymbol{\Upsilon}^{\text{gmaniso}} = \kappa_{\text{gmcross}}\, \boldsymbol{S} + \hat{\boldsymbol{z}} \times \Delta\kappa_{\text{gm}}\, (\hat{\boldsymbol{d}} \cdot \boldsymbol{S})\, \hat{\boldsymbol{d}}. \tag{71.140}$$

As in Section 71.3.8, we deduce the impacts on potential energy (assuming a linear equation of state) via the vertical component of the potential density skew flux,

$$\frac{1}{g}\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{1}{\rho_{\text{o}}} \int J^z\, \mathrm{d}V = -\int \nabla_{\text{h}} \varrho \cdot \boldsymbol{\Upsilon}\, \mathrm{d}V. \tag{71.141}$$

The governing differential equation (71.139) leads to

$$\boldsymbol{\Upsilon} \cdot (c^2\, \partial_{zz} - N^2)\, \boldsymbol{\Upsilon} = -N^2\, \boldsymbol{\Upsilon} \cdot \boldsymbol{\Upsilon}^{\text{gmaniso}} \tag{71.142}$$

which rearranges to

$$N^2\, \boldsymbol{\Upsilon} \cdot \boldsymbol{\Upsilon}^{\text{gmaniso}} = -c^2\, \partial_z(\boldsymbol{\Upsilon} \cdot \partial_z \boldsymbol{\Upsilon}) + c^2\, \partial_z \boldsymbol{\Upsilon} \cdot \partial_z \boldsymbol{\Upsilon} + N^2\, \boldsymbol{\Upsilon} \cdot \boldsymbol{\Upsilon}. \tag{71.143}$$

Integrating over a vertical column and making use of the homogeneous Dirichlet boundary conditions in equation (71.139) leads to

$$\frac{g}{\rho_\circ}\int \boldsymbol{\Upsilon}\cdot\nabla_{\!\mathsf{h}}\varrho\,\mathrm{d}z = -\int N^2\,\Delta\kappa_{\mathsf{gm}}(\hat{\boldsymbol{d}}\cdot\boldsymbol{S})\,(\hat{\boldsymbol{d}}\cdot\boldsymbol{\Upsilon})\,\mathrm{d}z + \int\left[c^2\,\partial_z\boldsymbol{\Upsilon}\cdot\partial_z\boldsymbol{\Upsilon} + N^2\,\boldsymbol{\Upsilon}\cdot\boldsymbol{\Upsilon}\right]\mathrm{d}z, \quad (71.144)$$

which can be rearranged into the equivalent form

$$\begin{aligned}&\frac{g}{\rho_\circ}\int \boldsymbol{\Upsilon}\cdot\nabla_{\!\mathsf{h}}\varrho\,\mathrm{d}z\\ &= \underbrace{\int\left[c^2\,\partial_z\boldsymbol{\Upsilon}\cdot\partial_z\boldsymbol{\Upsilon} + N^2\,(\boldsymbol{\Upsilon}\cdot\boldsymbol{\Upsilon} - (\hat{\boldsymbol{d}}\cdot\boldsymbol{\Upsilon})^2)\right]\mathrm{d}z}_{\text{positive semi-definite}} + \underbrace{\int N^2\,(\hat{\boldsymbol{d}}\cdot\boldsymbol{\Upsilon})\,\hat{\boldsymbol{d}}\cdot(\boldsymbol{\Upsilon}-\boldsymbol{S}\,\Delta\kappa_{\mathsf{gm}})\,\mathrm{d}z.}_{\text{sign indefinite}} \quad (71.145)\end{aligned}$$

The first term on the right hand side is positive semi-indefinite whereas the second term is sign indefinite. If the second term is positive, or smaller in magnitude than the first term, then the parameterization provides a column integrated sink of potential energy. Otherwise, potential energy for the column can increase. There are no existing numerical implementations of this scheme to determine its suitability for realistic ocean climate simulations.

Chapter 72

Ocean density and sea level

Conservative temperature, Θ, is the preferred means to measure the transport of enthalpy in the ocean (Section 26.11), and salinity, S, measures the concentration of dissolved salt matter. These two scalar fields are referred to as *active* tracers as they both impact density and in turn affect pressure and ocean currents. In this chapter we study how the evolution of Θ and S affects density as well as buoyancy. As part of this study, we examine how to compute air-sea bouyancy fluxes.

Θ and S are conservative tracers so that the net changes in potential enthalpy and salt over the global ocean domain arise from net imbalances in their boundary fluxes. Likewise, ocean mass is a conserved field, with global mass changes arising from imbalances in boundary mass fluxes such as those occuring from increases in land ice melt. However, ocean volume, and hence ocean density and buoyancy, are not conserved fields. Consequently, ocean volume can change even if there is no net volume transferred to the ocean. These points have direct impact on how global mean sea level is affected by ocean processes such as mixing and heating, with the rudiments presented in this chapter.

CHAPTER GUIDE

Basic notions of thermodynamics, such as Section 26.11, motivate the use of Conservative Temperature, Θ, as a measure of ocean enthalpy transfer, rather than *in situ* temperature or potential temperature. We also make use of the ideas of parameterized turbulent mixing discussed in Chapters 68 and 71 when formulating the budget equations for Θ and S. We use Cartesian tensors to reduce the mathematical overhead. Also note that we use subscripts on specific volume, ν, and density, ρ, for partial derivatives with respect to Θ and S. This is the only chapter in this book that makes use of subscript notation for partial derivatives, and we only use it for thermodynamic derivatives.

72.1 Loose threads

- Schematics for cabbeling and thermobarocity.

72.2 Material evolution of *in situ* density

Changes to the *in situ* density of seawater affects pressure forces in the ocean as well as the volume occupied by the ocean fluid (i.e., sea level). As discussed in Section 30.3.2, we write the seawater equation of state for density as a function of salinity, S, and Conservative Temperature, Θ, where Conservative Temperature is the potential enthalpy divided by a constant heat capacity (see Section 26.11.3 and *McDougall* (2003); *IOC et al.* (2010)). We thus make use of the empirical relation for the seawater density in the functional form

$$\rho = \rho(S, \Theta, p), \tag{72.1}$$

where S is the salinity rather than the salt concentration ($S = 1000\,\mathsf{S}$).

We formulate the material evolution of density as weighted by the specific volume[1]

$$\nu = \rho^{-1}, \tag{72.2}$$

so that we study

$$\frac{\mathrm{D} \ln \rho}{\mathrm{D}t} = \frac{\partial \ln \rho}{\partial \Theta} \frac{\mathrm{D}\Theta}{\mathrm{D}t} + \frac{\partial \ln \rho}{\partial S} \frac{\mathrm{D}S}{\mathrm{D}t} + \frac{\partial \ln \rho}{\partial p} \frac{\mathrm{D}p}{\mathrm{D}t} \tag{72.3a}$$

$$= -\alpha \frac{\mathrm{D}\Theta}{\mathrm{D}t} + \beta \frac{\mathrm{D}S}{\mathrm{D}t} + \frac{\dot{p}}{\rho\, c_{\mathrm{s}}^2}. \tag{72.3b}$$

[1] In other chapters we write the specific volume as $\nu_{\mathrm{s}} = 1/\rho$ to distinguish it from ν that is used for kinematic viscosity. However, in this chapter we write $\nu = 1/\rho$ to enable a shorthand for partial derivatives as defined by equation (72.8). We have no use kinematic viscosity in this chapter.

In this equation we introduced the thermal expansion coefficient, the haline contraction coefficient, the squared speed of sound, and the vertical pseudo-velocity in pressure

$$\alpha = -\left[\frac{\partial \ln \rho}{\partial \Theta}\right]_{p,S} \qquad \beta = \left[\frac{\partial \ln \rho}{\partial S}\right]_{p,\Theta} \qquad c_s^2 = \left[\frac{\partial p}{\partial \rho}\right]_{S,\Theta} \qquad \dot{p} = \frac{\mathrm{D}p}{\mathrm{D}t}. \tag{72.4}$$

For the the remainder of this section we unpack the processes contributing to the density material time evolution appearing in equation (72.3).

72.2.1 Material changes to pressure

To garner some exposure to the physics of $\dot{p}$ as it appears in equation (72.3), we consider the special case of a hydrostatic fluid, where the volume per time per horizontal area of fluid crossing a surface of constant hydrostatic pressure is given by (see Section 64.3.6)

$$w^{(\mathrm{p})} = \frac{\partial z}{\partial p}\frac{\mathrm{D}p}{\mathrm{D}t} = -(\rho\, g)^{-1}\, \dot{p}. \tag{72.5}$$

The transport measured by $w^{(\mathrm{p})}$ is the pressure-coordinate analog of the vertical velocity component, $w = \mathrm{D}z/\mathrm{D}t$, that arises in a geopotential coordinate representation of the vertical. That is, fluid moving into regions of increasing hydrostatic pressure ($\dot{p} > 0$) represents downward movement of fluid, with $w^{(\mathrm{p})} < 0$ in this case. Conversely, motion into decreasing hydrostatic pressure represents upward motion, with $w^{(\mathrm{p})} > 0$. This vertical movement generally occurs in the presence of waves, currents, and mixing; i.e., both reversible and irreversible processes give rise to vertical motion.

72.2.2 Material changes to Θ and S

We now focus on the salinity and temperature contributions to the evolution of *in situ* density. To do so, assume that the material evolution of Θ and S are given by the convergence of a subgrid scale flux

$$\rho \frac{\mathrm{D}\Theta}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}^{(\Theta)} \tag{72.6a}$$

$$\rho \frac{\mathrm{D}S}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}^{(\mathrm{S})}. \tag{72.6b}$$

The Conservative Temperature equation (72.6a) was derived in Section 26.11, whereas the Absolute Salinity equation (72.6b) follows from our derivation of the tracer equation in Section 20.1.[2]

72.2.3 General expression for density changes

The expressions (72.6a) and (72.6b) for material changes in Θ and S then lead to

$$-\alpha \frac{\mathrm{D}\Theta}{\mathrm{D}t} + \beta \frac{\mathrm{D}S}{\mathrm{D}t} = \nu_\Theta \nabla \cdot \boldsymbol{J}^{(\Theta)} + \nu_S \nabla \cdot \boldsymbol{J}^{(\mathrm{S})} \tag{72.7a}$$

$$= \nabla \cdot [\nu_\Theta \boldsymbol{J}^{(\Theta)} + \nu_S \boldsymbol{J}^{(\mathrm{S})}] - \left[\boldsymbol{J}^{(\Theta)} \cdot \nabla \nu_\Theta + \boldsymbol{J}^{(\mathrm{S})} \cdot \nabla \nu_S\right] \tag{72.7b}$$

[2] We here ignore remineralization processes that can contribute to a source term in the salinity equation (72.6b). Such source terms are discussed in *IOC et al.* (2010).

where again $\nu = \rho^{-1}$ is the specific volume and its partial derivatives are written

$$\nu_\Theta = \frac{\partial \nu}{\partial \Theta} = \frac{\alpha}{\rho} \qquad \text{and} \qquad \nu_S = \frac{\partial \nu}{\partial S} = -\frac{\beta}{\rho}. \tag{72.8}$$

Bringing the above results together leads to the density equation

$$\frac{\mathrm{D} \ln \rho}{\mathrm{D}t} - \frac{\dot{p}}{\rho \, c_{\mathrm{s}}^2} = \nabla \cdot [\nu_\Theta \, \boldsymbol{J}^{(\Theta)} + \nu_S \, \boldsymbol{J}^{(S)}] - \left[\boldsymbol{J}^{(\Theta)} \cdot \nabla \nu_\Theta + \boldsymbol{J}^{(S)} \cdot \nabla \nu_S\right], \tag{72.9}$$

which has the equivalent form

$$\frac{\mathrm{D} \rho}{\mathrm{D}t} - \frac{\dot{p}}{c_{\mathrm{s}}^2} = \nabla \cdot [\alpha \, \boldsymbol{J}^{(\Theta)} - \beta \, \boldsymbol{J}^{(S)}] - \left[\boldsymbol{J}^{(\Theta)} \cdot \nabla \alpha - \boldsymbol{J}^{(S)} \cdot \nabla \beta\right]. \tag{72.10}$$

We brought the source term from motion across pressure surfaces (Section 72.2.1) onto the left hand side, as this term appears in the absence of subgrid processes. The first term on the right hand side represents the divergence of a buoyancy flux due to subgrid scale fluxes of Conservative Temperature and salinity. In turn, density increases in regions where the buoyancy flux diverges (e.g., Θ reducing and S increasing). These fluxes arise from a variety of mixing processes, some of which are surveyed in Section 71.1.1. The second term on the right hand side of equations (72.9) and (72.10) relates to properties of the locally referenced potential density surface. We study this source term in Section 72.3 as it appears from the neutral diffusion process. Further effects arise from unresolved eddy-induced stirring, with that process contributing to the material time derivative operator to render a residual mean velocity (Section 71.1.4).

72.2.4 Unpacking the subgrid contributions

Recall from Section 71.1 that the subgrid scale fluxes are generally written in terms of a second order eddy transport tensor, $\boldsymbol{E}$, so that

$$\boldsymbol{J}^{(\Theta)} = -\rho \, \boldsymbol{E} \cdot \nabla \Theta \quad \text{and} \quad \boldsymbol{J}^{(S)} = -\rho \, \boldsymbol{E} \cdot \nabla S. \tag{72.11}$$

Furthermore, $\boldsymbol{E}$ is typically decomposed as in equation (71.8) into a symmetric downgradient diffusion tensor, $\boldsymbol{K}$, and an anti-symmetric skew diffusion (or stirring) tensor, $\boldsymbol{A}$,

$$\boldsymbol{E} = \boldsymbol{K} + \boldsymbol{A}. \tag{72.12}$$

We decompose the contributions to density according to these subgrid tensors using the following manipulations

$$\begin{aligned} \frac{\mathrm{D} \rho}{\mathrm{D}t} - \frac{\dot{p}}{c_{\mathrm{s}}^2} &= \alpha \, \nabla \cdot \boldsymbol{J}^{(\Theta)} - \beta \nabla \cdot \boldsymbol{J}^{(S)} && \text{(72.13a)} \\ &= -\alpha \, \nabla \cdot (\rho \, \boldsymbol{E} \cdot \nabla \Theta) + \beta \, \nabla \cdot (\rho \, \boldsymbol{E} \cdot \nabla S). && \text{(72.13b)} \end{aligned}$$

Expanding the Θ term leads to

$$\begin{aligned} \alpha \, \nabla \cdot \boldsymbol{J}^{(\Theta)} &= -\alpha \, \nabla \cdot (\rho \, \boldsymbol{E} \cdot \nabla \Theta) && \text{(72.14a)} \\ &= -\alpha \, \nabla \cdot (\rho \, \boldsymbol{A} \cdot \nabla \Theta) - \alpha \, \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla \Theta) && \text{(72.14b)} \\ &= -\alpha \, \nabla \cdot (\rho \, \boldsymbol{A}) \cdot \nabla \Theta - \alpha \, \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla \Theta), && \text{(72.14c)} \\ &= -\alpha \, \boldsymbol{v}^* \cdot \nabla \Theta - \alpha \, \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla \Theta). && \text{(72.14d)} \end{aligned}$$

To reach this result we made use of the identities

$$\begin{aligned}
\nabla \cdot (\rho \, \boldsymbol{A} \cdot \nabla \Theta) &= \partial_m (\rho \, A^{mn} \, \partial_n \Theta) && \text{expose tensor indices} && (72.15a)\\
&= \partial_m (\rho \, A^{mn}) \, \partial_n \Theta + \rho \, A^{mn} \, \partial_m \partial_n \Theta && \text{product rule} && (72.15b)\\
&= \partial_m (\rho \, A^{mn}) \, \partial_n \Theta && A^{mn} \, \partial_m \partial_n \Theta = 0 && (72.15c)\\
&= -\rho \, \boldsymbol{v}^* \cdot \nabla \Theta && \partial_m (\rho \, A^{mn}) = -\rho \, v^{*n}. && (72.15d)
\end{aligned}$$

In the final equality we introduced the density weighted eddy-induced velocity, $\rho \, \boldsymbol{v}^*$, defined by equation (71.11). The same manipulations for the salinity term lead to

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} - \frac{\dot{p}}{c_s^2} + \rho \boldsymbol{v}^* \cdot (-\alpha \nabla \Theta + \beta \nabla S) = -\alpha \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla \Theta) + \beta \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla S). \tag{72.16}$$

We can write this expression in terms of the residual mean material time operator

$$\frac{\mathrm{D}^\dagger}{\mathrm{D}t} = \partial_t + \boldsymbol{v}^\dagger \cdot \nabla = \frac{\mathrm{D}}{\mathrm{D}t} + \boldsymbol{v}^* \cdot \nabla \tag{72.17}$$

through adding and subtracting $c_s^{-2} \, \boldsymbol{v}^* \cdot \nabla p$

$$\rho \, \boldsymbol{v}^* \cdot (-\alpha \nabla \Theta + \beta \nabla S) = \boldsymbol{v}^* \cdot (-\rho \, \alpha \nabla \Theta + \rho \, \beta \nabla S + c_s^{-2} \, \nabla p) - c_s^{-2} \, \boldsymbol{v}^* \cdot \nabla p = \boldsymbol{v}^* \cdot (\nabla \rho - c_s^{-2} \, \nabla p), \tag{72.18}$$

which then leads to

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} - \frac{\dot{p}}{c_s^2} + \rho \boldsymbol{v}^* \cdot (-\alpha \nabla \Theta + \beta \nabla S) = \frac{\mathrm{D}^\dagger \rho}{\mathrm{D}t} - \frac{1}{c_s^2} \frac{\mathrm{D}^\dagger p}{\mathrm{D}t}, \tag{72.19}$$

so that

$$\frac{\mathrm{D}^\dagger \rho}{\mathrm{D}t} - \frac{1}{c_s^2} \frac{\mathrm{D}^\dagger p}{\mathrm{D}t} = -\alpha \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla \Theta) + \beta \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla S). \tag{72.20}$$

Transport from the symmetric tensor, $\boldsymbol{K}$, corresponds to diffusion so long as the tensor is positive definite. The diffusion operator in the residual mean evolution equation (72.20) can be written

$$\begin{aligned}
&-\alpha \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla \Theta) + \beta \nabla \cdot (\rho \, \boldsymbol{K} \cdot \nabla S)\\
&\qquad = \nabla \cdot [\rho \, \boldsymbol{K} \cdot (-\alpha \nabla \Theta + \beta \nabla S)] + \rho \, \nabla \alpha \cdot \boldsymbol{K} \cdot \nabla \Theta - \rho \, \nabla \beta \cdot \boldsymbol{K} \cdot \nabla S, \qquad (72.21)
\end{aligned}$$

so that the *in situ* density evolves according to

$$\frac{\mathrm{D}^\dagger \rho}{\mathrm{D}t} - \frac{1}{c_s^2} \frac{\mathrm{D}^\dagger p}{\mathrm{D}t} = \underbrace{-\nabla \cdot [\rho \, \boldsymbol{K} \cdot (\alpha \nabla \Theta - \beta \nabla S)]}_{\text{conservative processes}} + \underbrace{\rho \, \nabla \alpha \cdot \boldsymbol{K} \cdot \nabla \Theta - \rho \, \nabla \beta \cdot \boldsymbol{K} \cdot \nabla S.}_{\text{sources from nonlinear EOS processes}} \tag{72.22}$$

We now discuss the physical processes associated with the right hand side terms.

- LINEAR EQUATION OF STATE: A linear equation of state has $\nabla \alpha = \nabla \beta = 0$ and is independent of pressure, so that the evolution equation (72.22) takes the form

  $$\frac{\mathrm{D}^\dagger \rho}{\mathrm{D}t} = -\nabla \cdot [\rho \, \boldsymbol{K} \cdot (\alpha \nabla \Theta - \beta \nabla S)] \, . \tag{72.23}$$

  Under the residual mean transport with a linear equation of state, density remains materially constant in the absence of any diffusion.

- NONLINEAR EQUATION OF STATE: A nonlinear equation of state is characterized by spatially

dependent thermal expansion and haline contraction coefficients. Mixing of Θ and S in the presence of a nonlinear equation of state generally gives rise to material evolution of *in situ* density through *cabbeling* and *thermobaricity* (*McDougall*, 1987b). We offer a summary of these processes in Section 72.3.

- NEUTRAL DIFFUSION:

  Neutral diffusion from Section 71.4 maintains a density-compensated diffusive flux of Θ and S so that

  $$\boldsymbol{K}^{\text{neutral}} \cdot (\alpha \nabla\Theta - \beta \nabla S) = 0. \tag{72.24}$$

  Hence, neutral diffusion leaves *in situ* density changed only via the nonlinear equation of state processes.

- ISOTROPIC SMALL SCALE DIFFUSION:

  As discussed in Section 71.1.3, it is common to parameterize fine scale mixing processes using an isotropic diffusivity so that the diffusion tensor is given by

  $$\boldsymbol{K}^{\text{iso}} = \kappa \, \mathbb{I}, \tag{72.25}$$

  where $\mathbb{I}$ is the unit tensor and $\kappa > 0$ is the isotropic eddy diffusivity.

72.2.5 Synthesis of the density equation

In summary, the material time evolution equation for *in situ* density in the presence of subgrid scale processes takes the form

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = \underbrace{\frac{1}{c_s^2}\frac{\mathrm{D}p}{\mathrm{D}t}}_{\text{compressibility}} \underbrace{- \boldsymbol{v}^* \cdot (-\alpha\nabla\Theta + \beta\nabla S)}_{\text{eddy-induced advection}} \underbrace{- \nabla \cdot [\rho\, \kappa\, (-\alpha\, \nabla\Theta + \beta\, \nabla S)]}_{\text{small scale diffusive mixing}} + \underbrace{\rho\, \nabla\alpha \cdot \boldsymbol{K} \cdot \nabla\Theta - \rho\, \nabla\beta \cdot \boldsymbol{K} \cdot \nabla S.}_{\text{nonlinear EOS processes from eddy mixing}} \tag{72.26}$$

We thus have the following physical processes contributing to the evolution of *in situ* density.

- ADIABATIC COMPRESSION: Material changes to pressure in the presence of a finite sound speed lead to changes in the fluid density.

- SMALL SCALE MIXING: Small scale mixing is parameterized by an isotropic diffusivity, κ. This diffusivity is the same for all tracers, with the exception of double-diffusive processes whereby material tracers (e.g., salinity, nutrients) have a diffusivity distinct from temperature (*Schmitt*, 1994). Given the dominance of vertical stratification over the horizontal, it is common to approximate the isotropic diffusion operator with a vertical diffusion operator (but see Section 4 of *McDougall et al.* (2014) for caveats).

- EDDY-INDUCED STIRRING: For subgrid scale stirring, such as from mesoscale (and sub-mesocale) eddies, we introduce a parameterized eddy-induced advection operator. When combined with the resolved advection, we are led to a residual mean material time derivative, $\mathrm{D}^\dagger/\mathrm{D}t$.

- EDDY-INDUCED DIFFUSION: Subgrid scale eddy-induced stirring leads to a direct cascade of Θ and S variance to the small scales. Mixing arising from this cascade is parameterized by neutral diffusion, whereby the diffusive fluxes of Θ and S are density compensated according to the constraint (72.24).

- NONLINEAR EOS PROCESSES: Mixing of Θ and S in the presence of a nonlinear equation of state means that *in situ* density evolves due to cabbeling and thermobaricity (Section 72.3). The dominant contributions to these processes arise from eddy induced mixing (i.e., neutral diffusion) (*McDougall*, 1987b), though small scale mixing also has a contribution.

72.3 Cabbeling and thermobaricity

We now return to the density equation (72.10)

$$\frac{\mathrm{D} \ln \rho}{\mathrm{D}t} - \frac{\dot{p}}{\rho \, c_s^2} = \nabla \cdot [\nu_\Theta \, \boldsymbol{J}^{(\Theta)} + \nu_S \, \boldsymbol{J}^{(S)}] - \left(\boldsymbol{J}^{(\Theta)} \cdot \nabla \nu_\Theta + \boldsymbol{J}^{(S)} \cdot \nabla \nu_S \right), \tag{72.27}$$

and here focus on Θ and S fluxes arising just from the neutral diffusion process described in Section 71.4. The neutrality condition (71.88) is a fundamental property of neutral diffusion, and it takes the following form in terms of specific volume

$$\nu_\Theta \, \boldsymbol{J}^{(\Theta)} + \nu_S \, \boldsymbol{J}^{(S)} = 0. \tag{72.28}$$

Consequently, neutral diffusion affects density evolution only through the source term

$$\left[\frac{\mathrm{D} \ln \rho}{\mathrm{D}t} \right]_{\text{ntrl diff}} = -\boldsymbol{J}^{(\Theta)} \cdot \nabla \nu_\Theta - \boldsymbol{J}^{(S)} \cdot \nabla \nu_S. \tag{72.29}$$

In the remainder of this section we manipulate the source term in this expression with the goal to identify the variety of physical processes associated with neutral diffusion in the presence of a nonlinear equation of state.

72.3.1 Basic manipulations

As a first step, eliminate the salt flux by using the neutrality condition (72.28)

$$\boldsymbol{J}^{(\Theta)} \cdot \nabla \nu_\Theta + \boldsymbol{J}^{(S)} \cdot \nabla \nu_S = \boldsymbol{J}^{(\Theta)} \cdot [\nu_S \, \nabla \nu_\Theta - \nu_\Theta \, \nabla \nu_S] / \nu_S. \tag{72.30}$$

Next, expand the gradients of the specific volume to write

$$\nabla \nu_\Theta = \nu_{\Theta\Theta} \, \nabla \Theta + \nu_{\Theta S} \, \nabla S + \nu_{\Theta p} \, \nabla p \quad \text{and} \quad \nabla \nu_S = \nu_{SS} \, \nabla S + \nu_{\Theta S} \, \nabla \Theta + \nu_{Sp} \, \nabla p, \tag{72.31}$$

so that

$$\begin{aligned} \nu_S \, \nabla \nu_\Theta - \nu_\Theta \, \nabla \nu_S = \nabla \Theta \, (\nu_S \, \nu_{\Theta\Theta} - \nu_\Theta \, \nu_{\Theta S}) \\ + \nabla S \, (\nu_S \, \nu_{\Theta S} - \nu_\Theta \, \nu_{SS}) + \nabla p \, (\nu_S \, \nu_{\Theta p} - \nu_\Theta \, \nu_{Sp}). \end{aligned} \tag{72.32}$$

We again make use of the neutrality condition (72.28), as well as the symmetry condition (71.89d) to write

$$\boldsymbol{J}^{(\Theta)} \cdot \nabla S \, (\nu_S \, \nu_{\Theta S} - \nu_\Theta \, \nu_{SS}) = -\boldsymbol{J}^{(\Theta)} \cdot \nabla \Theta \left[\nu_\Theta \, \nu_{\Theta S} - \nu_{SS} \frac{(\nu_\Theta)^2}{\nu_S} \right]. \tag{72.33}$$

Bringing these results together leads to

$$\begin{aligned} \boldsymbol{J}^{(\Theta)} \cdot \nabla \nu_\Theta + \boldsymbol{J}^{(S)} \cdot \nabla \nu_S = \boldsymbol{J}^{(\Theta)} \cdot \nabla p \, (\nu_{\Theta p} - \nu_{pS} \, \nu_\Theta / \nu_S) \\ + \boldsymbol{J}^{(\Theta)} \cdot \nabla \Theta \, [\nu_{\Theta\Theta} - 2 \, \nu_{\Theta S} \, \nu_\Theta / \nu_S + \nu_{SS} \, (\nu_\Theta / \nu_S)^2], \end{aligned} \tag{72.34}$$

which can be written in terms of density partial derivatives as

$$\boldsymbol{J}^{(\Theta)} \cdot \nabla \nu_\Theta + \boldsymbol{J}^{(S)} \cdot \nabla \nu_S = -\rho^{-2}\, \boldsymbol{J}^{(\Theta)} \cdot \nabla p\, (\rho_{\Theta p} - \rho_{pS}\, \rho_\Theta / \rho_S) \\ - \rho^{-2}\, \boldsymbol{J}^{(\Theta)} \cdot \nabla \Theta\, [\rho_{\Theta\Theta} - 2\, \rho_{\Theta S}\, \rho_\Theta / \rho_S + \rho_{SS}\, (\rho_\Theta / \rho_S)^2]. \quad (72.35)$$

72.3.2 A tidy form

We next write the bracket terms appearing in equation (72.35) in forms consistent with those written by *McDougall* (1987b). For that purpose, introduce the *thermobaricity* parameter (dimensions of inverse temperature times inverse pressure) whose form is given by

$$\mathcal{T} = \beta\, \partial_p \left[\frac{\alpha}{\beta}\right] \quad (72.36a)$$
$$= \frac{\partial \alpha}{\partial p} - \frac{\alpha}{\beta}\, \frac{\partial \beta}{\partial p} \quad (72.36b)$$
$$= \rho\, \nu_S\, \partial_p (\nu_\Theta / \nu_S) \quad (72.36c)$$
$$= -\rho^{-1}\, \rho_S\, \partial_p (\rho_\Theta / \rho_S) \quad (72.36d)$$
$$= -\rho^{-1}\, (\rho_{\Theta p} - \rho_{pS}\, \rho_\Theta / \rho_S), \quad (72.36e)$$

and the *cabbeling* parameter (dimensions of squared inverse temperature)

$$\mathcal{C} = \frac{\partial \alpha}{\partial \Theta} + 2 \frac{\alpha}{\beta} \frac{\partial \alpha}{\partial S} - \left(\frac{\alpha}{\beta}\right)^2 \frac{\partial \beta}{\partial S} \quad (72.37a)$$
$$= -\rho^{-1}\, [\rho_{\Theta\Theta} - 2\, \rho_{\Theta S}\, (\rho_\Theta / \rho_S) + \rho_{SS}\, (\rho_\Theta / \rho_S)^2] \quad (72.37b)$$
$$= \rho\, [\nu_{\Theta\Theta} - 2\, \nu_{\Theta S}\, (\nu_\Theta / \nu_S) + \nu_{SS}\, (\nu_\Theta / \nu_S)^2] \quad (72.37c)$$

to render the very compact result

$$\boldsymbol{J}^{(\Theta)} \cdot \nabla \nu_\Theta + \boldsymbol{J}^{(S)} \cdot \nabla \nu_S = \rho^{-1}\, \boldsymbol{J}^{(\Theta)} \cdot (\mathcal{T}\, \nabla p + \mathcal{C}\, \nabla \Theta) \quad (72.38)$$

which in turn yields the material evolution of *in situ* density due to neutral diffusion

$$\left[\frac{\mathrm{D}\rho}{\mathrm{D}t}\right]_{\text{ntrl diff}} = -\boldsymbol{J}^{(\Theta)} \cdot (\mathcal{T}\, \nabla p + \mathcal{C}\, \nabla \Theta). \quad (72.39)$$

72.3.3 Cabbeling

Consider the mixing of two seawater elements. Let the fluid elements separately have distinct Conservative Temperature and/or salinity, but equal locally referenced potential density. For a linear equation of state, whereby density is a linear function of Θ and S, then the resulting mixed fluid element has the same density as the unmixed separate elements. However, for a nonlinear equation of state, the mixed element generally has a different density. Furthermore, a property of seawater is that the density of the mixed element is greater than the unmixed elements. This densification upon mixing is a physical process known as *cabbeling* (*McDougall*, 1987b).

The sign definite nature of cabbeling (i.e., cabbeling always results in denser fluid elements after mixing) is a direct result of the geometry of the locally referenced potential density surface when viewed in Conservative Temperature and salinity space. This property in turn manifests

with the following inequality for the cabbeling parameter

$$\mathcal{C} = \frac{\partial \alpha}{\partial \Theta} + 2 \frac{\alpha}{\beta} \frac{\partial \alpha}{\partial S} - \left[\frac{\alpha}{\beta}\right]^2 \frac{\partial \beta}{\partial S} \geq 0. \tag{72.40}$$

Given the downgradient nature of the neutral diffusive fluxes, we have

$$\text{cabbeling} \equiv -\mathcal{C}\, \boldsymbol{J}^{(\Theta)} \cdot \nabla \Theta \geq 0, \tag{72.41}$$

thus providing a mathematical expression for the cabbeling source (with dimensions of density per time). That is, cabbeling results in a positive material evolution of density; i.e., density increases due to cabbeling. An increase in the density within a column of fluid results in the reduction of the sea level due to compression of the column.

72.3.4 Thermobaricity

The thermobaricity parameter

$$\mathcal{T} = \beta\, \partial_p(\alpha/\beta) \tag{72.42}$$

is nonzero due to pressure dependence of the ratio of the thermal expansion coefficient to the haline contraction coefficient. As both thermal and haline effects are present, the parameter $\mathcal{T}$ is more precisely split into two terms

$$\begin{aligned} \mathcal{T} &= \frac{\partial \alpha}{\partial p} - \frac{\alpha}{\beta} \frac{\partial \beta}{\partial p} \\ &= -\frac{\rho_{\Theta p}}{\rho} + \frac{\rho_\Theta}{\rho_S} \frac{\rho_{pS}}{\rho}. \end{aligned} \tag{72.43}$$

Thermobaricity is the common name for the sum, since pressure variations in the thermal expansion coefficient dominate those of the haline contraction coefficient. The thermal expansion coefficient generally increases as pressure increases, thus making the thermobaric parameter positive.

Since the neutral gradient of Θ need not be oriented in a special manner relative to the neutral gradient of pressure, there is no sign-definite nature to the thermobaricity source term (with units of density per time)

$$\text{thermobaricity} \equiv -\mathcal{T}\, \boldsymbol{J}^{(\Theta)} \cdot \nabla p \tag{72.44}$$

appearing in equation (72.38). Thus, thermobaricity can either increase or decrease density, depending on details of the density and fluxes. However, as noted by *McDougall and You* (1990), thermobaricity typically increases density in much of the World Ocean.

72.3.5 Comments

Griffies and Greatbatch (2012) discuss the impacts on global mean sea level from thermobaricity and cabbeling as diagnosed from an ocean model. Given that cabbeling always densifies and thermobaricity is also dominated by densification, these processes lead to a general reduction in global mean sea level. *Klocker and McDougall* (2010a), *Groeskamp et al.* (2016), and *Groeskamp et al.* (2019) diagnose cabbeling and thermobaricity from observational based measurements, with *Groeskamp et al.* (2019) also offering a more robust numerical method for performing that diagnostic calculation.

Cabbeling and thermobaricity lead to watermass transformation and associated transport of water across neutral directions. However, these processes are distinct from other mixing processes such as breaking gravity waves (Section 71.1). Namely, cabbeling and thermobarocity

arise from the transport of Θ and S by mesoscale eddies along neutral directions, which in turn is parameterized via neutral diffusion of these two active tracers. Transient mesoscale eddies impart a downscale cascade of tracer variance that is ultimately halted by irreversible molecular mixing, or microscale processes active before reaching the molecular level. This mixing is the ultimate cause for cabbeling and thermobaricity, with the overall strength of the cabbeling and thermobaricity determined by the strength of the mesoscale transport.

72.4 Salt and freshwater budgets

We specialize the kinematics of material tracers given in Section 20.4, here focusing on seawater, which we treat as a two component fluid comprised of salt and freshwater concentrations. We extend this discussion in Section 72.6 by studying the role of surface boundary salt, enthalpy, and water transports on changes in ocean buoyancy.

72.4.1 Salt and freshwater

Seawater is comprised of two material tracers: freshwater plus a suite of dissolved trace "salts". The ratio of salts is roughly constant over the World Ocean. We are thus able to make use of a single effective mass concentration known as the *salt concentration*[3]

$$\mathsf{S} = \frac{\text{mass of salt}}{\text{mass of seawater}} = \frac{\text{mass of salt}}{\text{mass of freshwater} + \text{mass of salt}} \tag{72.45}$$

to specify the amount of salt within an element of seawater. In practice oceanographers choose to work with the *salinity*,[4]

$$S = 1000\,\mathsf{S}, \tag{72.46}$$

which converts from typical salt concentrations of $\mathsf{S} = 0.035$ to a salinity of $S = 35$. The complement to salt concentration is the freshwater concentration or mass fraction for an element of seawater

$$\mathsf{F} = \frac{\text{mass of freshwater}}{\text{mass of seawater}} = \frac{\text{mass of freshwater}}{\text{mass of freshwater} + \text{mass of salt}} = 1 - \mathsf{S}. \tag{72.47}$$

Other trace matter occurs at very low concentrations so as to make seawater, in effect, a two-component fluid consisting of freshwater plus dissolved salt.[5] We here derive the mass budget for salt and freshwater as well as the associated kinematic boundary conditions.

72.4.2 Mass budgets

Following our discussion of the tracer equation in Section 20.1, the mass budget equations for an element of seawater take the form

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho\, \boldsymbol{v}) = 0 \qquad \text{seawater} \tag{72.48}$$

$$\frac{\partial (\rho\, \mathsf{S})}{\partial t} + \nabla \cdot (\rho\, \boldsymbol{v}\, \mathsf{S} + \boldsymbol{J}^{(\mathsf{S})}) = 0 \qquad \text{salt} \tag{72.49}$$

[3] We use the salt concentration, S, in this section to avoid 1/1000 factors needed if working with salinity, $S = 1000\,\mathsf{S}$.

[4] More precisely, the salinity, S, as defined by equation (72.46) is the *Absolute Salinity*. Absolute Salinity is distinct from the *practical salinity* determined by conductivity measurements. *IOC et al.* (2010) provides a full accounting of the theory and practice of ocean salinity.

[5] See *IOC et al.* (2010) for more discussion of the variations of salt concentration ratios over the ocean, as well as the impacts from biogeochemical tracers.

$$\frac{\partial(\rho \mathsf{F})}{\partial t} + \nabla \cdot (\rho \boldsymbol{v} \mathsf{F} + \boldsymbol{J}^{(\mathsf{F})}) = 0 \qquad \text{freshwater.} \tag{72.50}$$

Equation (72.48) is the mass budget for seawater and equation (72.49) is the mass budget for salt. The freshwater budget (72.50) is derived by subtracting the salt budget (72.49) from the seawater mass budget (72.48). Hence, only two of the three mass budget equations (72.48)-(72.50) are independent.

We make use of the barycentric velocity in the above conservation laws, where the barycentric velocity for the ocean is given by

$$\boldsymbol{v} = \mathsf{S}\, \boldsymbol{v}^{(\mathsf{S})} + \mathsf{F}\, \boldsymbol{v}^{(\mathsf{F})}. \tag{72.51}$$

The velocities $\boldsymbol{v}^{(\mathsf{S})}$ and $\boldsymbol{v}^{(\mathsf{F})}$ are, respectively, the molecular center of mass velocities for salt and freshwater within a fluid element, in which case

$$\frac{\partial \mathsf{S}}{\partial t} + \boldsymbol{v}^{(\mathsf{S})} \cdot \nabla \mathsf{S} = 0 \qquad \text{and} \qquad \frac{\partial \mathsf{F}}{\partial t} + \boldsymbol{v}^{(\mathsf{F})} \cdot \nabla \mathsf{F} = 0. \tag{72.52}$$

Furthermore, the fluxes $\boldsymbol{J}^{(\mathsf{S})}$ and $\boldsymbol{J}^{(\mathsf{F})}$ arise from the difference between the salt and freshwater velocities from the barycentric velocity

$$\boldsymbol{J}^{(\mathsf{S})} = \rho \mathsf{S} \, (\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v}) \qquad \text{and} \qquad \boldsymbol{J}^{(\mathsf{F})} = \rho \mathsf{F} \, (\boldsymbol{v}^{(\mathsf{F})} - \boldsymbol{v}). \tag{72.53}$$

These fluxes are often parameterized by downgradient diffusive fluxes

$$\boldsymbol{J}^{(\mathsf{S})} = -\rho \boldsymbol{K} \cdot \nabla \mathsf{S} \qquad \text{and} \qquad \boldsymbol{J}^{(\mathsf{F})} = -\rho \boldsymbol{K} \cdot \nabla \mathsf{F}, \tag{72.54}$$

where $\boldsymbol{K}$ is the kinematic diffusivity tensor for salt in seawater, which is a positive definite symmetric tensor. We use the same diffusivity tensor for salt and freshwater since the diffusion of one is balanced by the other. When concerned with molecular processes, the diffusivity tensor is isotropic with diffusivities set by the molecular value of 10^{-9} m^2 s^{-1}. However, as discussed in Section 71.1, the eddy diffusivity is far larger than the molecular diffusivity in the presence of turbulent eddy processes, which also introduces anisotropies to the diffusion tensor.

The advective flux of seawater is comprised of a salt flux plus a freshwater flux

$$\rho \boldsymbol{v} = \rho \mathsf{S}\, \boldsymbol{v}^{(\mathsf{S})} + \rho \mathsf{F}\, \boldsymbol{v}^{(\mathsf{F})}. \tag{72.55}$$

Conversely, the salt flux and freshwater flux can be represented as a *non-advective flux* plus an advective flux where advection is defined by the barycentric velocity

$$\rho \mathsf{S}\, \boldsymbol{v}^{(\mathsf{S})} = \rho \mathsf{S} \, (\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v}) + \rho \mathsf{S}\, \boldsymbol{v} = \boldsymbol{J}^{(\mathsf{S})} + \rho \mathsf{S}\, \boldsymbol{v} \tag{72.56a}$$

$$\rho \mathsf{F}\, \boldsymbol{v}^{(\mathsf{F})} = \rho \mathsf{F} \, (\boldsymbol{v}^{(\mathsf{F})} - \boldsymbol{v}) + \rho \mathsf{F}\, \boldsymbol{v} = \boldsymbol{J}^{(\mathsf{F})} + \rho \mathsf{F}\, \boldsymbol{v}. \tag{72.56b}$$

The non-advective fluxes, $\boldsymbol{J}^{(\mathsf{S})}$ and $\boldsymbol{J}^{(\mathsf{F})}$, lead to an exchange of mass with zero net movement of mass. In contrast, the advective flux moves mass as determined by the barycentric velocity. Furthermore, note that the center of mass velocities, $\boldsymbol{v}^{(\mathsf{S})}$ and $\boldsymbol{v}^{(\mathsf{F})}$, offer a conceptual framework of use to formulate the kinematic boundary conditions. Even so, they offer no new information beyond that contained in the fluxes $\boldsymbol{J}^{(\mathsf{S})}$ and $\boldsymbol{J}^{(\mathsf{F})}$.

72.5 Surface boundary conditions for S and Θ

In this section we summarize the surface boundary conditions holding for the salinity and Conservative Temperature equations. This treatment complements that given in Section 20.4.3.

72.5.1 Salt and freshwater

In deriving the boundary condition (20.83) in Section 19.6.3, we made use of the barycentric velocity, $\boldsymbol{v}$, for an element of seawater. We can garner further kinematic insights into the two-component ocean system by decomposing the total mass flux into contributions from salt and freshwater

$$\mathcal{Q}_{\mathsf{m}} = \mathcal{Q}_{\mathsf{S}} + \mathcal{Q}_{\mathsf{F}}, \tag{72.57}$$

and by introducing the center of mass velocities for salt and freshwater according to

$$\begin{aligned}
-\mathcal{Q}_{\mathsf{m}} &= \rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} && \text{(72.58a)}\\
&= \rho\,[\mathsf{S}\,\boldsymbol{v}^{(\mathsf{S})} + \mathsf{F}\,\boldsymbol{v}^{(\mathsf{F})} - \boldsymbol{v}^{(\eta)}] \cdot \hat{\boldsymbol{n}} && \text{(72.58b)}\\
&= \rho\,[\mathsf{S}\,(\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v}^{(\eta)} + \boldsymbol{v}^{(\eta)}) + \mathsf{F}\,\boldsymbol{v}^{(\mathsf{F})} - \boldsymbol{v}^{(\eta)}] \cdot \hat{\boldsymbol{n}} && \text{(72.58c)}\\
&= \mathsf{S}\,\rho\,(\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} + (1-\mathsf{S})\,\rho\,(\boldsymbol{v}^{(\mathsf{F})} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} && \text{(72.58d)}\\
&= \mathsf{S}\,\rho\,(\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} + \mathsf{F}\,\rho\,(\boldsymbol{v}^{(\mathsf{F})} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} && \text{(72.58e)}\\
&\equiv -(\mathcal{Q}_{\mathsf{S}} + \mathcal{Q}_{\mathsf{F}}), && \text{(72.58f)}
\end{aligned}$$

where we wrote

$$\begin{aligned}
\mathsf{S}\,\rho\,(\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} &= -\mathcal{Q}_{\mathsf{S}} && \text{(72.59a)}\\
\mathsf{F}\,\rho\,(\boldsymbol{v}^{(\mathsf{F})} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} &= -\mathcal{Q}_{\mathsf{F}}. && \text{(72.59b)}
\end{aligned}$$

In these equations, we introduced the velocity, $\boldsymbol{v}^{(\eta)}$, of a point fixed to the free surface. We only need the projection of this velocity in the outward normal direction, which is written by equation (19.92)

$$\boldsymbol{v}^{(\eta)} \cdot \hat{\boldsymbol{n}} = \frac{\partial\eta/\partial t}{|\nabla(z-\eta)|} = \frac{\partial\eta/\partial t}{\sqrt{1+|\nabla\eta|^2}} \Longrightarrow \boldsymbol{v}^{(\eta)} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \partial_t \eta\, \mathrm{d}A, \tag{72.60}$$

where $\mathrm{d}\mathcal{S}$ is the area element on the free surface and $\mathrm{d}A$ is its horizontal projection. Note that in many regions, the ocean surface is impermeable to salt, in which case the ocean surface acts as a material surface in terms of the salt velocity

$$\rho\,(\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{zero surface salt flux.} \tag{72.61}$$

The key exception to this boundary condition concerns sea ice, whereby salt is exchanged between liquid seawater and sea ice upon the melting or freezing of ice.

For most applications, it is preferable to make use of equation (72.56a) to eliminate the salt velocity $\boldsymbol{v}^{(\mathsf{S})}$ in favor of the non-advective flux $\boldsymbol{J}^{(\mathsf{S})} = \rho\,\mathsf{S}\,(\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v})$, in which case the kinematic boundary condition (72.59a) takes the form

$$-\mathcal{Q}_{\mathsf{S}} = \mathsf{S}\,\rho\,(\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} = \mathsf{S}\,\rho\,(\boldsymbol{v}^{(\mathsf{S})} - \boldsymbol{v} + \boldsymbol{v} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}} = \boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} - \mathsf{S}\,\mathcal{Q}_{\mathsf{m}}. \tag{72.62}$$

Turning this equation around leads to the non-advective flux

$$\boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} = \mathsf{S}\,\mathcal{Q}_{\mathsf{m}} - \mathcal{Q}_{\mathsf{S}} = \mathsf{S}\,\mathcal{Q}_{\mathsf{F}} - \mathsf{F}\,\mathcal{Q}_{\mathsf{S}}, \tag{72.63}$$

which relates the mass transport crossing the ocean surface at $z = \eta$ (right hand side) to the non-advective salt transport on the ocean side of the surface boundary (left hand side). A form of this equation was also given by equation (20.85). To support intuition and to check signs, consider the case with $\mathcal{Q}_{\mathsf{S}} = 0$ so that $\boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} = \mathsf{S}\,\mathcal{Q}_{\mathsf{F}}$. This expression means there is an upward non-advective flux of salt ($\boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} > 0$) on the ocean side of the $z = \eta$ boundary in the presence of an input of freshwater through the ocean surface ($\mathsf{S}\,\mathcal{Q}_{\mathsf{F}} > 0$). For the converse, let $\mathcal{Q}_{\mathsf{F}} = 0$ so

that $\boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} = -\mathsf{F}\, \mathcal{Q}_{\mathsf{S}}$. Now, there is a downward non-advective flux of salt ($\boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} < 0$) on the ocean side of the $z = \eta$ boundary in the presence of salt input through the ocean surface ($\mathsf{F}\, \mathcal{Q}_{\mathsf{S}} > 0$).

72.5.2 The non-advective salt flux boundary condition

The above properties of boundary mass transfer result from the kinematic property of a fluid element whose mass is constant, and so the transfer of freshwater across the boundary of a fluid element is compensated by an opposite transfer of salt. The ocean boundary interface acts as a boundary for the fluid elements adjacent to the surface. Hence, to move mass across the $z = \eta$ interface requires mass to be replenished to the surface fluid elements.

Diffusive closure for the non-advective flux

Consider an ocean without any mixing, such as for a perfect fluid. In this case, mass arriving to the ocean surface from $\mathcal{Q}_{\mathsf{m}} > 0$ will not be incorporated into the ambient ocean fluid, but instead will form a separate unmixed surface lens. When mass is exchanged across the ocean surface, mixing is required to incorporate the mass into the ambient ocean fluid. To determine the level of mixing, assume that $\boldsymbol{J}^{(\mathsf{S})}$ takes the form of a diffusive flux (72.54) so that the boundary condition (72.63) becomes

$$\boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} = -\rho\, [\boldsymbol{K} \cdot \nabla \mathsf{S}] \cdot \hat{\boldsymbol{n}} = \mathsf{S}\, \mathcal{Q}_{\mathsf{m}} - \mathcal{Q}_{\mathsf{S}} = \mathsf{S}\, \mathcal{Q}_{\mathsf{F}} - F\, \mathcal{Q}_{\mathsf{S}}. \tag{72.64}$$

This equation sets the level of diffusion on the ocean side of the surface boundary that is needed to generate the non-advective transport. The diffusive mixing of salt and freshwater mediate the transfer of mass across the ocean surface so to incorporate that mass into the ambient ocean fluid. For example, freshwater added to the ocean ($\mathcal{Q}_{\mathsf{F}} > 0$) diffuses downward as salt diffuses upward toward the surface.

Salt dissolved within the mass transport

In the case when salt is transported across the ocean boundary, as occurs with sea ice melting and formation, it does so largely dissolved in the water that is transported. There can also be a non-advective transport, such as via parameterized turbulent fluxes, so that the net salt flux is given by

$$\mathcal{Q}_{\mathsf{S}} = S_{\mathsf{m}}\, \mathcal{Q}_{\mathsf{m}} + \mathcal{Q}_{\mathsf{S}}^{\text{non-adv}}. \tag{72.65}$$

If there are more sources of this transfer then a relation such as this holds for each process. We are thus led to the net salt flux

$$\mathcal{Q}_{\mathsf{S}} = -[\rho\, \mathsf{S}\, (\boldsymbol{v} - \boldsymbol{v}^{(\eta)}) + \boldsymbol{J}^{(\mathsf{S})}] \cdot \hat{\boldsymbol{n}} = \mathsf{S}\, \mathcal{Q}_{\mathsf{m}} - \boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} = S_{\mathsf{m}}\, \mathcal{Q}_{\mathsf{m}} + \mathcal{Q}_{\mathsf{S}}^{\text{non-adv}}. \tag{72.66}$$

which leads to the non-advective salt flux on the ocean side of the boundary

$$-\boldsymbol{J}^{(\mathsf{S})} \cdot \hat{\boldsymbol{n}} = \mathcal{Q}_{\mathsf{S}}^{\text{non-adv}} + (S_{\mathsf{m}} - \mathsf{S})\, \mathcal{Q}_{\mathsf{m}}. \tag{72.67}$$

Figure 72.1 provides a schematic summary of the salt flux boundary condition. Furthermore, note that this boundary condition is consistent with that derived in Section 20.4.3 for a general tracer, in particular with equation (20.82).

Treatment in observational analyses and numerical models

In ocean climate modeling applications, the salt mass flux, $\mathcal{Q}_{\mathsf{S}}$, typically does not affect the kinematic boundary conditions. This approximation is reasonable given that the dominant

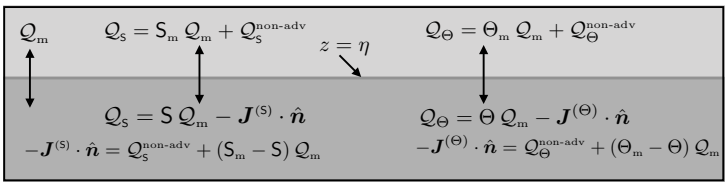

FIGURE 72.1: A schematic of an infinitesimal region of the ocean surface boundary at $z = \eta(x, y, t)$, with $z < \eta$ the ocean. $\mathcal{Q}_m\, dS = Q_m\, dA$ is the mass transport (mass per time) that crosses the interface and carries a tracer concentration. We depict the case for salt concentration, S, and Conservative Temperature, Θ, and the expressions for their net boundary fluxes. These boundary conditions are derived in Section 72.5.2 for salinity and Section 72.5.3 for Conservative Temperature.

contributor to the mass flux, $\mathcal{Q}_m$, is the freshwater. Even so, there remains a net salt transported across the ocean surface in the presence of sea ice melt and formation. The above boundary conditions, in particular equations (72.66) and (72.67), remain unchanged. Furthermore, it is necessary to specify the boundary tracer concentration, $S(z = \eta)$. For salt, this value is typically set equal to that within the ocean model surface grid cell. This choice is also common for observation-based studies.

72.5.3 Conservative Temperature boundary condition

Conservative Temperature, potential temperature, potential vorticity, and passive tracers each satisfy the tracer equation (72.49), with distinct tracer flux vectors $\boldsymbol{J}$. However, they are not material tracers and so the kinematic constraints holding for salt do not hold for these other tracers. We describe the thermodynamic properties of Conservative Temperature in Section 26.11 and the processes affecting its boundary fluxes in Section 72.6. Here we begin our treatment of this tracer by outlining its surface boundary condition.

As per the general discussion in Section 20.4.3, the net surface boundary flux of Conservative Temperature is written

$$\mathcal{Q}_\Theta = \Theta_m\,\mathcal{Q}_m + \mathcal{Q}_\Theta^{\text{non-adv}} = -[\rho\,\Theta\,(\boldsymbol{v} - \boldsymbol{v}^{(\eta)}) + \boldsymbol{J}^{(\Theta)}] \cdot \hat{\boldsymbol{n}} = \Theta\,\mathcal{Q}_m - \boldsymbol{J}^{(\Theta)} \cdot \hat{\boldsymbol{n}}. \tag{72.68}$$

In this equation, $\mathcal{Q}_\Theta^{\text{non-adv}}$ arises from the non-advective enthalpy fluxes outside the ocean domain that impact on the upper ocean interface, such as from radiant and turbulent fluxes, whereas Θ_m is the Conservative Temperature of the boundary mass flux. Rearrangement leads to the net expression for the non-advective flux on the ocean side of the upper ocean boundary

$$-\boldsymbol{J}^{(\Theta)} \cdot \hat{\boldsymbol{n}} = \mathcal{Q}_\Theta^{\text{non-adv}} + (\Theta_m - \Theta)\,\mathcal{Q}_m, \tag{72.69}$$

where $\Theta = \Theta(z = \eta)$ is the Conservative Temperature at the surface interface. A common assumption made for models and observational studies is to set $\Theta_m - \Theta(z = \eta) = 0$, in which case

$$-\boldsymbol{J}^{(\Theta)} \cdot \hat{\boldsymbol{n}} = \mathcal{Q}_\Theta^{\text{non-adv}} \quad \text{if} \quad \Theta_m = \Theta(z = \eta). \tag{72.70}$$

Figure 72.1 provides a schematic summary of the Θ flux boundary condition.

72.5.4 Comments and further reading

We make use of many results from this section when discussing surface ocean buoyancy fluxes in Section 72.6 and water mass transformation in Section 73.6. Furthermore, *Nurser and Griffies* (2019) offer further discussion of the kinematic boundary condition for salt and freshwater, with that paper motivated by questions related to water mass transformation considered in Section 73.6.

72.6 Surface boundary fluxes of buoyancy

As introduced in Chapter 30, buoyancy measures the gravitational acceleration of a fluid element relative to that of the fluid environment surrounding the element. A reduction in density for the fluid element is associated with an increase in buoyancy; that is, the fluid element becomes more *buoyant*. Changes in buoyancy arise through changes in density associated with temperature and salinity changes, with buoyancy changes computed relative to a fixed pressure level. In this way, buoyancy changes are directly related to processes that impact locally referenced potential density through changes in the temperature and salinity of a fluid element.

In this section we derive the equation describing the changes in ocean buoyancy due to enthalpy (commonly referred to as "heat"), salt, and water fluxes crossing the ocean surface boundary. For this purpose, we expose certain of the issues associated with coupling numerical models of the ocean, atmosphere, and land. A detailed treatment of boundary layer physics is well outside of our scope. We thus take a phenomenological perspective, developing budget equations but not diving into details of the turbulent exchange of matter and enthalpy across the ocean surface boundary. Similar, though simpler, considerations holds for the ocean bottom boundary, with this an insulating and material boundary except in regions of geothermal fluxes.

72.6.1 Outlining the surface boundary fluxes of enthalpy and salt

Broadly, the surface boundary fluxes are associated with the following physical processes.

- Turbulent processes transfer enthalpy through latent and sensible heating.
- Longwave radiation cools the upper ocean, with this radiation affected by the upper ocean skin temperature.
- Penetrative shortwave radiation is absorbed in seawater and so increases buoyancy in regions where the thermal expansion coefficient is positive.[6]
- All of the above processes are referred to as *non-advective* transports in that they are not associated with a net mass transport across the ocean surface. In contrast, advective processes transfer enthalpy and salt across the ocean surface through the transfer of mass.
- Salt is transferred between the liquid ocean and sea ice when sea ice melts and forms. This transfer is proportional to the water mass flux and the difference in salinity between the liquid ocean and solid sea ice. There may be additional turbulent salt fluxes as well, but there is a negligible transfer of salt associated with precipitation, evaporation, or river runoff.

72.6.2 Evolution from surface boundary fluxes

We now develop finite volume budget equations for potential enthalpy (via Conservative Temperature, Θ), salt, and seawater mass for a grid cell region next to the ocean surface, with a focus on contributions due to surface boundary fluxes. For that purpose, introduce the following quantities for a grid cell,

$$M = \int_{\text{cell}} \rho \, \mathrm{d}V = \langle \rho \rangle \, V \qquad V = \int_{\text{cell}} \mathrm{d}V = A \, \overline{h} \qquad A = \int_{\text{cell}} \mathrm{d}A \tag{72.71a}$$

$$\overline{h} \, A = \int_{\text{cell}} \left[\int_{\text{cell}} \mathrm{d}z \right] \mathrm{d}A \qquad \langle C \rangle \, M = \int_{\text{cell}} C \, \rho \, \mathrm{d}V, \tag{72.71b}$$

[6] The Baltic Sea is an outlier in the World Ocean, whose fresh and cold waters often realize a negative thermal expansion so that heating can increase density rather than reduce it.

so that $\langle \rho \rangle$ is the cell averaged density, $\langle C \rangle$ is the cell averaged tracer concentration, $\overline{h}$ is the cell area averaged thickness, V is the cell volume, and A is the cell horizontal area. These definitions allow us to write

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\text{cell}} \rho\, C\, \mathrm{d}V\right] = \frac{\mathrm{d}}{\mathrm{d}t}\left[\langle C \rangle\, M\right] = A\, \frac{\mathrm{d}}{\mathrm{d}t}\left[\overline{h}\, \langle C \rangle\, \langle \rho \rangle\right], \tag{72.72}$$

where the horizontal area of a cell is assumed to be constant in time and that the cell is bounded by vertical side walls. The surface boundary fluxes have similar grid cell area averages.

Focusing just on contributions from surface boundary transport leads to the budget equations

$$\partial_t(\rho\, h\, \Theta) = Q_{\mathsf{m}}\, \Theta_{\mathsf{m}} + Q_{\Theta}^{\text{non-adv}} \tag{72.73a}$$

$$\partial_t\,(\rho\, h\, S) = Q_{\mathsf{m}}\, S_{\mathsf{m}} + Q_{\mathsf{S}}^{\text{non-adv}} \tag{72.73b}$$

$$\partial_t\,(\rho\, h) = Q_{\mathsf{m}}, \tag{72.73c}$$

where we used a partial time derivative since we are holding the horizontal position fixed. Furthermore, we reduced notational clutter by dropping the angle brackets for volume average and the horizontal overline for area average. For a three-dimensional budget, the right hand side to these equations is combined with fluxes crossing interior cell boundaries. Finally, we wrote the fluxes as

$$Q_{\mathsf{m}}\, A = \mathcal{Q}_{\mathsf{m}}\, \mathcal{S} \quad \text{and} \quad Q_{\Theta}^{\text{non-adv}}\, A = \mathcal{Q}_{\Theta}^{\text{non-adv}}\, \mathcal{S} \quad \text{and} \quad Q_{\mathsf{S}}^{\text{non-adv}}\, A = \mathcal{Q}_{\mathsf{S}}^{\text{non-adv}}\, \mathcal{S}, \tag{72.74}$$

where $\mathcal{S}$ is the area on the free surface and A is the corresponding horizontal area of the grid cell.[7]

72.6.3 Buoyancy tendency from surface fluxes

For many purposes, it is of interest to quantify the impacts on ocean buoyancy arising from surface boundary fluxes. For that purpose, we here develop the budget for buoyancy in a surface model grid cell region, focusing on surface flux contributions.

Buoyancy has a local time tendency given by

$$-\frac{\rho_o}{g}\, \frac{\partial b}{\partial t} = \rho_\Theta\, \frac{\partial \Theta}{\partial t} + \rho_S\, \frac{\partial S}{\partial t}, \tag{72.75}$$

where we introduced the shorthand

$$\rho_\Theta = \left[\frac{\partial \rho}{\partial \Theta}\right]_{S,p} \qquad \text{and} \qquad \rho_S = \left[\frac{\partial \rho}{\partial S}\right]_{\Theta,p} \tag{72.76}$$

for the partial derivatives of density with respect to Conservative Temperature and salinity, respectively, each with pressure held constant. We wish to form an evolution equation for buoyancy at the ocean surface grid cell just due to the effects of surface forcing. For this purpose, multiply the temperature equation (72.73a) by ρ_Θ and add to the salinity equation (72.73b) multiplied by ρ_S

$$\rho_\Theta\left[\frac{\partial(\rho\, h\, \Theta)}{\partial t}\right] + \rho_S\left[\frac{\partial(\rho\, h\, S)}{\partial t}\right] = Q_{\mathsf{m}}\,(\rho_\Theta\, \Theta_{\mathsf{m}} + \rho_S\, S_{\mathsf{m}}) + \rho_\Theta\, Q_{\Theta}^{\text{non-adv}} + \rho_S\, Q_{\mathsf{S}}^{\text{non-adv}}. \tag{72.77}$$

Now use the mass budget (72.73c) and introduce the buoyancy tendency according to equation

[7] The surface area, $\mathcal{S}$, along the $z = \eta$ boundary is not generally horizontal and it is not generally constant in time. Yet its horizontal projection, A, is time independent since we fix the horizontal positions for the vertical cell walls.

(72.75) to render an expression for the time tendency of the surface ocean buoyancy

$$-(\rho_o/g)\,\rho\,h\left[\frac{\partial b}{\partial t}\right]^{\text{surface}} = Q_m\left[\rho_\Theta\,(\Theta_m-\Theta)+\rho_S\,(S_m-S)\right]+\rho_\Theta\,Q_\Theta^{\text{non-adv}}+\rho_S\,Q_S^{\text{non-adv}}. \tag{72.78}$$

Introducing the thermal expansion and saline contraction coefficients

$$\alpha = -\frac{1}{\rho}\left[\frac{\partial \rho}{\partial \Theta}\right]_{S,p} \qquad \text{and} \qquad \beta = \frac{1}{\rho}\left[\frac{\partial \rho}{\partial S}\right]_{\Theta,p} \tag{72.79}$$

yields

$$\left[\frac{\partial b}{\partial t}\right]^{\text{surface}} = \frac{g}{\rho_o\,h}\left(Q_m\left[\alpha\,(\Theta_m-\Theta)-\beta\,(S_m-S)\right]+\alpha\,Q_\Theta^{\text{non-adv}}-\beta\,Q_S^{\text{non-adv}}\right) \tag{72.80a}$$

$$= \frac{g}{\rho_o\,h}\left(\alpha\left[Q_m\,(\Theta_m-\Theta)+Q_\Theta^{\text{non-adv}}\right]-\beta\left[Q_m\,(S_m-S)+Q_S^{\text{non-adv}}\right]\right). \tag{72.80b}$$

In regions where the thermal expansion coefficient is positive ($\alpha > 0$), adding a boundary mass ($Q_m > 0$) that has $\Theta_m > \Theta$ increases the buoyancy of the surface ocean; i.e., adding relatively warm water increases surface ocean buoyancy. Likewise, where the haline contraction coefficient is positive ($\beta > 0$), adding boundary mass with $S_m < S$ increases buoyancy of the surface ocean; i.e., adding relatively freshwater increases surface ocean buoyancy. The same behavior holds for the turbulent fluxes, where $Q_\Theta^{\text{non-adv}} > 0$ (adding turbulent thermal energy to the ocean) increases surface ocean buoyancy whereas $Q_S^{\text{non-adv}} > 0$ (adding salt to the ocean) decreases buoyancy. Finally, note that in some contexts it is useful to take the limit as the thickness, h, becomes vanishingly small and to introduce a Dirac delta (see Chapter 7) and thus write[8]

$$\left[\frac{\partial b}{\partial t}\right]^{\text{surface}} = \frac{g\,\delta(z-\eta)}{\rho_o}\left(Q_m\left[\alpha\,(\Theta_m-\Theta)-\beta\,(S_m-S)\right]+\alpha\,Q_\Theta^{\text{non-adv}}-\beta\,Q_S^{\text{non-adv}}\right) \tag{72.81a}$$

$$= \frac{g\,\delta(z-\eta)}{\rho_o}\left(\alpha\left[Q_m\,(\Theta_m-\Theta)+Q_\Theta^{\text{non-adv}}\right]-\beta\left[Q_m\,(S_m-S)+Q_S^{\text{non-adv}}\right]\right). \tag{72.81b}$$

This form is of use when organizing processes according to interior processes and surface boundary processes, such as when considering water mass transformation analysis in Section 73.8. Also note that we encountered a similar approach when discussing potential vorticity in Section 45.7 when introducing the Dirac delta sheet formulation of the potential vorticity boundary condition. We are afforded the ability to formulate the boundary condition in this manner, so long as the boundary condition is of the Neumann type, with general considerations detailed in Section 9.4.8.

72.6.4 Comments

The buoyancy flux expression (72.80b) is of use for boundary layer parameterizations, such as the KPP scheme of *Large et al.* (1994) and *Van Roekel et al.* (2018). It is furthermore used when studying water mass transformations as reviewed by *Groeskamp et al.* (2019) and summarized in Chapter 73.

[8] From Chapter 7, we know that the Dirac delta, $\delta(z-\eta)$, has dimensions of inverse length, so that equation (72.81b) is dimensionally consistent.

72.7 Global mean sea level

In this section we consider some basic features of global mean sea level by making use of the mass budget of liquid seawater. This analysis highlights the distinction between the mass budget and the volume (sea level) budget. In particular, mass satisfies a conserved budget, so that the total ocean mass is affected only through boundary fluxes. In contrast, volume, just like buoyancy, has interior sources and sinks so that the ocean volume can change even if there are no boundary fluxes of volume.

72.7.1 Definitions and assumptions

Seawater mass is a conserved quantity so that the total liquid seawater mass, $\mathcal{M}$, changes only via boundary mass fluxes

$$\frac{d\mathcal{M}}{dt} = \mathcal{A}\, \overline{Q_m}, \tag{72.82}$$

where $\mathcal{A}$ is the ocean surface area, $\overline{Q_m}$ is the area averaged surface mass flux, and we assume there is no mass entering through the ocean bottom. The global volume of liquid seawater

$$\mathcal{V} = \mathcal{M}/\langle \rho \rangle \tag{72.83}$$

changes due to mass changes *and* changes to the global mean density, $\langle \rho \rangle$. Throughout this section we assume the surface area is constant in time, thus neglecting the relatively small changes associated with volume changes along sloping beaches. We also assume a temporally constant area averaged ocean bottom depth, $\overline{H}$. These two assumptions mean that changes in ocean volume arise just from changes in global mean sea level, $\overline{\eta}$. Since around the year 2000, measurements estimate that global area mean sea level has increased at a rate of

$$\left[\frac{d\overline{\eta}}{dt}\right]_{\text{observed}} \approx 3 \text{ mm yr}^{-1}, \tag{72.84}$$

and that this rate is increasing (positive sea level acceleration). As part of the analysis in this section we make use of the following phenomenological numbers and make a few assumptions to facilitate calculations.

- global seawater volume $\mathcal{V} \approx 1.3 \times 10^{18}$ m^3
- global ocean surface area $\mathcal{A} \approx 3.6 \times 10^{14}$ m^2
- global ocean mean density $\langle \rho \rangle \approx 1035$ kg m^{-3}
- specific heat capacity for seawater $c_p \approx 3992$ J kg^{-1}K^{-1}
- Ignore mass fluxes transported through the sea floor, which are small relative to surface mass fluxes.
- Ignore salinity and pressure effects on density, so that changes in global mean density arise just from changes in global mean Conservative Temperature.
- Assume a constant thermal expansion coefficient

$$\alpha = -\frac{1}{\rho}\left[\frac{\partial \rho}{\partial \Theta}\right]_{S,p} \approx 2 \times 10^{-4} \text{ K}^{-1}. \tag{72.85}$$

  This is not a great approximation, since the thermal expansion coefficient ranges over the ocean by a factor of 10. Nonetheless, for this section it is sufficient for deducing rough

numbers that are consistent with errors in measurements for global boundary enthalpy and mass fluxes.

72.7.2 Budget for global mean sea level

Expression (72.83) for ocean volume leads to its time derivative

$$\frac{\mathrm{d}\mathcal{V}}{\mathrm{d}t} = \frac{1}{\langle\rho\rangle}\frac{\mathrm{d}\mathcal{M}}{\mathrm{d}t} - \frac{\mathcal{M}}{\langle\rho\rangle^2}\frac{\mathrm{d}\langle\rho\rangle}{\mathrm{d}t} \tag{72.86a}$$

$$= \frac{\mathcal{A}\,\overline{Q_{\mathsf{m}}}}{\langle\rho\rangle} - \frac{\mathcal{V}}{\langle\rho\rangle}\frac{\mathrm{d}\langle\rho\rangle}{\mathrm{d}t}, \tag{72.86b}$$

where we used equation (72.82) to express mass changes in terms of the surface mass flux. Additionally, the ocean volume is given by

$$\mathcal{V} = \int \mathrm{d}A \int_{-H}^{\eta} \mathrm{d}z = \mathcal{A}\,(\overline{H} + \overline{\eta}), \tag{72.87}$$

so that its time changes arise from changes in the global mean sea level

$$\frac{\mathrm{d}\mathcal{V}}{\mathrm{d}t} = \mathcal{A}\,\frac{\mathrm{d}\overline{\eta}}{\mathrm{d}t}. \tag{72.88}$$

Combining the two volume equations (72.86b) and (72.88) yields the budget equation for global mean sea level

$$\frac{\mathrm{d}\overline{\eta}}{\mathrm{d}t} = \frac{\overline{Q_{\mathsf{m}}}}{\langle\rho\rangle} - \frac{\mathcal{V}}{\mathcal{A}\,\langle\rho\rangle}\frac{\mathrm{d}\langle\rho\rangle}{\mathrm{d}t}. \tag{72.89}$$

The first term arises from changes in ocean mass (increasing total mass increases sea level) whereas the second term arises from changes in global mean seawater density (increasing the mean density decreases sea level).

72.7.3 Changes due to mass input

To ground these formula in phenomenology, assume that a surface mass flux gives one-half of the observed sea level rise

$$\frac{1}{2}\left[\frac{\mathrm{d}\overline{\eta}}{\mathrm{d}t}\right]_{\text{observed}} = \frac{\overline{Q_{\mathsf{m}}}}{\langle\rho\rangle}. \tag{72.90}$$

This distribution of measured sea level is roughly correct. With $\langle\rho\rangle = 1035$ kg m^{-3} and $\mathrm{d}\overline{\eta}/\mathrm{d}t \approx 3$ mm yr^{-1}, we need an area averaged mass flux across the ocean surface

$$\overline{Q_{\mathsf{m}}} \approx 5 \times 10^{-8} \text{ kg m}^{-2}\text{ s}^{-1}. \tag{72.91}$$

Integrated over the global ocean area, this flux leads to a mass transport of

$$\mathcal{T} = \mathcal{A}\,\overline{Q_{\mathsf{m}}} \approx 1.8 \times 10^{7} \text{ kg s}^{-1} \approx 0.015 \times \mathcal{T}^{\mathsf{river}}. \tag{72.92}$$

That is, global mean sea level rises at a rate of 1.5 mm yr^{-1} if there is a net additional mass added to the ocean equal to roughly 1.5% of the net river water entering the ocean, $\mathcal{T}^{\mathsf{river}}$. This additional net mass is largely coming from the melting of land-ice in the form of mountain glaciers and ice sheets.

72.7.4 Steric changes due to changes in density

Steric effects generally refer to properties of a substance associated with the space occupied by atoms. In the sea level context, steric effects refer to changes in sea level associated with density changes, with changes in density associated with changes in the volume occupied by seawater molecules. Changes in global mean sea level arising from changes in the global mean density are called *global steric sea level changes*. From the sea level budget equation (72.89) we know that steric changes are written mathematically as

$$\left[\frac{d\overline{\eta}}{dt}\right]_{\text{steric}} \equiv -\frac{\mathcal{V}}{\mathcal{A}\,\langle\rho\rangle}\,\frac{d\langle\rho\rangle}{dt}. \tag{72.93}$$

Global mean density changes in time primarily from changes in global mean Conservative Temperature. If we assume the ocean thermal expansion is constant, then

$$\frac{1}{\langle\rho\rangle}\frac{d\langle\rho\rangle}{dt} = -\alpha\frac{d\langle\Theta\rangle}{dt}, \tag{72.94}$$

so that steric sea level changes are primarily driven by *thermosteric* effects

$$\left[\frac{d\overline{\eta}}{dt}\right]_{\text{thermosteric}} \equiv \frac{\alpha\,\mathcal{V}}{\mathcal{A}}\,\frac{d\langle\Theta\rangle}{dt}, \tag{72.95}$$

with increasing water temperature, in the presence of $\alpha > 0$, leading to higher sea levels. With $\alpha \approx 2 \times 10^{-4}$ K^{-1} and $d\overline{\eta}/dt \approx 1.5$ mm yr^{-1}, we have

$$\frac{d\langle\Theta\rangle}{dt} \approx 0.2 \text{ K century}^{-1}. \tag{72.96}$$

That is, a global thermosteric sea level rise of 1.5 mm yr^{-1} corresponds to a rate of increase in the global volume mean ocean temperature of roughly 0.2 K century^{-1}.

72.7.5 Enthalpy flux imbalances giving rise to thermosteric sea level

A global mean ocean temperature change can arise from an area averaged surface ocean enthalpy flux

$$\overline{Q_{\text{H}}} \approx \langle\rho\rangle\, c_{\text{p}}\, \overline{H}\, \frac{d\langle\Theta\rangle}{dt}, \tag{72.97}$$

with numbers leading to

$$\overline{Q_{\text{H}}} \approx 1 \text{ W m}^{-2}. \tag{72.98}$$

That is, a surface ocean enthalpy flux of roughly 1 W m^{-2} (ocean area normalized) gives rise to a global mean thermosteric sea level rise of roughly 1.5 mm yr^{-1}.

An enthalpy flux of 1 W m^{-2} is small compared to, say, that crossing the surface of a typical light bulb. However, 1 W m^{-2} is comparable to that accumulating within the earth system due to increases in greenhouse gases (*Otto et al.*, 2013). That is, 1 W m^{-2} averaged over the global ocean, or 0.7 W m^{-2} averaged over the surface area of the planet,[9] is roughly the net heating associated with anthropogenic climate change. Such seemingly small increases in surface heating represent a nontrivial increase in the earth's energy budget that are leading to the observed climate changes and sea level rise.

As specific means to gauge the magnitude of 1 W m^{-2} distributed over the ocean surface area, $\mathcal{A}$, let us compare it to the enthalpy flux due to blasting one atomic bomb per second

[9] The ocean covers roughly 70% of the earth surface. This factor is commonly forgotten when quoting heat flux numbers, so it is important to note whether the number refers to global area normalized or ocean area normalized.

($\Delta t = 1$ s) and uniformly distributing the bomb's released energy, $\mathcal{E}_{\text{bomb}}$, over the ocean surface area every second. Estimates render $\mathcal{E}_{\text{bomb}} \approx 6.3 \times 10^{13}$ J, so that distributing this energy over the ocean area, and doing so each second, corresponds to a surface ocean enthalpy flux of

$$\mathcal{Q}^{\text{bomb}} = \frac{\mathcal{E}_{\text{bomb}}}{\mathcal{A}\, \Delta t} \approx 0.17 \text{ W m}^{-2}. \tag{72.99}$$

Hence, an enthalpy flux of 1 W m^{-2} due to anthropogenic climate warming corresponds to $1/0.17 \approx 6$ atomic bomb blasts per second. This way of framing the net heating of the ocean due to anthropogenic climate change dramatically illustrates the magnitude of the global warming problem.[10]

72.7.6 Global sea level in a Boussinesq ocean

The sea level for a Boussinesq ocean evolves according to the kinematic free surface equation (21.81)

$$\partial_t \eta^{\text{bouss}} = -\nabla \cdot \boldsymbol{U} + Q_{\text{m}}/\rho_{\circ}, \tag{72.100}$$

where

$$\boldsymbol{U} = \int_{-H}^{\eta} \boldsymbol{u}\, \mathrm{d}z \tag{72.101}$$

is the depth integrated horizontal velocity and $\rho_{\circ}$ is the Boussinesq reference density. This equation results from ignoring all changes to density, except for those related to the buoyancy force appearing in the momentum equations. Integrating the sea surface height equation (72.100) over the surface area of the global ocean reveals that the global mean Boussinesq sea level evolves according to

$$\frac{\mathrm{d}\overline{\eta^{\text{bouss}}}}{\mathrm{d}t} = \frac{\overline{Q_{\text{m}}}}{\rho_{\circ}}. \tag{72.102}$$

Hence, $\overline{\eta^{\text{bouss}}}$ changes only so long as there are boundary mass fluxes. In contrast to the real ocean, the sea level computed from a Boussinesq ocean is unaffected by a surface enthalpy flux, $\overline{Q_{\text{H}}} \neq 0$. This result in turn means that we cannot use the prognostic sea surface height, η^{bouss}, level from a Boussinesq ocean model to compute changes the global mean sea level. Instead, corrections are required, as first identified by *Greatbatch* (1994) and further detailed in Appendix D of *Griffies and Greatbatch* (2012).

72.7.7 Why global halosteric sea level changes are negligible

When freshwater enters the ocean, such as from melting continental ice sheets, it adds to the ocean mass and in turn increases global mean sea level. This change is referred to as *barystatic sea level change* according to the sea level terminology paper from *Gregory et al.* (2019). Although ocean salinity changes upon changing the freshwater content, the net effect on global mean sea level is almost entirely barystatic since the global halosteric effect is negligible. We can understand why the global halosteric effect is so tiny by recognizing that freshwater entering the ocean sees its salinity increase whilst the ambient seawater is itself freshened. These compensating salinity changes (which are often mistakenly ignored) have corresponding compensating sea level changes, thus bringing the global halosteric effect to near zero.

We here summarize the two-bucket thought experiment from Appendix B of *Gregory et al.* (2019). In this experiment, one bucket holds freshwater and the other holds seawater, with the Conservative Temperature and pressures assumed to be identical for the two buckets. By

[10] Importantly, for the global warming problem it is not that industrialization is directly adding 1 W m^{-2} to the planet. Rather, increases in the concentration of greenhouse gases, caused by the burning of fossil fuels, increases the amount of solar radiation that remains within the atmosphere rather than being radiated to space.

working through this example we expose the rather tiny effects on global mean sea level arising from halosteric effects.

Formulating the change in volume

Consider two buckets containing seawater with mass M_n, volume V_n, density $\rho_n = M_n/V_n$, and salinity S_n, where $n = 1, 2$ labels the two buckets. Now fully mix the water in the two buckets, whereby the total mass, M, of seawater remains constant, as does the total mass of salt

$$M = M_1 + M_2 \quad \text{and} \quad M\,S = M_1\,S_1 + M_2\,S_2, \tag{72.103}$$

where S is the salinity of the homogenized fluid so that $M\,S$ is the total mass of salt in the combined system. Now place a mass M_1 of the homogenized fluid back in the first bucket, and a mass M_2 into the second bucket. Our goal is to compute the change in seawater volume

$$\delta V = \delta V_1 + \delta V_2. \tag{72.104}$$

In determining this volume change, we ignore pressure changes as well as changes in enthalpy associated with the heat of mixing. So the only change in volume arises from changes in the salinity.

Since the mass of each bucket remains the same before and after homogenization, then the density of seawater in each bucket changes only due to the volume changes

$$\delta\rho_n = \delta(M_n/V_n) = -(M_n/V_n^2)\,\delta V_n \Longrightarrow \delta\rho_n/\rho_n = -\delta V_n/V_n. \tag{72.105}$$

That is, the relative change in density equals to minus the relative change in volume. Now the density changes arise just from salinity changes, in which

$$\delta\rho_n/\rho_n = \beta_n\,\delta S_n, \tag{72.106}$$

where β_n is the haline contraction coefficient that measures changes in density when fixing pressure and Conservative Temperature. We are thus led to the volume change

$$\delta V = -(V_1\,\delta\rho_1/\rho_1 + V_2\,\delta\rho_2/\rho_2) = -(V_1\,\beta_1\,\delta S_1 + V_2\,\beta_2\,\delta S_2). \tag{72.107}$$

We can simplify this expression by making use of salt conservation in equation (72.103), thus constraining salinity changes according to

$$M_1\,\delta S_1 + M_2\,\delta S_2 = 0 \Longrightarrow \delta S_2 = -(M_1/M_2)\,\delta S_1, \tag{72.108}$$

in which case the volume change takes on the form

$$\delta V = -V_1\,\delta S_1\,(\beta_1 - \beta_2\,\rho_1/\rho_2). \tag{72.109}$$

The haline contraction coefficient changes only by a few percent globally (see *Roquet et al.* (2015) or Figure 1 in *Griffies et al.* (2014)), in which case we set $\beta_1 = \beta_2 = \beta$. Furthermore, to connect to sea level changes we assume the horizontal cross-sectional area of the two buckets is the same, so that the water column thickness differs between the two buckets by the amount

$$\delta h = -h_1\,\beta\,\delta S_1\,(1 - \rho_1/\rho_2). \tag{72.110}$$

Oceanographic numbers

We can compute the relative change in thickness using equation (72.110) and plugging in some numbers. Namely, we assume the first bucket is initially filled with freshwater ($S_1 = 0$) whereas the second bucket is initially filled with ambient seawater, with $S_2 = 35$ ppt a representative value. Homogenization of the two buckets then raises salinity in the first bucket and lowers it for the second. Assume the first bucket has its salinity raised to by $\delta S_1 = S/2$, let the density ratio be $\rho_1/\rho_2 = 1000/1028$, and haline contraction coefficient be $\beta = 0.8 \times 10^{-3}$. These values then yield a thickness change

$$\delta h/h_1 = -3.8 \times 10^{-4}. \tag{72.111}$$

Hence, for every meter of fresh water added to the ocean surface, the halosteric effect contributes a 0.38 mm contraction of the water thickness. That is, the total volume of homogenized water equals to the sum of the volume initially in the two separate buckets to within better than 0.04%. We conclude that the volume change is almost entirely barystatic, so that the global halosteric effect is entirely negligible when considering global sea level changes.

It is important to emphasize that this bucket thought experiment only concerns global sea level. In contrast, regional halosteric effects can be important for studies of sea level patterns, and as such they are the topic of many studies such as *Griffies et al.* (2014).

Comments on global thermosteric sea level changes

The above derivation for the global halosteric changes can be directly transferred to the case of mixing two buckets whose water has different Conservative Temperatures but identical pressure and salinity. Conservation of salt is here replaced by conservation of potential enthalpy, so that the relative thickness change is given by

$$\delta h/h_1 = \alpha\, \delta\Theta_1\, (1 - \rho_1/\rho_2), \tag{72.112}$$

where α is the thermal expansion coefficient. Taking $\alpha \approx 2 \times 10^{-4}$ K^{-1}, we find that δh from thermal effects are on the same order as those from haline effects given by equation (72.110). That is, the contributions to the column thickness are dominated by the barystatic (mass) effects.

However, there is a key distinction between thermal and haline contributions to sea level. Namely, thermal properties are also affected by boundary radiant and turbulent enthalpy fluxes that are not necessarily associated with boundary mass fluxes. These extra effects of boundary heating were studied in Section 72.7.5, where we identified the key role for ocean warming on global thermosteric sea level changes. Such changes are certainly not negligible, comparing to the observed global barystatic contributions.

72.7.8 Further study

The discussion of steric and thermosteric sea level changes are further explored in *Griffies and Greatbatch* (2012) and *Griffies et al.* (2014). The global halosteric discussion is based on Appendix B of the sea level terminology paper from *Gregory et al.* (2019). The *Gregory et al.* (2019) paper is also notable for providing a conceptual rationalization of the often confusing terminology used in sea level studies.

Chapter 73

WATER MASS TRANSFORMATION THEORY

A *water mass* refers to a region of seawater characterized by a suite of quasi-homogeneous properties used to distinguish this water from other water masses. Water masses are typically formed through surface boundary processes. As these waters enter the ocean interior they are advected over basin scales while they are also eroded or *transformed* by irreversible mixing processes. Water masses offer a conceptual means to partition or bin the ocean into distinct classes whose origin, movement, and transformation can be measured, modeled, and studied. Scalar properties generally used to classify water masses are simpler to measure than vector properties such as velocity and vorticity. Hence, a water mass perspective offers the means to infer ocean circulation within water mass space without directly measuring vector fields.

In this chapter we develop the mathematical and physical basis for *water mass transformation* theory, which considers the budgets for seawater mass and tracer mass within layers or classes defined by properties such as buoyancy, Conservative Temperature, salinity, or biogeochemical tracers. The budgets can become rather complex in appearance, given the variety of domains considered in the analysis. To reduce confusion, just remember that these equations are no more than fancy scalar budgets equations. It is through these variants of the scalar budgets, and through examining the processes affecting the budgets, that water mass transformation theory offers a novel lens for describing and understanding facets of geophysical fluid mechanics. Indeed, this lens is distinct from the Eulerian and Lagrangian kinematics considered elsewhere in this book, and it has found great use throughout oceanography and atmospheric sciences, in particular for questions where irreversible transformation is central to the story.

Readers of this chapter may appreciate the following paraphrase from A. Sommerfeld's quote. We gave it at the start of the thermodynamics part of this book (Part IV), and it seems appropriate for the study of water mass transformation.

> Water mass analysis appears somewhat mysterious and puzzling on first encounter. On second encounter things start to fall into place, except perhaps for a few pesky math niceties. On third encounter, when deciding to do calculations, one returns to that unsettled feeling of the first encounter. However, by now, familiarity with the words and maths means that the mystery presents no practical bother. One simply turns the crank without thinking too much about the underlying foundations.

In hopes of partially dispelling the mystery, and maintaining an appreciation for the fundamental processes, we here couple the mathematical equations with schematics, conceptual descriptions, and thought experiments. To do so, we work through a number of budget analysis questions with the aim to ground the theory with examples motivated from the growing literature.

CHAPTER GUIDE

Readers of this chapter should be familiar with the vector calculus encountered in Chapter 2; mass budget kinematics from Chapter 19; tracer budget kinematics from Chapter 20; elements of the generalized vertical coordinates from Chapters 63 and 64; and nearly all of the material presented earlier in this part of the book, including the mathematics and physics of advection and diffusion in Chapters 68, 69, features of parameterized tracer transport and mixing studied in Chapter 71, and buoyancy budgets in Chapter 72, including boundary conditions. Mastery of water mass transformation theory can require years of pondering the fundamentals in the pursuit of applications.

73.1 Conceptual framework

Water mass analysis is a mathematical formalism supporting the study of budgets for seawater mass and tracer mass within layers or classes defined by properties such as Archimedean buoyancy (Chapter 30; shortened to "buoyancy" here), Conservative Temperature, salinity, or biogeochemical tracers. *Water mass transformation theory* is concerned with processes affecting the evolution of fluid within layers and in the characterization of circulation inferred from this evolution. The theory is very useful for oceanography since it is common to describe seawater geography in terms of characteristic water properties, with the evolution of those water masses of primary interest to physical and biogeochemical oceanography.[1]

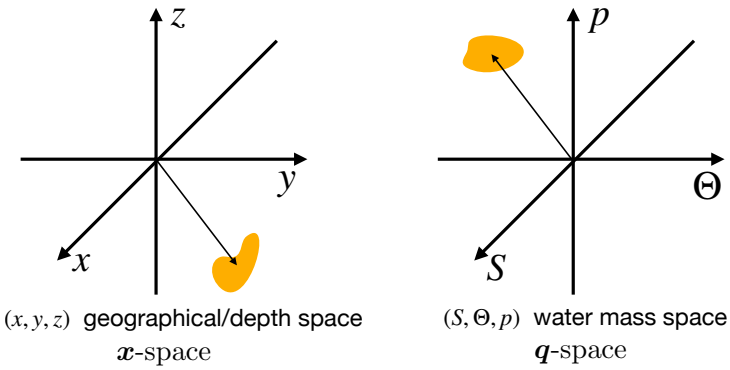

FIGURE 73.1: Left panel: a fluid element is positioned in geographical/depth $\boldsymbol{x}$-space according to its horizontal (x, y) (longitude, latitude) position and its vertical geopotential, z. Right panel: the same fluid element is positioned in a particular water mass configuration space ($\boldsymbol{q}$-space, here defined by $\boldsymbol{q} = (S, \Theta, p)$ with salinity, S, Conservative Temperature, Θ, and pressure, p. Mapping between the two spaces is generally not 1-to-1. Namely, a point in $\boldsymbol{q}$-space can be occupied by more than one point in $\boldsymbol{x}$-space. The reason is that more than a single point in $\boldsymbol{x}$-space can have the same values for (S, Θ, p). Although the coordinate axes in $\boldsymbol{q}$-space are depicted here as mutually orthogonal, there is no objective means to determine angles in $\boldsymbol{q}$-space since it contains no metric. Rather, $\boldsymbol{q}$-space, just like thermodynamic state space (Section 22.1.4), forms a *differentiable manifold* that has no metric.

73.1.1 The novel lens of water mass configuration space

Water mass configuration space (denoted $\boldsymbol{q}$-space) is the space we work within to study water mass transformations. This space has some or all of its coordinates set by properties other than geographic/depth coordinates.[2] For example, in Figure 73.1 we present the three-dimensional $\boldsymbol{q}$-space given by $\boldsymbol{q} = (S, \Theta, p)$, where the position (or bin) for a fluid element is determined by its Conservative Temperature, Θ, salinity, S, and pressure, p. Operationally, we fill $\boldsymbol{q}$-space by forming histograms that result in a $\boldsymbol{q}$-space distribution of seawater properties. For example, a one-dimensional $\boldsymbol{q}$-space results from binning the ocean according to potential density, whereas

[1] Water masses often originate through extremely large buoyancy fluxes at the high latitudes that form waters such as the Antarctic Bottom Water (AABW) and North Atlantic Deep Water (NADW). *Talley et al.* (2011) provides a great place to embark on a study ocean water mass phenomenology.

[2] We prefer the term "configuration space" over the alternative "phase space", since phase space in Hamiltonian dynamics specifically refers to position and momentum coordinates (see Chapter 12). In contrast, configuration space, as used in our discussion of water masses, can be determined by most any property or geographic position.

retaining latitudinal information along with potential density renders a two-dimensional $\boldsymbol{q}$-space. Typically $\boldsymbol{q}$-space has three or fewer dimensions, given the three dimensionality of $\boldsymbol{x}$-space. There no implied constraint that any of the $\boldsymbol{q}$-space coordinates are monotonic with respect to $\boldsymbol{x}$-space. Indeed, there is no presumption that points in $\boldsymbol{q}$-space maintain a 1-to-1 relation to points in $\boldsymbol{x}$-space. For example, many points in $\boldsymbol{x}$-space may fall into a single point (or bin) within $\boldsymbol{q}$-space.

The lack of 1-to-1 mapping between water mass configuration space and geographic/depth space is a fundamental kinematic distinction from the 1-to-1 relation that holds between the Eulerian and Lagrangian descriptions of fluid motion (see Chapter 17). The lack of a 1-to-1 relation can be frustrating since circulation viewed in $\boldsymbol{q}$-space generally has incomplete $\boldsymbol{x}$-space information, whereas oceanographers wish to know where on the planet something is happening.[3] Even so, abandoning the 1-to-1 relation can be liberating since working within $\boldsymbol{q}$-space offers a framework to infer $\boldsymbol{q}$-space circulation even without measuring velocity of the fluid in geographical space. Correspondingly, ocean circulation when viewed through a water mass lens can offer understanding that complements traditional Eulerian or Lagrangian views.

Water mass configuration space generally has no metric, particularly when none of the chosen coordinates are geographical (latitude or longitude) or depth.[4] Hence, there is generally no notion of distance or angles between points in water mass configuration space. For example, what does it mean to be orthogonal in temperature-salinity space or when studying the density-binned distribution of seawater? The absence of a metric is something we have already seen when studying thermodynamic configuration space in Chapter 22 (see in particular Section 22.1.4). Mathematically, we say that both thermodynamic configuration space and water mass configuration space are *differentiable manifolds*. Even so, one commonly sees a point in thermodynamic space depicted on a diagram with orthogonal axes (e.g., pressure-volume diagrams), or a position in water mass configuration space similarly depicted with orthogonal axes as in Figure 73.1. Yet this depiction is arbitrary since there is no geometric structure afforded to such spaces since there is no metric tensor, which in turn means we cannot determine angles or orthogonality. Depictions with orthogonal axes merely satisfy a subjective desire for geometric structure when in fact there is none afforded to the manifold.[5]

73.1.2 Transformation and formation

Water moves through water mass configuration space as it is modified or *transformed* by boundary and interior ocean processes that cause water to cross surfaces defined by the chosen water mass property.[6] Stated differently, a transformation process leads to material changes in the property of a fluid element, with sources of transformation arising from mixing, solar radiation, and chemical reactions. The convergence (i.e., the local imbalance) of such transformation processes leads to the *formation* and destruction of water mass classes. As water moves through water mass configuration space we are afforded a distinct view of ocean circulation that has both direct and indirect connections to circulation in geographical/depth space. Notably, and quite trivially, we measure zero motion along a coordinate axis in water mass configuration space when the property defining that axis remains materially unchanged. For example, adiabatic and isohaline processes such as linear waves can render nontrivial motion in geographical/depth space whereas they lead to no motion in (S, Θ) space.

[3] Auxiliary methods such as the water tagging method of *Groeskamp et al.* (2014) can be used to recover some geographical information.

[4] See Section 4.1 for a discussion of the metric tensor needed to measure distance.

[5] Differential forms provide a suitable formalism for conducting calculus on a differential manifold sans a metric as detailed by *Nurser et al.* (2022). This topic is, however, outside the scope of this book.

[6] In many parts of this book the word "transformation" refers to coordinate transformations. Here, "transformation" refers to a process acting to change a seawater property; i.e., to change one or more of the $\boldsymbol{q}$-space coordinates.

If one is interested in processes that do not give rise to material changes in a fluid property, then the corresponding water mass configuration space generally offers a rather bland kinematic perspective. Furthermore, given the possible non-local $\boldsymbol{x}$-space aspects of water mass configuration space, it provides an unnatural venue to study forces and stresses acting between spatially adjacent fluid elements. Hence, the study of momentum and vorticity dynamics is better handled via Eulerian or Lagrangian kinematics. Where water mass configuration space shines is by revealing the dynamics associated with processes that affect material changes to those properties defining the water mass classes. For example, a water mass perspective has found use in framing key questions of primary interest in the Anthropocene, such as ocean buoyancy and its transformation through interior and boundary mixing, ocean heat uptake and transport, the hydrological cycle, steric sea level rise, and irreversible changes to biogeochemical properties (see *Groeskamp et al.* (2019) for a review with many references).

73.2 Buoyancy transformation and formation

Archimedean buoyancy is a common property used to distribute seawater, with Archimedean buoyancy commonly approximated by potential density (Chapter 30). In this section we introduce the notions of *transformation* and *formation* when partitioning the ocean according to density (γ) classes that locally measure buoyancy.[7] The ideas presented here extend to any scalar property used to bin the ocean fluid.

Quantitatively, the transformation of seawater refers to a measure of the mass per time of water that moves across an isosurface of one of the $\boldsymbol{q}$-space coordinates. Alternatively, a transformation refers to the movement from one $\boldsymbol{q}$-space bin to another bin within the $\boldsymbol{q}$-space distribution. For a $\boldsymbol{q}$-space containing density as one of its coordinates, we say that the transformation is positive if water moves to larger density and negative if it enters a lighter density layer. Indeed, one generally says that movement to a larger value for the water mass property refers to a positive transformation whereas the opposite motion is a negative transformation. Water mass *formation* refers to the difference in transformation across the surfaces bounding a layer, so that formation measures the change in mass of the layer. Evidently, formation is the $\boldsymbol{q}$-space convergence of transformation.

Both transformation and formation have dimensions of mass per time (or volume per time when considering Boussinesq oceans; Chapter 29) and are typically measured in Sverdrup units:

$$1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1} \qquad \text{volume-Sverdrup} \tag{73.1a}$$

$$1 \text{ Sv} = 10^9 \text{ kg s}^{-1} \qquad \text{mass-Sverdrup.} \tag{73.1b}$$

The mass-Sverdrup can be routinely used for Boussinesq fluids merely by multiplying the volume-Sverdrup by the constant Boussinesq reference density, ρ_o.

73.2.1 A three-layer thought experiment

To illustrate the concepts of transformation and formation, bin the World Ocean into density classes so that $\boldsymbol{q}$-space is just one dimensional. We thus lose all information about latitude, longitude, and depth, retaining only the information provided by γ-classes. Furthermore, partition the World Ocean into just three density layers (also called classes or bins) that are

[7] Many researchers make use of the *neutral density* coordinate defined by *Jackett and McDougall* (1997).

bounded by four density interfaces:

$$\text{light density layer} = [\gamma - \delta\gamma/2, \gamma + \delta\gamma/2] \tag{73.2a}$$
$$\text{middle density layer} = [\gamma + \delta\gamma/2, \gamma + 3\,\delta\gamma/2] \tag{73.2b}$$
$$\text{heavy density layer} = [\gamma + 3\,\delta\gamma/2, \gamma + 5\,\delta\gamma/2], \tag{73.2c}$$

where $\delta\gamma > 0$ is the size of the density bins. Figure 73.2 depicts a sample mass distribution; i.e., the mass census for seawater binned into these three density layers.[8] Now consider a physical, chemical, or biological process that results in water leaving the middle density layer and entering both the light layer and the heavy layer.[9] Let $G(\sigma)$ measure the mass per time that water crosses the density interface $\gamma = \sigma$; i.e., $G(\sigma)$ is the transformation. This particular thought experiment has the following transformations across the various layer interfaces

$$G(\sigma) = \begin{cases} 0 & \sigma = \gamma - \delta\gamma/2 \quad \text{closed boundary} \\ < 0 & \sigma = \gamma + \delta\gamma/2 \quad \text{mass moves to light density from middle density} \\ > 0 & \sigma = \gamma + 3\,\delta\gamma/2 \quad \text{mass moves from middle density to heavy density} \\ 0 & \sigma = \gamma + 5\,\delta\gamma/2 \quad \text{closed boundary.} \end{cases} \tag{73.3}$$

The difference in the transformation across the interface boundaries of a particular layer determines the formation/destruction of water in that layer. Here, the convergence of water into the light and heavy layers means that there is a positive formation of water in these two density layers. In contrast, the divergence of water from the middle density layer means there is a negative formation or a destruction of some of its water. We write these layer formations mathematically as follows

$$\text{light-formation} = -[G(\gamma + \delta\gamma/2) - G(\gamma - \delta\gamma/2)] > 0 \tag{73.4a}$$
$$\text{middle-formation} = -[G(\gamma + 3\,\delta\gamma/2) - G(\gamma + \delta\gamma/2)] < 0 \tag{73.4b}$$
$$\text{heavy-formation} = -[G(\gamma + 5\,\delta\gamma/2) - G(\gamma + 3\,\delta\gamma/2)] > 0. \tag{73.4c}$$

The minus sign out front emphasizes that the formation is the layer integrated *convergence* of the transformation.

73.2.2 How processes lead to transformations

The central focus of water mass transformation analysis is the movement of water between layers or classes, with this movement modifying the water mass distribution within the chosen water mass configuration space. Here we outline a few of the processes that affect this movement within water mass space, again focusing on buoyancy yet with an easy generalization to any other property that defines the water mass. Notably, we are not concerned with whether the fluid element moves in $\boldsymbol{x}$-space, the boundary moves, or both, since it is only the relative motion that changes the water mass distribution in $\boldsymbol{q}$-space. Indeed, we cannot determine motion of the fluid element in $\boldsymbol{x}$-space without direct information about the velocity. We return to this notion when providing a mathematical expression for these ideas in Section 73.4.1.

[8] A realistic ocean experiences boundary forcing that makes the maximum and minimum density a function of time. It is thus common to fix the lower density limit to be well below the lightest water in the ocean and the upper density limit well above the maximum density, thus ensuring that all seawater is contained by the chosen binning. We introduce such "infinity" bounds in Section 73.3.3.

[9] Since the layer is the result of binning over the World Ocean, there can be some regions within a bin that experience processes that decrease the density, whereas other regions where density increases. In this manner, some water within the bin moves to a denser bin whereas other water moves to a lighter bin.

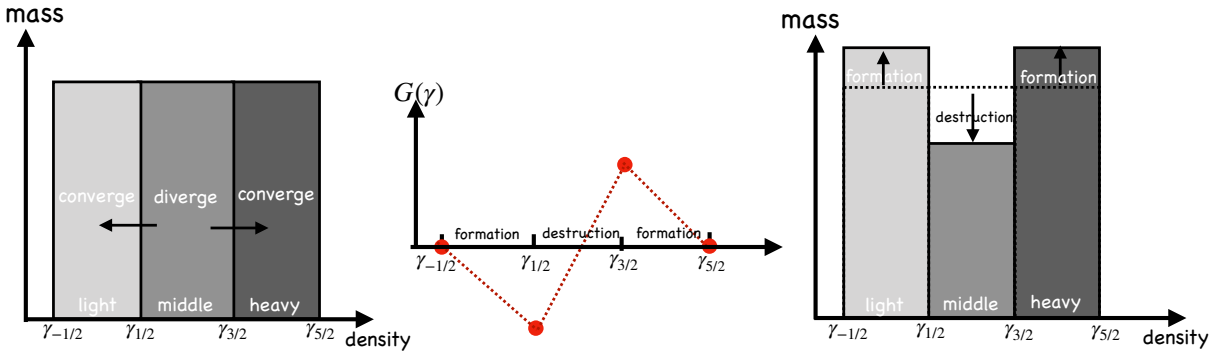

FIGURE 73.2: A sample mass distribution of the ocean binned into three density layers (light, middle, heavy) bounded by four density interfaces: $\gamma_{n/2} = \gamma + n\,\delta\gamma/2$ for $n = -1, 1, 3, 5$. The left panel depicts an ocean state with equal mass in each layer. Some process is then imagined to cause water to diverge from the middle layer and converge to the light and heavy layers. The right panel shows the mass distribution after the water has moved, so that the middle layer has experienced a negative *formation* (i.e., net loss of mass) whereas the light and heavy layers have experienced a positive *formation* (i.e., net mass gain). The middle panel depicts the *transformation*, G, which measures the mass per time moving across the layer boundaries. By convention, $G > 0$ for water moving into a heavier density layer and $G < 0$ for water entering a lighter density layer. The addition of more layers refines the picture (e.g., by smoothing the plot of G) but it does not modify the basic ideas illustrated in this thought experiment.

Interior transformation from mixing

Mixing moves water across layer boundaries in $\boldsymbol{q}$-space, with $\boldsymbol{q}$-space coordinates/properties materially modified in the presence of mixing (so long as there are spatial gradients in the property). For example, recall our discussion in Chapter 20 where as saw that mixing causes tracers to move between fluid elements even as mixing does not alter the net mass of fluid elements (see the discussion of barycentric velocity in Section 20.1.2). Hence, in the presence of mixing, seawater fluid elements retain a fixed mass, and yet the mass is redistributed among layers defined by property isosurfaces since the isosurfaces move in the presence of mixing.

Surface mass fluxes

Rain and evaporation alter the mass of the ocean. In turn, the layers where rain and evaporation occur; i.e., layers that outcrop, have their mass altered through the surface mass fluxes. Additionally, if the buoyancy of the mass flux differs from that of the ocean layer that it enters/leaves, then the buoyancy of the ocean layer is modified upon mixing the ambient seawater with the water entering the ocean.

Surface and bottom boundary transformation

Buoyancy surfaces that outcrop at the ocean surface or incrop at the ocean bottom are exposed to boundary fluxes that generally modify the buoyancy of the fluid within a layer. This modification causes the layer boundaries to move so that the mass distributed within the layers can be modified if the mass moves with a velocity distinct from the buoyancy surface. A particularly striking example occurs in the upper ocean boundary layer where surface forcing leads to the seasonal migration of density outcrops. The associated lateral movement of density layers causes water to entrain and detrain from a layer since the layer boundaries generally have a velocity distinct from fluid elements. In so doing, the seasonal cycle of surface buoyancy forcing can inflate or deflate a buoyancy layer by moving the layer boundaries so that the layer entrains or detrains mass.

Penetrative shortwave radiation provides another means to modify water masses, with penetrative radiation a function of the optical properties of the fluid. This radiation provides a

source of heating that can penetrate into the upper few tens of meters in the ocean, and can impact on the temperature and density structure of the ocean layers affected by radiation.

Finally, layers that intersect the ocean bottom are exposed to geothermal heating as well as enhanced mixing from bottom boundary layer mixing. Each of these processes affects a transformation of the buoyancy, thus modifying the buoyancy layer interfaces and mass distribution within the layers.

Interior sources and sinks

When studying water masses defined by biogeochemical tracers (e.g., carbon, oxygen, nutrients), there are a variety of chemical reactions and biological processes that act to modify these properties. These processes generally cannot be represented mathematically as the convergence of a flux. They are thus sometimes referred to as "non-conservative" processes (see Section 26.12) and written as a source/sink term.

73.3 Mathematical framework

In this section we develop a suite of mathematical tools of use to quantify the conceptual ideas presented in Sections 73.1 and 73.2. In particular, we develop a formalism for integrating properties within a region bounded by isosurfaces of a scalar field, $\lambda = \lambda(\boldsymbol{x}, t)$. The formulation is given from both a geometric perspective afforded by $\boldsymbol{x}$-space, and a complementary distributional perspective afforded by binning seawater mass according to λ-classes that define a one-dimensional $\boldsymbol{q}$-space. As in our study of Eulerian and Lagrangian kinematics elsewhere in this book, it is here useful to be adept at both the $\boldsymbol{x}$-space perspective and the distributional $\boldsymbol{q}$-space perspective.

In Section 73.2 we considered λ to be the buoyancy field, $\lambda = \gamma$, whereas here we assume it is a generic scalar field, $\lambda(\boldsymbol{x}, t)$. In contrast to the case of a generalized vertical coordinate (Chapters 63 and 64), we make no assumption regarding the stratification of λ. Rather, λ-isosurfaces are free to overturn or even to be situated in spatially disconnected regions. This freedom is motivated by the behavior of most oceanographic scalar properties, which commonly exhibit vertically unstratified or negatively stratified profiles, particularly within boundary layers. This degree of freedom comes at the cost of losing the 1-to-1 relation between $\boldsymbol{x}$-space and $\boldsymbol{q}$-space, as mentioned in Section 73.1.1.

73.3.1 Seawater mass in an infinitesimal cylinder

Consider the calculation of seawater mass within an infinitesimal λ-layer bounded by two isosurfaces, $[\lambda - \delta\lambda/2, \lambda + \delta\lambda/2]$, as in Figure 73.3. The mass within a tiny cylinder extending from one interface to the other is given by the seawater density, ρ, multiplied by the volume of the cylinder,[10]

$$\delta M = \rho \, \delta V = \rho \, \delta h \, \delta \mathcal{S}, \tag{73.5}$$

where $\delta\mathcal{S}$ is the cross-sectional area element and δh is the layer thickness. The geometric thickness, δh, is related to the differential λ-increment separating the two interfaces according to

$$\delta\lambda = \nabla\lambda \cdot \delta\boldsymbol{x} = |\nabla\lambda| \, \hat{\boldsymbol{n}} \cdot \delta\boldsymbol{x} = |\nabla\lambda| \, \delta h \qquad \text{with} \qquad \hat{\boldsymbol{n}} = \nabla\lambda \, |\nabla\lambda|^{-1}, \tag{73.6}$$

[10]Recall our notational convention is as follows: δ refers to an infinitesimal increment of a property measured within the fluid whereas d is a differential increment used for computing integrals. We made use of the same geometric analysis in Section 41.1.2 when studying potential vorticity.

where $\delta\boldsymbol{x}$ is a position vector connecting points on the two interfaces. We thus see that the layer thickness is given by

$$\delta h = \frac{\delta\lambda}{|\nabla\lambda|}, \tag{73.7}$$

which connects a geometric property of the layer, δh, to the λ-increment, $\delta\lambda > 0$. For a given λ-increment, the layer thickness is smaller with more tightly packed λ-isosurfaces as reflected by a larger $|\nabla\lambda|$. Furthermore, the geometric thickness is oriented according to the normal direction, $\hat{\boldsymbol{n}}$, so that δh measures the distance between the λ-interfaces in the direction of the normal direction. It follows that the seawater mass within the cylinder is given by

$$\delta M = \rho\,\delta V = \rho\,\delta h\,\delta\mathcal{S} = \frac{\rho\,\delta\lambda\,\delta\mathcal{S}}{|\nabla\lambda|}. \tag{73.8}$$

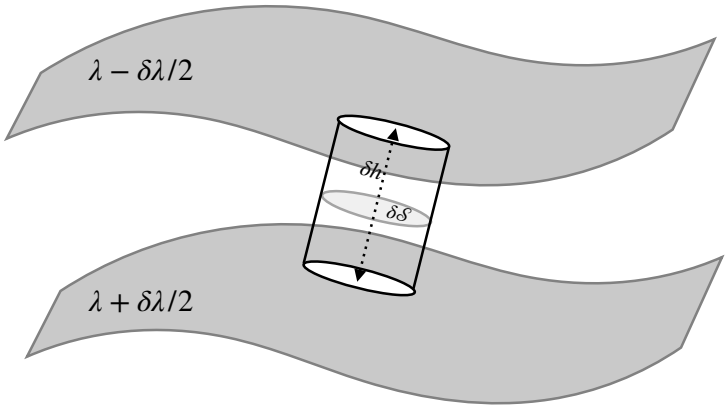

FIGURE 73.3: This schematic shows an infinitesimally thin λ-layer bounded by two interfaces $[\lambda - \delta\lambda/2, \lambda + \delta\lambda/2]$, with the λ-increment $\delta\lambda > 0$. The cylinder region extends between the two iso-surfaces and it has thickness $\delta h = \delta\lambda/|\nabla\lambda|$ and cross-sectional area $\delta\mathcal{S}$. The cylinder is oriented according to the normal direction, $\hat{\boldsymbol{n}} = |\nabla\lambda|^{-1}\,\nabla\lambda$. We assume $|\nabla\lambda| \neq 0$, as required to define a normal direction. Indeed, if $\nabla\lambda = 0$ then we could not perform a binning according to λ classes, so the $|\nabla\lambda| \neq 0$ assumption is basic to the use of the scalar field, λ, for water mass analysis.

73.3.2 Seawater mass within a finite region

Making use of the infinitesimal cylinder mass (73.8) allows us to write the mass of seawater within the λ-region $\lambda_1 \leq \lambda \leq \lambda_2$

$$M(\lambda_1, \lambda_2) \equiv \int_{\Omega(\lambda_1 \leq \lambda \leq \lambda_2)} \mathrm{d}M = \int_{\lambda_1}^{\lambda_2} \left[\int_{\partial\Omega(\lambda)} \frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda|} \right] \mathrm{d}\lambda. \tag{73.9}$$

In this equation, $\Omega(\lambda_1 \leq \lambda \leq \lambda_2)$ is the region in space bounded by the λ_1-interface and λ_2-interface, and $\partial\Omega(\lambda)$ is the surface defined by a λ-isosurface. The $\partial\Omega(\lambda)$ integral is taken over the area of the λ-isosurface, which is then integrated over the range, $\lambda_1 \leq \lambda \leq \lambda_2$, to thus accumulate the layer mass.

73.3.3 Seawater mass distribution/density function

The region bounded by the layer interfaces can have any shape in space and can even be spatially disconnected. This complexity motivates us to introduce the *mass distribution* function by

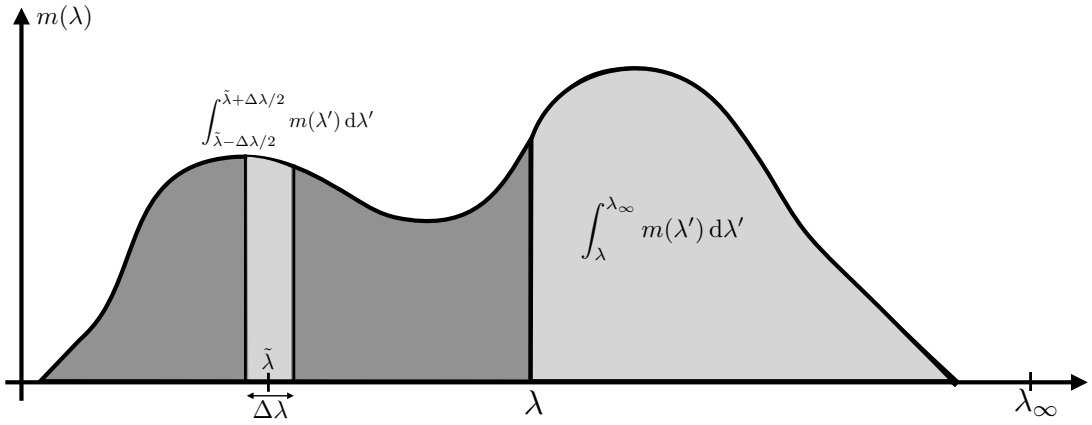

FIGURE 73.4: An example mass distribution function, $m(\lambda) = \mathrm{d}M/\mathrm{d}\lambda$, which measures the mass of seawater per λ-increment. Integration over a finite λ-region measures the seawater mass within that region. For example, the mass within a $\Delta\lambda$-layer is given by $M(\widetilde{\lambda} - \Delta\lambda/2, \widetilde{\lambda} + \Delta\lambda/2) = \int_{\widetilde{\lambda}-\Delta\lambda/2}^{\widetilde{\lambda}+\Delta\lambda/2} m(\lambda')\,\mathrm{d}\lambda'$ whereas the mass within the λ_∞-region is $M(\lambda, \lambda_\infty) = \int_{\lambda}^{\lambda_\infty} m(\lambda')\,\mathrm{d}\lambda'$, where we assume that λ_∞ is an arbitrary fixed value that is larger than any λ realized within the ocean.

integrating the mass over the surface, $\partial\Omega(\lambda)$

$$m(\lambda) \equiv \frac{\mathrm{d}M}{\mathrm{d}\lambda} = \int_{\partial\Omega(\lambda)} \frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda|}. \tag{73.10}$$

A mass distribution function is quite useful when the distribution is highly non-local in geographic/depth space. It is also effective when using multiple water mass coordinates such as Θ and S as discussed in *Nurser et al.* (2022). These points motivate leaving the $\boldsymbol{x}$-space perspective altogehter to simply define the mass distribution function so that

$$\mathrm{d}M = m(\lambda)\,\mathrm{d}\lambda = \text{fluid mass within the infinitesimal } \lambda\text{-layer } [\lambda - \mathrm{d}\lambda/2, \lambda + \mathrm{d}\lambda/2], \tag{73.11}$$

with an illustration given by Figure 73.4. The mass distribution function is the mass density within λ space; i.e., the mass per λ. Knowledge of the mass distribution function allows us to compute the seawater mass within a finite region, as in equation (73.9), according to

$$M(\lambda_1, \lambda_2) \equiv \int_{\Omega(\lambda_1 \le \lambda \le \lambda_2)} \mathrm{d}M = \int_{\lambda_1}^{\lambda_2} m(\lambda)\,\mathrm{d}\lambda. \tag{73.12}$$

73.3.4 Example regions

To help ground the previous expressions for mass, consider some example regions commonly considered in water mass analysis.

$\Delta\lambda$-layer defined by $[\lambda_1, \lambda_2] = [\lambda - \Delta\lambda/2, \lambda + \Delta\lambda/2]$

A $\Delta\lambda$-layer is defined with the bounding interface values

$$\lambda_1 = \lambda - \Delta\lambda/2 \ \text{ and } \ \lambda_2 = \lambda + \Delta\lambda/2, \tag{73.13}$$

for some finite difference increment $\Delta\lambda > 0$. In this case the layer mass is

$$M(\lambda - \Delta\lambda/2, \lambda + \Delta\lambda/2) = \int_{\lambda-\Delta\lambda/2}^{\lambda+\Delta\lambda/2} \left[\int_{\partial\Omega(\lambda')} \frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda'|} \right] \mathrm{d}\lambda' = \int_{\lambda-\Delta\lambda/2}^{\lambda+\Delta\lambda/2} m(\lambda')\,\mathrm{d}\lambda'. \tag{73.14}$$

Characterizing ocean properties according to their value of λ is generally performed by decomposing the ocean into $\Delta\lambda$-bins and forming histograms to estimate the continuous distribution.

λ_∞-region defined by $[\lambda_1, \lambda_2] = [\lambda, \lambda_\infty]$

A λ_∞-region is defined with

$$\lambda_1 = \lambda \text{ and } \lambda_2 = \lambda_\infty, \tag{73.15}$$

where λ_∞ is an arbitrary fixed constant that is larger than any value of λ realized in the ocean. The region mass is thus given by

$$M(\lambda, \lambda_\infty) = \int_{\Omega(\lambda \le \lambda_\infty)} \mathrm{d}M = \int_\lambda^{\lambda_\infty} \left[\int_{\partial\Omega(\lambda')} \frac{\rho \, \mathrm{d}\mathcal{S}}{|\nabla\lambda'|} \right] \mathrm{d}\lambda' = \int_\lambda^{\lambda_\infty} m(\lambda') \, \mathrm{d}\lambda'. \tag{73.16}$$

An example λ_∞-region is shown in Figure 73.5. The λ_∞-region as so defined provides an expression for the differential mass increment

$$M(\lambda, \lambda_\infty) = \int_\lambda^{\lambda_\infty} m(\lambda') \, \mathrm{d}\lambda' \Longrightarrow \mathrm{d}M(\lambda, \lambda_\infty) = -m(\lambda) \, \mathrm{d}\lambda, \tag{73.17}$$

which follows since λ_∞ is a constant.

The value of the fixed constant, λ_∞, is arbitrarily large, indeed it could be infinite. We can set it to an arbitrarily large constant value since there is no contribution to the integral from regions with λ' outside the range realized within the ocean, merely since there is no ocean mass in that region. As an example, let $\lambda = \Theta$, the Conservative Temperature, in which the region $\Theta \le \Theta_\infty$ encompasses the ocean region where the Conservative Temperature is larger (warmer) than Θ.

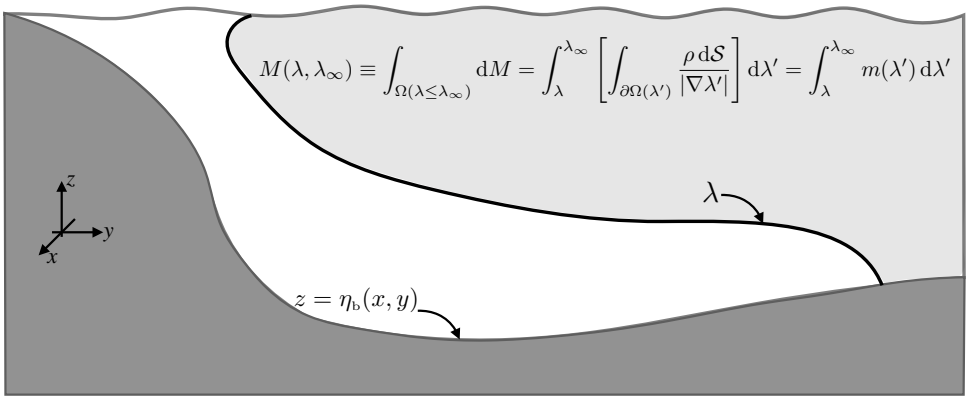

FIGURE 73.5: Depicting the mass of fluid within a λ_∞-region, where $\lambda \le \lambda_\infty$ with λ_∞ is an arbitrary constant that is larger than any value of λ in the ocean domain. This figure is oriented for the southern hemisphere with Antarctica on the left. An example of such a region is for $\lambda = \Theta$, whereby warmer waters are typically shallower and towards the equator.

$\lambda_{-\infty}$-region defined by $[\lambda_1, \lambda_2] = [\lambda_{-\infty}, \lambda]$

A $\lambda_{-\infty}$-region is defined with

$$\lambda_1 = \lambda_{-\infty} \text{ and } \lambda = \lambda, \tag{73.18}$$

where $\lambda_{-\infty}$ is an arbitrary constant that is smaller than any value of λ realized in the ocean. The region mass is thus given by

$$M(\lambda_{-\infty},\lambda) \equiv \int_{\Omega(\lambda_{-\infty}\le\lambda)} \mathrm{d}M = \int_{\lambda_{-\infty}}^{\lambda} \left[\int_{\partial\Omega(\lambda')} \frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda'|}\right] \mathrm{d}\lambda' = \int_{\lambda_{-\infty}}^{\lambda} m(\lambda')\,\mathrm{d}\lambda'. \tag{73.19}$$

This mass is the complement of that contained in the λ_∞-region. The $\lambda_{-\infty}$-region mass implies a corresponding differential mass increment via

$$M(\lambda_{-\infty},\lambda) = \int_{\lambda_{-\infty}}^{\lambda} m(\lambda')\,\mathrm{d}\lambda' \Longrightarrow \mathrm{d}M(\lambda_{-\infty},\lambda) = m(\lambda)\,\mathrm{d}\lambda. \tag{73.20}$$

$\lambda_{\pm\infty}$-region defined by $[\lambda_1,\lambda_2] = [\lambda_{-\infty},\lambda_\infty]$

The full ocean is contained in the $\lambda_{\pm\infty}$-region

$$\lambda_1 = \lambda_{-\infty} \;\text{ and }\; \lambda_2 = \lambda_\infty, \tag{73.21}$$

so that the full ocean mass is written

$$M(\lambda_{-\infty},\lambda_\infty) = \int_{\Omega(\lambda_{-\infty}\le\lambda\le\lambda_\infty)} \mathrm{d}M = \int_{\lambda_{-\infty}}^{\lambda_\infty} \left[\int_{\partial\Omega(\lambda)} \frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda|}\right] \mathrm{d}\lambda = \int_{\lambda_{-\infty}}^{\lambda_\infty} m(\lambda')\,\mathrm{d}\lambda'. \tag{73.22}$$

Difference of mass between two λ_∞-regions

The difference in mass between two λ_∞-regions is given by

$$M(\lambda_1,\lambda_\infty) - M(\lambda_2,\lambda_\infty) = \int_{\lambda_1}^{\lambda_\infty} \left[\int_{\partial\Omega(\lambda)} \frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda|}\right] \mathrm{d}\lambda - \int_{\lambda_2}^{\lambda_\infty} \left[\int_{\partial\Omega(\lambda)} \frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda|}\right] \mathrm{d}\lambda. \tag{73.23}$$

The arbitrary constant, λ_∞, drops out when taking the difference so that we are left with the mass within the intersection of the two regions

$$M(\lambda_1,\lambda_2) = M(\lambda_1,\lambda_\infty) - M(\lambda_2,\lambda_\infty) = \int_{\lambda_1}^{\lambda_2} \left[\int_{\partial\Omega(\lambda)} \frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda|}\right] \mathrm{d}\lambda = \int_{\lambda_1}^{\lambda_2} m(\lambda')\,\mathrm{d}\lambda'. \tag{73.24}$$

73.3.5 Integrals of arbitrary functions

We can extend the above formalism to integrals of an arbitrary function, $\mathcal{F}(\boldsymbol{x},t)$, over a region defined by $\lambda_{1,2}$-interfaces

$$\mathcal{G}_{\mathcal{F}}(\lambda_1,\lambda_2) \equiv \int_{\Omega(\lambda_1\le\lambda\le\lambda_2)} \mathcal{F}\,\mathrm{d}M = \int_{\lambda_1}^{\lambda_2} \left[\int_{\partial\Omega(\lambda)} \frac{\mathcal{F}\,\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda|}\right] \mathrm{d}\lambda. \tag{73.25}$$

Performing the area integral amounts to binning the function according to λ-increments, in which case we define the distribution function

$$m_{\mathcal{F}}(\lambda) = \int_{\partial\Omega(\lambda)} \frac{\mathcal{F}\,\rho\,\mathrm{d}\mathcal{S}}{|\nabla\lambda|}, \tag{73.26}$$

so that an integral over the distribution is given by

$$\mathcal{I}_{\mathcal{F}}(\lambda_1, \lambda_2) = \int_{\lambda_1}^{\lambda_2} m_{\mathcal{F}}(\lambda)\, \mathrm{d}\lambda. \tag{73.27}$$

In particular, consider the integral over a λ_∞-region

$$\mathcal{I}_{\mathcal{F}}(\lambda, \lambda_\infty) = \int_{\lambda}^{\lambda_\infty} \left[\int_{\partial\Omega(\lambda')} \frac{\mathcal{F}\, \rho\, \mathrm{d}\mathcal{S}}{|\nabla\lambda'|} \right] \mathrm{d}\lambda' = \int_{\lambda}^{\lambda_\infty} m_{\mathcal{F}}(\lambda')\, \mathrm{d}\lambda', \tag{73.28}$$

which has the derivative

$$\frac{\partial \mathcal{I}_{\mathcal{F}}(\lambda, \lambda_\infty)}{\partial \lambda} = -\int_{\partial\Omega(\lambda)} \frac{\mathcal{F}\, \rho\, \mathrm{d}\mathcal{S}}{|\nabla\lambda|} = -m_{\mathcal{F}}(\lambda), \tag{73.29}$$

as follows from the fundamental theorem of calculus. Note how the derivative removes the reference value, λ_∞. Analogously, the integral over a $\lambda_{-\infty}$-region has the derivative

$$\frac{\partial \mathcal{I}_{\mathcal{F}}(\lambda_{-\infty}, \lambda)}{\partial \lambda} = \int_{\partial\Omega(\lambda)} \frac{\mathcal{F}\, \rho\, \mathrm{d}\mathcal{S}}{|\nabla\lambda|} = m_{\mathcal{F}}(\lambda). \tag{73.30}$$

73.3.6 Moments of λ

Setting $\mathcal{F} = \lambda$ in the integral (73.25) renders

$$\Lambda(\lambda_1, \lambda_2) \equiv \int_{\Omega(\lambda_1 \le \lambda \le \lambda_2)} \lambda\, \mathrm{d}M = \int_{\Omega(\lambda_1 \le \lambda \le \lambda_2)} \lambda\, \rho\, \mathrm{d}V = \int_{\lambda_1}^{\lambda_2} \left[\int_{\partial\Omega(\lambda)} \frac{\lambda\, \rho\, \mathrm{d}\mathcal{S}}{|\nabla\lambda|} \right] \mathrm{d}\lambda. \tag{73.31}$$

If λ is a tracer concentration (tracer mass per seawater mass), then $\Lambda(\lambda_1, \lambda_2)$ is the mass of tracer within the layer. Observe that λ can be pulled outside of the surface integral in equation (73.31) since λ is constant along $\partial\Omega(\lambda)$, thus rendering

$$\Lambda(\lambda_1, \lambda_2) = \int_{\lambda_1}^{\lambda_2} \left[\int_{\partial\Omega(\lambda)} \frac{\rho\, \mathrm{d}\mathcal{S}}{|\nabla\lambda|} \right] \lambda\, \mathrm{d}\lambda = \int_{\lambda_1}^{\lambda_2} m(\lambda)\, \lambda\, \mathrm{d}\lambda. \tag{73.32}$$

We can likewise define any higher powers as

$$\Lambda^{(n)}(\lambda_1, \lambda_2) \equiv \int_{\lambda_1}^{\lambda_2} \left[\int_{\partial\Omega(\lambda)} \frac{\rho\, \mathrm{d}\mathcal{S}}{|\nabla\lambda|} \right] \lambda^n\, \mathrm{d}\lambda = \int_{\lambda_1}^{\lambda_2} m(\lambda)\, \lambda^n\, \mathrm{d}\lambda = M(\lambda_1, \lambda_2)\, \langle \lambda^n \rangle. \tag{73.33}$$

The final equality introduced the mean value for the power

$$\langle \lambda^n \rangle = \frac{\int_{\lambda_1}^{\lambda_2} m(\lambda)\, \lambda^n\, \mathrm{d}\lambda}{\int_{\lambda_1}^{\lambda_2} m(\lambda)\, \mathrm{d}\lambda} \tag{73.34}$$

as defined over the $[\lambda_1, \lambda_2]$ region. We refer to $\langle \lambda^n \rangle$ as the n-moment of λ, with $n = 1$ yielding the mean.

73.3.7 Internal and external λ-moments

Now specify the region $[\lambda_1, \lambda_2] = [\widetilde{\lambda}, \lambda_\infty]$ for the moment equation (73.33). Making use of the differential mass increment, $\mathrm{d}M(\lambda, \lambda_\infty) = -m(\lambda)\, \mathrm{d}\lambda$ as in equation (73.17) allows us to integrate

the moment equation by parts

$$\Lambda^{(n)}(\widetilde{\lambda}, \lambda_\infty) = \int_{\widetilde{\lambda}}^{\lambda_\infty} \lambda^n \, m(\lambda) \, \mathrm{d}\lambda \tag{73.35a}$$

$$= -\int_{\widetilde{\lambda}}^{\lambda_\infty} \lambda^n \, \mathrm{d}M \tag{73.35b}$$

$$= \int_{\widetilde{\lambda}}^{\lambda_\infty} \left[-\mathrm{d}(\lambda^n \, M) + n \, M \, \lambda^{n-1} \, \mathrm{d}\lambda \right] \tag{73.35c}$$

$$= -\lambda_\infty^n \, M(\lambda_\infty, \lambda_\infty) + \lambda^n \, M(\widetilde{\lambda}, \lambda_\infty) + n \int_{\lambda}^{\lambda_\infty} M(\lambda, \lambda_\infty) \, \lambda^{n-1} \, \mathrm{d}\lambda \tag{73.35d}$$

$$= \lambda^n \, M(\widetilde{\lambda}, \lambda_\infty) + n \int_{\lambda}^{\lambda_\infty} M(\lambda, \lambda_\infty) \, \lambda^{n-1} \, \mathrm{d}\lambda, \tag{73.35e}$$

where the final equality follows since $M(\lambda_\infty, \lambda_\infty) = 0$. Making use of equation (73.33) thus leads to

$$M(\widetilde{\lambda}, \lambda_\infty) \, \langle \lambda^n \rangle = \underbrace{M(\widetilde{\lambda}, \lambda_\infty) \, \widetilde{\lambda}^n}_{\text{external moment}} + \underbrace{n \int_{\widetilde{\lambda}}^{\lambda_\infty} M(\lambda, \lambda_\infty) \, \lambda^{n-1} \, \mathrm{d}\lambda}_{\text{internal moment}}. \tag{73.36}$$

We refer to the rightmost term as the *internal moment* since it is an integral over the region, whereas $M(\widetilde{\lambda}, \lambda_\infty) \, \widetilde{\lambda}^n$ is the *external moment*, which is the region mass times the boundary value, $\widetilde{\lambda}^n$. We choose the moniker "external" since the external moment increases in direct proportion to the mass crossing the ocean layer boundaries, including the external boundaries. In Section 73.6 we develop a budget for the $n = 1$ moment, in which the internal moment from equation (73.36) takes the form

$$M(\widetilde{\lambda}, \lambda_\infty) \, [\langle \lambda \rangle - \widetilde{\lambda}] = \int_{\widetilde{\lambda}}^{\lambda_\infty} M(\lambda, \lambda_\infty) \, \mathrm{d}\lambda. \tag{73.37}$$

We return to the notion of internal and external moments in Section 73.10.2.

73.3.8 Further study

The formulation given here in terms of mass distribution functions follows that of *Walin* (1977) and *Walin* (1982). In these two papers, Walin pioneered the formalism of water mass analysis, which is sometimes referred to as *Walin analysis* in his honor. The concept of internal and external tracer moments follows the internal and external heat introduced by *Holmes et al.* (2019).

73.4 Water mass transformation across a λ-surface

We here develop the formalism to quantify transport of seawater crossing an interior λ-interface. This transport is referred to as the *water mass transformation* and is written as $G(\lambda)$. Figure 73.6 illustrates how this transformation appears in a mass budget for a $\Delta\lambda$-layer, with details provided in this section. We assume that λ satisfies a tracer equation as discussed in Section 73.4.3.

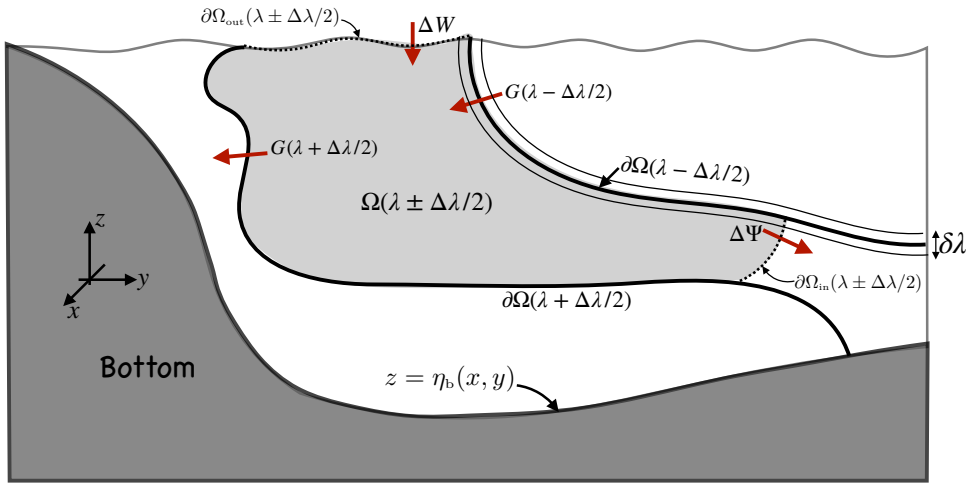

FIGURE 73.6: A layer of seawater with scalar property λ within the range $[\lambda - \Delta\lambda/2, \lambda + \Delta\lambda/2]$ and defined over a geographical domain $\Omega(\lambda \pm \Delta\lambda/2)$. In this example, λ increases to the south, towards Antarctica, with $\lambda = \gamma$ (density) an example (Section 73.2). The net seawater mass transport crossing the layer interfaces, $\partial\Omega(\lambda \pm \Delta\lambda/2)$, is $G(\lambda \pm \Delta\lambda/2)$, with $G > 0$ for water moving to regions of larger λ. The seawater mass crossing the layer through the geographical bounds, $\partial\Omega_{\text{in}}(\lambda \pm \Delta\lambda/2)$, is written $\Delta\Psi(\lambda \pm \Delta\lambda/2)$, with $\Delta\Psi(\lambda \pm \Delta\lambda/2) > 0$ for water leaving $\Omega(\lambda \pm \Delta\lambda/2)$. The boundary $\partial\Omega_{\text{in}}(\lambda \pm \Delta\lambda/2)$ is absent when the domain extends across a basin or the global ocean (e.g., see Figure 73.8). The mass crossing the sea surface, $\partial\Omega_{\text{out}}(\lambda \pm \Delta\lambda/2)$, through rain, evaporation, melt, or rivers is written $\Delta W(\lambda \pm \Delta\lambda/2)$, with $\Delta W(\lambda \pm \Delta\lambda/2) > 0$ for mass entering $\Omega(\lambda \pm \Delta\lambda/2)$. A layer interface can have an arbitrary stratification, such as the vertically non-monotonic profile depicted here for the $\lambda + \Delta\lambda/2$ interface. Additionally, the domain $\Omega(\lambda \pm \Delta\lambda/2)$ can generally be disconnected. The net domain boundaries are written $\partial\Omega_{\text{in}}(\lambda \pm \Delta\lambda/2) + \partial\Omega_{\text{out}}(\lambda \pm \Delta\lambda/2) + \partial\Omega(\lambda + \Delta\lambda/2) + \partial\Omega(\lambda - \Delta\lambda/2)$. The $\delta\lambda$ layer surrounding the $\partial\Omega(\lambda - \Delta\lambda/2)$ interface arises as part of the method detailed in Section 73.4.2 for computing G according to the λ-derivative of an integral over the $\delta\lambda$ layer.

73.4.1 Dia-surface flux and interior transformation

The object that measures the local water mass transformation is the dia-surface flux detailed in Section 64.3.7. This flux is given by

$$w^{\text{dia}} = \hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\lambda)}) = \frac{\dot{\lambda}}{|\nabla\lambda|} \quad \text{with} \quad \hat{\boldsymbol{n}} = \frac{\nabla\lambda}{|\nabla\lambda|} \quad \text{and} \quad \dot{\lambda} = \frac{\mathrm{D}\lambda}{\mathrm{D}t}, \tag{73.38}$$

and with $w^{\text{dia}} > 0$ for water moving to regions of larger λ. It is computed as the projection of the relative velocity, $(\boldsymbol{v} - \boldsymbol{v}^{(\lambda)})$, onto the direction normal to the surface, with the relative velocity being the difference between the fluid particle velocity, $\boldsymbol{v}$, and the velocity of a point on the λ-interface, $\boldsymbol{v}^{(\lambda)}$. The velocity of a point on the surface satisfies the following kinematic constraint[11]

$$(\partial_t + \boldsymbol{v}^{(\lambda)} \cdot \nabla)\, \lambda = 0. \tag{73.39}$$

This constraint is based on assuming $\boldsymbol{v}^{(\lambda)}$ measures the velocity of a point fixed to the λ-surface. Evidently, the dia-surface flux, w^{dia}, locally measures the flux of seawater (volume per area per time) that penetrates a λ-interface in the direction of increasing λ.

The interior water mass transformation, $G(\lambda)$, is the area integral of $\rho\, w^{\text{dia}}$ over the full extent of the λ-surface

$$G(\lambda) \equiv \int_{\partial\Omega(\lambda)} \rho\, w^{\text{dia}}\, \mathrm{d}\mathcal{S} = \int_{\partial\Omega(\lambda)} \rho\, \hat{\boldsymbol{n}} \cdot (\boldsymbol{v} - \boldsymbol{v}^{(\lambda)})\, \mathrm{d}\mathcal{S} = \int_{\partial\Omega(\lambda)} \frac{\rho\, \dot{\lambda}}{|\nabla\lambda|}\, \mathrm{d}\mathcal{S}, \tag{73.40}$$

[11] We encountered the relation (73.39) in Section 19.6.2 when deriving the kinematic boundary condition for a moving surface.

where $\partial\Omega(\lambda)$ is the surface occupied by the λ-interface (see Figure 73.6). Furthermore, the dimensions of $G(\lambda)$ are mass per time

$$G(\lambda) \quad [\equiv] \quad \mathrm{M\ T}^{-1}, \tag{73.41}$$

thus measuring the mass per time crossing the λ-interface.

Based on the definition (73.40), we see that interior water mass transformation across a λ-interface occurs when there is a material change, $\dot{\lambda} \neq 0$, in the property defining the interface. Interior material changes arise from mixing, which generally causes irreversible changes to λ, thus driving seawater across the moving λ-interfaces. Material changes can also arise from sources and sinks, as when considering buoyancy surfaces in the presence of a nonlinear equation of state (Chapter 72). Sources and sinks are also commonly encountered by biogeochemical tracers.

73.4.2 Transformation as the derivative of an integral

Following the discussion from Section 73.3.5, we set $\mathscr{F} = \dot{\lambda}$ and consider the mass integral

$$\mathscr{I}_{\dot{\lambda}}(\lambda, \lambda_\infty) = \int_{\Omega(\lambda \leq \lambda_\infty)} \dot{\lambda}' \, \mathrm{d}M = \int_\lambda^{\lambda_\infty} \left[\int_{\partial\Omega(\lambda')} \frac{\rho \, \dot{\lambda}'}{|\nabla \lambda'|} \, \mathrm{d}\mathcal{S} \right] \mathrm{d}\lambda' = \int_\lambda^{\lambda_\infty} G(\lambda') \, \mathrm{d}\lambda'. \tag{73.42}$$

The fundamental theorem of calculus leads to the expression of the water mass transformation as the derivative

$$G(\lambda) = -\frac{\partial \mathscr{I}_{\dot{\lambda}}(\lambda, \lambda_\infty)}{\partial \lambda} \qquad \text{fund. thm of calculus} \tag{73.43a}$$

$$= -\lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \left[\int_{\lambda+\delta\lambda/2}^{\lambda_\infty} G(\lambda') \mathrm{d}\lambda' - \int_{\lambda-\delta\lambda/2}^{\lambda_\infty} G(\lambda') \mathrm{d}\lambda' \right] \qquad \text{definition of derivative} \tag{73.43b}$$

$$= \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\lambda-\delta\lambda/2}^{\lambda+\delta\lambda/2} G(\lambda') \mathrm{d}\lambda' \qquad \text{combine integral limits} \tag{73.43c}$$

$$= \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda \pm \delta\lambda/2)} \dot{\lambda}' \, \mathrm{d}M \qquad \text{equation (73.42)} \tag{73.43d}$$

$$= \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda \pm \delta\lambda/2)} \dot{\lambda}' \, \rho \, \mathrm{d}V \qquad \mathrm{d}M = \rho \, \mathrm{d}V. \tag{73.43e}$$

Evidently, the calculation of interior water mass transformation requires information about the material time change, $\dot{\lambda}$, a weighting of the time changes according to the mass, $\mathrm{d}M = \rho \, \mathrm{d}V$, and a binning of $\rho \, \dot{\lambda} \, \mathrm{d}V$ according to λ-classes. Note that in the final equality, equation (73.43e), the limit $\delta\lambda \to 0$ might appear to lead to a singularity. However, as seen by the form in equation (73.43c), the integration region volume also gets smaller as $\delta\lambda \to 0$ so that the limit is well defined.

73.4.3 Kinematic and process methods of transformation

There are complementary methods to view interior water mass transformation: the *process method* and the *kinematic method*. The two methods are mathematically identical and so they offer two means to compute the same transformation. The kinematic method tells us *how* transformation happens whereas the process method tells us *why*. We here detail these two methods.

Kinematic method

The kinematic method focuses on the kinematic means for realizing dia-surface transport, thus providing information concerning how interior transformation occurs. It does so by binning processes contributing to the right hand side of

$$\rho \dot{\lambda} = \partial_t(\rho \lambda) + \nabla \cdot (\rho \lambda \boldsymbol{v}), \tag{73.44}$$

which arises from the local time tendency plus advection, so that

$$G(\lambda) = \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda \pm \delta\lambda/2)} [\partial_t(\rho \lambda) + \nabla \cdot (\rho \lambda \boldsymbol{v})] \, \mathrm{d}V. \tag{73.45}$$

This method is operationally simpler than the process method since there are fewer terms to bin. However, it does not provide information about why there is transformation, with that information requiring us to bin tendencies arising from individual processes.

Process method

The *process method* focuses on physical processes leading to movement of fluid across the λ-interface, thus providing information concerning *why* interior transformation occurs. It does so by binning processes contributing to the right hand side of the tracer equation

$$\rho \dot{\lambda} = -\nabla \cdot \boldsymbol{J} + \rho \dot{\Upsilon}, \tag{73.46}$$

where $\boldsymbol{J}$ is a flux arising from non-advective processes such as diffusion, and $\dot{\Upsilon}$ is a source/sink term (dimensions of λ per time) that cannot be written as the convergence of a flux. The tracer equation (73.46) inserted into the transformation equation (73.43e) leads to

$$G(\lambda) = \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda \pm \delta\lambda/2)} (-\nabla \cdot \boldsymbol{J} + \rho \dot{\Upsilon}) \, \mathrm{d}V \tag{73.47a}$$

$$= \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \oint_{\partial\Omega(\lambda \pm \delta\lambda/2)} (-\boldsymbol{J} \cdot \hat{\boldsymbol{n}}) \, \mathrm{d}\mathcal{S} + \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda \pm \delta\lambda/2)} \rho \dot{\Upsilon} \, \mathrm{d}V, \tag{73.47b}$$

The second equality made use of the divergence theorem to convert the volume integral into a surface integral. For the tracer sources, we assume they do not modify the seawater mass at a point so that there is no source in the seawater mass equation.

For many purposes it is useful to decompose the non-advective flux divergence into contributions from interior processes, such as ocean mixing, and boundary fluxes

$$\nabla \cdot \boldsymbol{J} = \nabla \cdot (\boldsymbol{J}^{\mathsf{int}} + \boldsymbol{J}^{\mathsf{out}} + \boldsymbol{J}^{\mathsf{bot}}). \tag{73.48}$$

By definition,

$$\boldsymbol{J}^{\mathsf{int}} \cdot \hat{\boldsymbol{n}} = 0 \quad \text{on } \partial\Omega_{\mathsf{out}}(\lambda \pm \delta\lambda/2) \text{ and } \partial\Omega_{\mathsf{bot}}(\lambda \pm \delta\lambda/2), \tag{73.49}$$

whereas $\boldsymbol{J}^{\mathsf{int}} \cdot \hat{\boldsymbol{n}}$ is generally nonzero on interior layer boundaries. In contrast, the boundary fluxes, $\boldsymbol{J}^{\mathsf{out}} \cdot \hat{\boldsymbol{n}}$ and $\boldsymbol{J}^{\mathsf{bot}} \cdot \hat{\boldsymbol{n}}$, are identically zero everywhere except on their respective boundaries. Correspondingly, it is convenient to bin the volume weighted convergence, $-\nabla \cdot \boldsymbol{J}^{\mathsf{int}} \, \mathrm{d}V$, according to λ-classes, and to likewise bin the area weighted boundary fluxes, $\boldsymbol{J}^{\mathsf{out}} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}$ and $\boldsymbol{J}^{\mathsf{bot}} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}$. In this way we write the non-advective contribution to water mass transformation in the form

$$G(\lambda)_{\text{non-adv}} = \underbrace{- \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda \pm \delta\lambda/2)} \nabla \cdot \boldsymbol{J}^{\mathsf{int}} \, \mathrm{d}V}_{\text{interior transformation = volume integral of convergence}}$$

$$\underbrace{-\lim_{\delta\lambda\to 0}\frac{1}{\delta\lambda}\int_{\partial\Omega_{\text{out}}(\lambda\pm\delta\lambda/2)}\boldsymbol{J}^{\text{out}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}}_{\text{surface transformation = area integral of surface boundary fluxes}}$$
$$\underbrace{-\lim_{\delta\lambda\to 0}\frac{1}{\delta\lambda}\int_{\partial\Omega_{\text{bot}}(\lambda\pm\delta\lambda/2)}\boldsymbol{J}^{\text{bot}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}}_{\text{bottom transformation = area integral of bottom boundary fluxes}}. \tag{73.50}$$

Again, this expression decomposes the contribution from interior processes, here represented as the volume integral of the interior flux convergence, from the surface and bottom contributions, here represented as the area integral of the boundary fluxes. This decomposition is further examined in Section 73.7 where we focus on the surface contribution to water mass transformation.

Since the boundary fluxes are, by definition, zero except on the boundaries, their divergence can be written in terms of a Dirac delta distribution[12]

$$\nabla\cdot[\boldsymbol{J}^{\text{out}}+\boldsymbol{J}^{\text{bot}}]=\boldsymbol{J}^{\text{out}}\cdot\hat{\boldsymbol{n}}\,\delta(z-\eta)+\boldsymbol{J}^{\text{bot}}\cdot\hat{\boldsymbol{n}}\,\delta(z-\eta_{\text{b}}). \tag{73.51}$$

Although this equation is more physically formal than mathematically rigorous, its use in the transformation equation (73.47a) correctly leads to the expression (73.50). Consequently, equation (73.51) proves to be a useful shorthand that is commonly used in the literature (e.g., *Groeskamp et al.* (2019)).[13]

Comments

As we saw, equality of the process method and kinematic method follows simply because the two provide equivalent expressions for the material time derivative. However, in the analysis of numerical model output, it can be nontrivial to realize this equivalance due to the extreme care required to diagnose the terms appearing in the scalar budget equation. See *Drake et al.* (2025) for a thorough discussion of the details as required for the MOM6 finite volume numerical ocean model.

73.4.4 Some details concerning interior transformation

We here consider some details of the water mass transformation arising just from interior processes such as diffusion.

A global integrated constraint on $G(\lambda)_{int}$

Consider the integrated water mass transformation given by equation (73.42), only now integrate over the full ocean domain

$$\mathcal{G}_{\dot{\lambda}}(\lambda_{-\infty},\lambda_{\infty})=\int_{\lambda_{-\infty}}^{\lambda_{\infty}}G(\lambda')\,\mathrm{d}\lambda'=\int_{\Omega(\lambda_{-\infty},\lambda_{\infty})}\rho\,\dot{\lambda}'\,\mathrm{d}V. \tag{73.52}$$

[12] We detail properties of the Dirac delta distribution in Chapter 7. It has dimensions equal to the inverse the dimensions of its argument (Section 7.3). For example, when the argument has dimensions of length then the Dirac delta has dimensions of inverse length. We thus see that equation (73.51) is dimensionally consistent.

[13] As detailed in Section 9.4.8, we are afforded the ability to introduce Dirac deltas into the boundary conditions (73.51) since the boundary conditions are Neumann (flux) conditions. A similar method was used for quasi-geostrophic potential vorticity in Section 45.7 and for the surface buoyancy fluxes in Section 72.6.3.

This integral vanishes for water mass transformations arising from conservative interior processes (i.e., those processes determined by the convergence of a flux)

$$[\mathcal{I}_{\dot\lambda}(\lambda_{-\infty}, \lambda_\infty)]_{\text{int}} = \int_{\lambda_{-\infty}}^{\lambda_\infty} G(\lambda')_{\text{int}} \, \mathrm{d}\lambda' \tag{73.53a}$$

$$= -\int_{\Omega(\lambda_{-\infty}, \lambda_\infty)} \nabla \cdot \boldsymbol{J}^{\text{int}} \, \mathrm{d}V \tag{73.53b}$$

$$= -\oint_{\partial\Omega(\lambda_{-\infty}, \lambda_\infty)} \boldsymbol{J}^{\text{int}} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} \tag{73.53c}$$

$$= 0, \tag{73.53d}$$

which follows since $\boldsymbol{J}^{\text{int}} \cdot \hat{\boldsymbol{n}} = 0$ on the ocean boundaries. Hence, there can be no net water mass transformation across a λ surface arising from conservative interior processes

$$\int_{\lambda_{-\infty}}^{\lambda_\infty} G(\lambda')_{\text{int}} \, \mathrm{d}\lambda' = 0. \tag{73.54}$$

Instead, conservative interior processes only lead to rearrangement of water within the λ-bins. This result follows since these interior processes conserve the total content of λ within the global domain. Equation (73.54) provides a constraint that should be verified by any numerical realization of water mass transformation.

Interior transformation across constant λ surfaces

We now focus on the transformation occuring along surfaces of constant λ (Figure 73.7) so that

$$G(\lambda)_{\text{int}} = -\lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda \pm \delta\lambda/2)} \nabla \cdot \boldsymbol{J}^{\text{int}} \, \mathrm{d}V \tag{73.55a}$$

$$= -\lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \left[\int_{\Omega(\lambda + \delta\lambda/2)} \hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{int}} \, \mathrm{d}\mathcal{S} - \int_{\Omega(\lambda - \delta\lambda/2)} \hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{int}} \, \mathrm{d}\mathcal{S} \right]. \tag{73.55b}$$

Transformation occurs if there is an imbalance between the diffusive transport across the two bounding surfaces, $\Omega(\lambda + \delta\lambda/2)$ and $\Omega(\lambda - \delta\lambda/2)$. As a special case, assume the ocean surface is a constant λ surface with $\lambda = \lambda_{\text{top}}$. Along this surface we have $\hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{int}} = 0$, so that the transformation at $\lambda_{\text{top}} - \delta\lambda/2$ has a contribution just from the flux crossing the $\Omega(\lambda_{\text{top}} - \delta\lambda)$ surface

$$\lim_{\delta\lambda \to 0} G(\lambda_{\text{top}} - \delta\lambda/2)_{\text{int}} = \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda_{\text{top}} - \delta\lambda)} \hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{int}} \, \mathrm{d}\mathcal{S}. \tag{73.56}$$

Likewise, along the top surface we have

$$G(\lambda_{\text{top}})_{\text{int}} = \lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\Omega(\lambda_{\text{top}} - \delta\lambda/2)} \hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{int}} \, \mathrm{d}\mathcal{S}, \tag{73.57}$$

where we set $\hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{int}} = 0$ for the surface $\Omega(\lambda_{\text{top}} + \delta\lambda/2)$, since this surface exists outside of the ocean.

The results (73.56) and (73.57) make it appear that $G(\lambda_{\text{top}} - \delta\lambda/2)_{\text{int}}$ and $G(\lambda_{\text{top}})_{\text{int}}$ are unbounded as $\delta\lambda \to 0$, so long as there is a nonzero diffusive transport through $\Omega(\lambda_{\text{top}} - \delta\lambda)$ or $\Omega(\lambda_{\text{top}} - \delta\lambda/2)$. However, this unbounded water mass transformation is not realized since the diffusive flux gets smaller in magnitude when approaching the ocean surface, and it does so in

order to satisfy the no-flux surface boundary condition (73.49) satisfied by interior processes[14]

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{J}^{\text{int}} = 0 \quad \text{at } z = \eta. \tag{73.58}$$

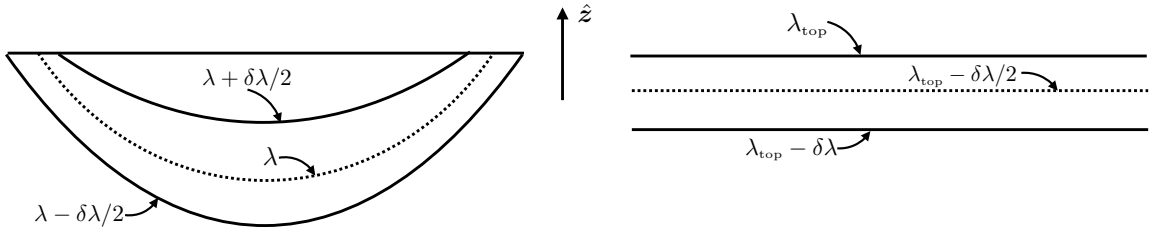

FIGURE 73.7: Example λ surfaces for studying interior transformation due to diffusion. The left panel shows λ surfaces that outcrop to the ocean surface, with the dotted surface the chosen λ surface across which we compute the water mass transformation. The right panel assumes the λ surfaces are flat and with $\lambda = \lambda_{\text{top}}$ the value along the ocean surface.

To further our understanding of the transformation in the region near the ocean surface, let the λ surfaces be flat near the ocean surface so that $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{z}}$ along $\Omega(\lambda_{\text{top}} - \delta\lambda)$. Setting the diffusive flux to

$$\boldsymbol{J} = -\rho_o \, \kappa \, \nabla\lambda \tag{73.59}$$

as per a Boussinesq fluid with reference density ρ_o and diffusivity $\kappa > 0$, leads to the transformation

$$G(\lambda_{\text{top}} - \delta\lambda/2)_{\text{int}} = \frac{1}{\delta\lambda} \int_{\Omega(\lambda_{\text{top}} - \delta\lambda)} (\rho_o \, \kappa \, \partial_z \lambda) \, \mathrm{d}\mathcal{S}. \tag{73.60}$$

With $\kappa \, \partial_z \lambda > 0$, the transformation is positive, $G(\lambda_{\text{top}} - \delta\lambda/2)_{\text{int}} > 0$, so that water is entrained into the layer bounded by $\lambda_{\text{top}} - \delta\lambda$ and λ_{top}. Note that in the absence of boundary fluxes, the value of λ_{top} is reduced due to diffusive mixing with interior waters since these waters have lower values of λ. Furthermore, as the surface is approached, $\partial_z \lambda$ reduces in magnitude to satisfy the no-flux condition, $\kappa \, \partial_z \lambda = 0$, at the ocean surface. In this manner, the transformation remains bounded even as $\delta\lambda \to 0$.

73.5 Budget for seawater mass in a $\Delta\lambda$-layer

In this section we construct the seawater mass budget for a $\Delta\lambda$-layer, making reference to Figure 73.6 for the notation. As a shorthand, we write the layer mass as

$$\Delta M(\lambda \pm \Delta\lambda/2) \equiv M(\lambda - \Delta\lambda/2, \lambda + \Delta\lambda/2), \tag{73.61}$$

along with a similar notation for other contributions to the layer mass budget.

73.5.1 Transport crossing interior open boundaries

As depicted in Figure 73.6, the layer region has an open boundary that is within the interior of the ocean. The mass transport leaving the layer through this interior open boundary is written

$$\Delta\Psi(\lambda \pm \Delta\lambda/2) = \int_{\partial\Omega_{\text{in}}(\lambda \pm \Delta\lambda/2)} \rho \, (\boldsymbol{v} - \boldsymbol{v}^{(\text{b})}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{73.62}$$

[14] As discussed in Sections 20.4.3, 72.5, and 73.8.3, when water is transported across the ocean surface the diffusive flux picks up a nonzero boundary contribution. That contribution is assumed to be part of the surface transformation in equation (73.50) so that the interior diffusive flux still satisfies the no-flux boundary condition (73.58). *Nurser and Griffies* (2019) discuss these points for salinity.

where $\boldsymbol{v}^{(\mathsf{b})}$ is the velocity for a point on the boundary and $\hat{\boldsymbol{n}}$ is the outward normal along the boundary. Introducing the mass distribution for this transport renders the equivalent expression

$$\Delta\Psi(\lambda \pm \Delta\lambda/2) = \int_{\lambda-\Delta\lambda/2}^{\lambda+\Delta\lambda/2} \dot{m}_{\Psi}(\lambda')\,\mathrm{d}\lambda', \tag{73.63}$$

where we introduced

$$\dot{m}_{\Psi}(\lambda)\,\mathrm{d}\lambda = \text{mass per time of } \lambda\text{-stuff crossing } \partial\Omega_{\mathsf{in}} \text{ within } [\lambda - \mathrm{d}\lambda/2, \lambda + \mathrm{d}\lambda/2]. \tag{73.64}$$

We make particular use of $\dot{m}_{\Psi}$ in Section 73.6 when studying the λ-budget in a $\Delta\lambda$-layer. One common example for an open interior boundary is when choosing a particular latitude, in which case $\boldsymbol{v}^{(\mathsf{b})} = 0$ and $\hat{\boldsymbol{n}} = \hat{\boldsymbol{y}}$ so that

$$\Delta\Psi(\lambda \pm \Delta\lambda/2) = \int_{\partial\Omega_{\mathsf{in}}(\lambda\pm\Delta\lambda/2)} \rho\, v\, \mathrm{d}x\, \mathrm{d}z. \tag{73.65}$$

In this case, $\partial\Omega_{\mathsf{in}}(\lambda\pm\Delta\lambda/2)$ specifies the depth and longitude range for the layer at its intersection along the constant latitude boundary.

73.5.2 Mass transport crossing the ocean surface

The mass transport crossing the ocean free surface is written

$$\Delta W(\lambda \pm \Delta\lambda/2) = -\int_{\partial\Omega_{\mathsf{out}}(\lambda\pm\Delta\lambda/2)} \rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\partial\Omega_{\mathsf{out}}(\lambda\pm\Delta\lambda/2)} \mathcal{Q}_{\mathsf{m}}\,\mathrm{d}\mathcal{S}, \tag{73.66}$$

where we made use of the surface kinematic boundary condition (19.78) to write

$$\rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\mathsf{b})}) \cdot \hat{\boldsymbol{n}} \equiv -\mathcal{Q}_{\mathsf{m}}, \tag{73.67}$$

where $\mathcal{Q}_{\mathsf{m}}\,\mathrm{d}\mathcal{S}$ is the mass transport of water crossing the free surface ($\mathcal{Q}_{\mathsf{m}} > 0$ for water entering the ocean). Introducing the mass distribution leads to the equivalent expression

$$\Delta W(\lambda \pm \Delta\lambda/2) = \int_{\lambda-\Delta\lambda/2}^{\lambda+\Delta\lambda/2} \dot{m}_{\mathsf{W}}(\lambda')\,\mathrm{d}\lambda', \tag{73.68}$$

where

$$\dot{m}_{\mathsf{W}}(\lambda)\,\mathrm{d}\lambda = \text{mass per time of } \lambda\text{-stuff crossing } \partial\Omega_{\mathsf{out}} \text{ within } [\lambda - \mathrm{d}\lambda/2, \lambda + \mathrm{d}\lambda/2]. \tag{73.69}$$

We make particular use of $\dot{m}_{\mathsf{W}}$ in Section 73.6 when studying the λ-budget in a $\Delta\lambda$-layer.

73.5.3 Mass budget

Bringing the above pieces together leads to the layer mass budget

$$\frac{\mathrm{d}\Delta M}{\mathrm{d}t} = -\Delta\Psi + \Delta W - [G(\lambda + \Delta\lambda/2) - G(\lambda - \Delta\lambda/2)], \tag{73.70}$$

where for brevity we dropped $\lambda \pm \Delta\lambda/2$ arguments for ΔM, $\Delta\Psi$, and ΔW. It is common to define the layer mass *formation* as the mass accumulation within the layer

$$\underbrace{\frac{\mathrm{d}\Delta M}{\mathrm{d}t} + \Delta\Psi}_{\text{storage + outflow}} = \underbrace{\Delta W - [G(\lambda + \Delta\lambda/2) - G(\lambda - \Delta\lambda/2)]}_{\text{formation into layer } \Omega_{(\lambda \pm \Delta\lambda/2)}}. \tag{73.71}$$

This equality defines water mass formation as the time change for the mass within the layer (sometimes referred to as the *storage term*), plus the net mass leaving the interior open boundary. Formation into a layer occurs if there is mass converging through transformation across interior layer interfaces, plus mass entering through the surface boundary outcrop region.

We arrive at a differential equation for the mass budget (73.71) by dividing through by the layer increment, $\Delta\lambda$, and taking the limit as this increment tends to zero

$$\frac{\partial}{\partial\lambda}\left[\frac{\mathrm{d}M}{\mathrm{d}t} + \Psi - W + G\right] = 0. \tag{73.72}$$

Integrating from a reference value $\lambda_{-\infty}$ to λ leads to

$$\int_{\lambda_{-\infty}}^{\lambda} \frac{\partial\Psi}{\partial\lambda}\,\mathrm{d}\lambda = \int_{\lambda_{-\infty}}^{\lambda} \frac{\partial}{\partial\lambda}\left[-\frac{\mathrm{d}M}{\mathrm{d}t} + W - G\right]\mathrm{d}\lambda \Longrightarrow \Psi = -\frac{\mathrm{d}M}{\mathrm{d}t} + W - G. \tag{73.73}$$

We dropped the contribution from the constant reference value, $\lambda_{-\infty}$, since it sits outside of the ocean domain. The differential water mass equation (73.73) is a continuous version of the discrete equation (73.71). We wrote this equation as an expression for Ψ given that an accumulation from the bottom up leads to a transport streamfunction in the steady state, as we discuss in Section 73.7.1.

73.6 Budget for λ mass in a λ_∞-region

We build from our understanding of the seawater mass budget in Section 73.5 to develop a budget for the mass of λ within the λ_∞-region of Section 73.3.4 and as illustrated in Figure 73.8. Part of our aim is to further develop the formalism while also offering added insights into the causes for water mass transformation, $G(\lambda)$.

We here choose to be specific by considering λ to be an intensive property such as a material tracer concentration, in which case $\lambda\,\rho\,\mathrm{d}V$ has dimensions of tracer mass.[15] For non-material scalar fields, such as Conservative Temperature or buoyancy, the dimensions are modified accordingly.

73.6.1 Processes affecting the mass of λ-stuff

Our starting point is the Leibniz-Reynolds budget for a scalar field derived in Section 20.2.4, here including the possibility of scalar sources

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\Omega(\lambda\le\lambda_\infty)} \rho\,\lambda\,\mathrm{d}V\right] = \int_{\Omega(\lambda\le\lambda_\infty)} \rho\,\dot{\Upsilon}\,\mathrm{d}V - \int_{\partial\Omega(\lambda\le\lambda_\infty)} \left[\rho\,\lambda\,(\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) + \boldsymbol{J}\right]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{73.74}$$

The right hand side of this budget equation can be decomposed into the following processes illustrated in Figure 73.8.

[15] See Section 20.2.1 for more on intensive and extensive fluid properties.

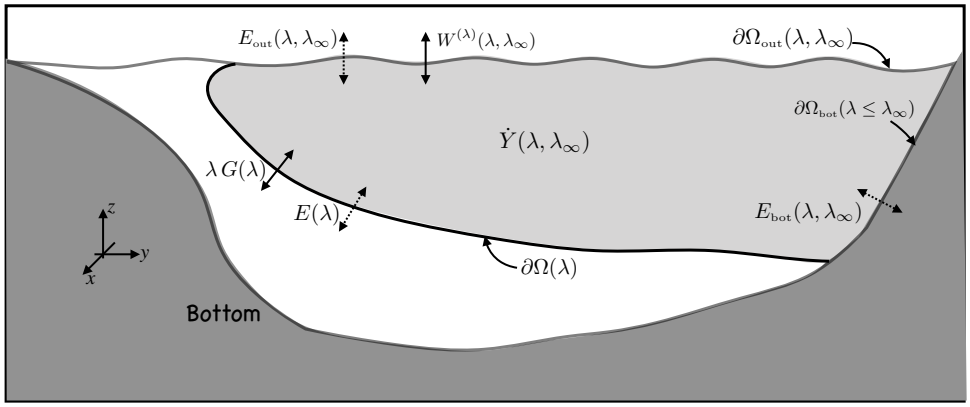

FIGURE 73.8: A λ_∞-region for studying the λ budget, with the region bounded by the solid-earth bottom, $\partial\Omega_{\text{bot}}(\lambda \le \lambda_\infty)$, the ocean surface boundary, $\partial\Omega_{\text{out}}(\lambda, \lambda_\infty)$, and the λ-interface, $\partial\Omega(\lambda)$. Hence, in contrast to the $\Delta\lambda$-region shown in Figure 73.6, the λ_∞-region has no interior open boundary. Along the surface boundary, the λ budget is affected by the non-advective transport, $E_{\text{out}}(\lambda, \lambda_\infty)$, arising from processes such as diffusion, plus advective transport, $W^{(\lambda)}(\lambda, \lambda_\infty)$, arising from mass transported across the surface that can carry a non-zero amount of λ. Along the bottom boundary, the λ budget is affected by non-advective transport, $E_{\text{bot}}(\lambda, \lambda_\infty)$, arising from processes such as geothermal heating. There is no corresponding advective transport along the bottom since we assume there is no mass crossing the ocean bottom. Along the interior boundary, $\partial\Omega(\lambda)$, the budget is affected by non-advective transport, $E(\lambda)$, arising from diffusion, as well as advective transport through $\lambda\, G(\lambda)$, with $G(\lambda)$ the interior water mass transformation from Section 73.4. Finally, there is the possibility for an interior volume source, $\dot{Y}(\lambda \le \lambda_\infty)$, particularly for buoyancy in the presence of a nonlinear equation of state, and for biogeochemical tracers.

Non-conservative sources and sinks

As noted in Section 73.4.3, the source term, $\rho\, \dot{\Upsilon}$, accounts for processes that cannot be represented as the convergence of a flux. We write its region integrated contribution using the shorthand

$$\dot{Y}(\lambda, \lambda_\infty) \equiv \int_{\Omega(\lambda \le \lambda_\infty)} \rho\, \dot{\Upsilon}\, \mathrm{d}V \equiv \int_{\lambda}^{\lambda_\infty} \dot{m}_{\Upsilon}(\lambda')\, \mathrm{d}\lambda'. \tag{73.75}$$

The final equality introduced the distribution function for the source, in which

$$\dot{m}_{\Upsilon}(\lambda)\, \mathrm{d}\lambda = \text{mass per time of } \lambda\text{-stuff created within } [\lambda - \mathrm{d}\lambda/2, \lambda + \mathrm{d}\lambda/2]. \tag{73.76}$$

Transport from non-advective processes

The contribution from boundary area integrated non-advective fluxes appears in the term

$$-\int_{\partial\Omega(\lambda \le \lambda_\infty)} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = -\int_{\partial\Omega_{\text{out}}(\lambda \le \lambda_\infty)} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \int_{\partial\Omega_{\text{bot}}(\lambda \le \lambda_\infty)} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \int_{\partial\Omega(\lambda)} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{73.77}$$

Recall the minus signs arise since a non-advective flux increases the λ content of the region if the flux is oriented into the region, whereas $\hat{\boldsymbol{n}}$ is the region outward normal. The surface, $\partial\Omega_{\text{out}}(\lambda \le \lambda_\infty)$, extends along the upper ocean boundary and supports non-advective surface boundary fluxes. Likewise, the boundary, $\partial\Omega_{\text{bot}}(\lambda \le \lambda_\infty)$, intersects the ocean bottom and generally experiences bottom boundary fluxes such as geothermal heating. Finally, the surface, $\partial\Omega(\lambda)$, has non-advective fluxes that cross the λ-interface, with diffusive fluxes the canonical example. The boundary area integrated non-advective fluxes give rise to non-advective transports, with dimensions of mass of λ-stuff per time, and they are written using the shorthand

$$-\int_{\partial\Omega(\lambda \le \lambda_\infty)} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = E_{\text{out}}(\lambda, \lambda_\infty) + E_{\text{bot}}(\lambda, \lambda_\infty) + E(\lambda), \tag{73.78}$$

with a term having a positive value if it increases the λ mass of the region. We furthermore find it useful to introduce the distribution functions according to

$$E_{\text{out}}(\lambda, \lambda_\infty) + E_{\text{bot}}(\lambda, \lambda_\infty) = \int_\lambda^{\lambda_\infty} \left[\dot{m}_{\mathsf{E}}^{\text{out}}(\lambda') + \dot{m}_{\mathsf{E}}^{\text{bot}}(\lambda') \right] \mathrm{d}\lambda', \tag{73.79}$$

where

$$\dot{m}_{\mathsf{E}}^{\text{out}}(\lambda)\, \mathrm{d}\lambda = \text{mass per time of } \lambda\text{-stuff from } \partial\Omega_{\text{out}} \text{ transport in } [\lambda - \mathrm{d}\lambda/2, \lambda + \mathrm{d}\lambda/2] \tag{73.80a}$$

$$\dot{m}_{\mathsf{E}}^{\text{bot}}(\lambda)\, \mathrm{d}\lambda = \text{mass per time of } \lambda\text{-stuff from } \partial\Omega_{\text{bot}} \text{ transport in } [\lambda - \mathrm{d}\lambda/2, \lambda + \mathrm{d}\lambda/2]. \tag{73.80b}$$

λ transported with interior boundary mass fluxes

We next consider the contribution to the budget equation (73.74) arising from the transport of λ with mass that crosses the interior boundary, $\partial\Omega(\lambda)$, whereby

$$-\int_{\partial\Omega(\lambda)} \rho\, \lambda\, (\boldsymbol{v} - \boldsymbol{v}^{(\lambda)}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = -\lambda \int_{\partial\Omega(\lambda)} \rho\, (\boldsymbol{v} - \boldsymbol{v}^{(\lambda)}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \lambda\, G(\lambda), \tag{73.81}$$

To reach this result we noted that λ can be pulled outside of the $\partial\Omega(\lambda)$ integral since it is constant along this surface, thus allowing for the introduction of the water mass transformation, $G(\lambda)$, given by equation (73.40).

Surface boundary mass fluxes

The final term contributing to the right hand side of the λ budget equation (73.74) arises from the surface mass transport along the boundary, $\partial\Omega_{\text{out}}(\lambda \leq \lambda_\infty)$,

$$-\int_{\partial\Omega(\lambda \leq \lambda_\infty)} \rho\, \lambda\, (\boldsymbol{v} - \boldsymbol{v}^{(\text{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\partial\Omega_{\text{out}}(\lambda \leq \lambda_\infty)} \lambda\, \mathcal{Q}_{\mathsf{m}}\, \mathrm{d}\mathcal{S} \equiv W^{(\lambda)}(\lambda, \lambda_\infty). \tag{73.82}$$

To reach the first equality we followed the steps in Section 73.5.2 by using the kinematic boundary condition (19.78) to introduce the surface mass transport, $\mathcal{Q}_{\mathsf{m}}\, \mathrm{d}\mathcal{S}$. The final equality introduced a shorthand that corresponds to the $W(\lambda, \lambda_\infty)$ from Section 73.5.2. In the following, we find it useful to introduce the mass distribution function, $\dot{m}_{\mathsf{W}}(\lambda)$, from equation (73.69), thus rendering

$$W(\lambda, \lambda_\infty) = \int_\lambda^{\lambda_\infty} \dot{m}_{\mathsf{W}}(\lambda')\, \mathrm{d}\lambda' \qquad \text{and} \qquad W^{(\lambda)}(\lambda, \lambda_\infty) = \int_\lambda^{\lambda_\infty} \lambda\, \dot{m}_{\mathsf{W}}(\lambda')\, \mathrm{d}\lambda'. \tag{73.83}$$

Following the discussion in Sections 72.5.2, we have not assumed a relation between λ along the interface, $\partial\Omega_{\text{out}}(\lambda \leq \lambda_\infty)$, and the concentration, λ_{m}, contained in the entering mass. We prefer to keep the discussion general for now, providing a relation only when necessary.

73.6.2 Summary of the λ budget

Bringing terms together leads to the expanded version of the mass budget (73.74) for λ-stuff, now written as

$$\frac{\mathrm{d}}{\mathrm{d}t} \left[\int_{\Omega(\lambda \leq \lambda_\infty)} \rho\, \lambda\, \mathrm{d}V \right] = \dot{Y}(\lambda, \lambda_\infty) + E_{\text{out}}(\lambda, \lambda_\infty) + E_{\text{bot}}(\lambda, \lambda_\infty) + E(\lambda) + W^{(\lambda)}(\lambda, \lambda_\infty) + \lambda\, G(\lambda), \tag{73.84}$$

which has the equivalent expression in terms of distribution functions

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_\lambda^{\lambda_\infty} \lambda'\, m(\lambda')\,\mathrm{d}\lambda' = \int_\lambda^{\lambda_\infty} \big[\dot m_{\mathsf{Y}}(\lambda') + \dot m_{\mathsf{E}}^{\mathsf{out}}(\lambda') + \dot m_{\mathsf{E}}^{\mathsf{bot}}(\lambda') + \lambda\, \dot m_{\mathsf{W}}(\lambda')\big]\,\mathrm{d}\lambda' + E(\lambda) + \lambda\, G(\lambda). \tag{73.85}$$

Setting λ to a global constant and assuming there are no seawater mass sources leads to the seawater mass budget for the λ_∞-region

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\Omega(\lambda\le\lambda_\infty)} \rho\,\mathrm{d}V\right] = W(\lambda,\lambda_\infty) + G(\lambda), \tag{73.86}$$

which takes on the following form in terms of distributions

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_\lambda^{\lambda_\infty} m(\lambda')\,\mathrm{d}\lambda' = \int_\lambda^{\lambda_\infty} \dot m_{\mathsf{W}}(\lambda')\,\mathrm{d}\lambda' + G(\lambda). \tag{73.87}$$

73.6.3 Processes leading to water mass transformation

We now massage the budget equations to explicitly identify terms leading to water mass transformation, $G(\lambda)$. For that purpose, make use of the moment equation (73.37) to write

$$\int_{\Omega(\lambda\le\lambda_\infty)} \rho\,\lambda\,\mathrm{d}V = M(\lambda,\lambda_\infty)\,\langle\lambda\rangle = M(\lambda,\lambda_\infty)\,\lambda + \int_\lambda^{\lambda_\infty} M(\lambda',\lambda_\infty)\,\mathrm{d}\lambda', \tag{73.88}$$

which then leads to

$$\frac{\mathrm{d}[M(\lambda,\lambda_\infty)\,\langle\lambda\rangle]}{\mathrm{d}t} = \lambda\,\frac{\mathrm{d}M(\lambda,\lambda_\infty)}{\mathrm{d}t} + \int_\lambda^{\lambda_\infty} \frac{\mathrm{d}M(\lambda',\lambda_\infty)}{\mathrm{d}t}\,\mathrm{d}\lambda'. \tag{73.89}$$

Integrated water mass transformation over the λ_∞-region

Use of the λ budget equation (73.84) for the left hand side of equation (73.89), and the mass budget equation (73.86) for the right hand side, yields

$$\begin{aligned}\dot Y(\lambda,\lambda_\infty) + E_{\mathsf{out}}(\lambda,\lambda_\infty) + E_{\mathsf{bot}}(\lambda,\lambda_\infty) + E(\lambda) + W^{(\lambda)}(\lambda,\lambda_\infty) + \lambda\, G(\lambda) \\ = \lambda\,[W(\lambda,\lambda_\infty) + G(\lambda)] + \int_\lambda^{\lambda_\infty} [W(\lambda',\lambda_\infty) + G(\lambda')]\,\mathrm{d}\lambda'.\end{aligned} \tag{73.90}$$

Observe that the $\lambda\, G(\lambda)$ term cancels on both sides of this equation. The three contributions from the surface boundary mass fluxes also cancel, as revealed through the following identity

$$W^{(\lambda)}(\lambda,\lambda_\infty) - \lambda\, W(\lambda,\lambda_\infty) = \int_\lambda^{\lambda_\infty} (\lambda'-\lambda)\,\dot m_{\mathsf{W}}(\lambda')\,\mathrm{d}\lambda' \tag{73.91a}$$

$$= \int_\lambda^{\lambda_\infty} \left[\int_{\lambda'}^{\lambda_\infty} \dot m_{\mathsf{W}}(\lambda'')\,\mathrm{d}\lambda''\right]\mathrm{d}\lambda' \tag{73.91b}$$

$$= \int_\lambda^{\lambda_\infty} W(\lambda',\lambda_\infty)\,\mathrm{d}\lambda', \tag{73.91c}$$

where the second equality follows from the double integral formula (6.107). To understand the physical reason we see no water mass transformation from surface mass fluxes, recall the discussion in Section 72.5.2. Namely, mixing and internal sources provide the only means for irreversible changes to water masses and thus to water mass transformation. In contrast, boundary mass transport contributes to transformation only if the mass participates in mixing.

That is, the mass associated with boundary mass transport is incorporated into the ocean (or leaves the ocean) only in the presence of mixing. It is thus reassuring that the formalism leads to this same conclusion. Furthermore, this result is consistent with the expression (73.47b), whereby the water mass transformation is, again, determined solely in terms of the non-advective fluxes at the region boundaries plus the interior source term.

Cancelling the mass transport terms thus leads to the integrated water mass transformation

$$\int_{\lambda}^{\lambda_\infty} G(\lambda')\, \mathrm{d}\lambda' = \dot{Y}(\lambda, \lambda_\infty) + E_{\text{out}}(\lambda, \lambda_\infty) + E_{\text{bot}}(\lambda, \lambda_\infty) + E(\lambda). \tag{73.92}$$

Each term in this equation has dimensions mass of λ-stuff per time. This equation is an integrated version of the expression (73.47b) for the water mass transformation, here having exposed the processes contributing to transformation over the range $\lambda \leq \lambda_\infty$. Evidently, the accumulated effects from sources within the interior, plus non-advective fluxes along the surface and interior boundaries, lead to an integrated interior water mass transformation.

Water mass transformation across the λ-interface

We derive an expression for the water mass transformation across the λ-interface by taking $\partial/\partial\lambda$ of equation (73.92) to reveal

$$G(\lambda) = -\frac{\partial}{\partial \lambda} \left[\dot{Y}(\lambda, \lambda_\infty) + E_{\text{out}}(\lambda, \lambda_\infty) + E_{\text{bot}}(\lambda, \lambda_\infty) + E(\lambda) \right], \tag{73.93}$$

thus revealing that the water mass transformation across a λ-surface is the λ-convergence of the mixing processes plus the interior sources. This equation takes on the following distributional form

$$G(\lambda) = \dot{m}_{\mathsf{Y}}(\lambda) + \dot{m}_{\mathsf{E}}^{\text{bot}}(\lambda) + \dot{m}_{\mathsf{E}}^{\text{out}}(\lambda) - \frac{\partial E(\lambda)}{\partial \lambda}. \tag{73.94}$$

73.7 Surface water mass transformation

We have articulated all the terms needed to form the $\Delta\lambda$-layer mass budget according to Figure 73.6 as well as the λ_∞-region mass budget according to Figure 73.8. In this section we focus on contributions to transformation from surface processes in the transformation equation (73.94)

$$G_{\text{out}}(\lambda) \equiv -\frac{\partial E_{\text{out}}(\lambda, \lambda_\infty)}{\partial \lambda} = \dot{m}_{\mathsf{E}}^{\text{out}}(\lambda) = -\lim_{\delta\lambda \to 0} \frac{1}{\delta\lambda} \int_{\partial\Omega_{\text{out}}(\lambda \pm \delta\lambda/2)} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{73.95}$$

where the final equality made use of equation (73.47b). Such *surface transformation* forms the focus of many studies of water mass transformation because it only requires surface boundary information, which is generally more accessible than information from interior ocean mixing processes or bottom geothermal processes. Furthermore, much of the transformation of water occurs in surface regions since this region is home to large contributions from surface boundary fluxes and associated ocean mixing. The basic equation we use is the non-advective flux equation (20.85), rewritten here for the scalar field λ

$$-\boldsymbol{J} \cdot \hat{\boldsymbol{n}} = \mathcal{Q}_\lambda - \lambda\, \mathcal{Q}_{\text{m}} = \mathcal{Q}_\lambda^{\text{non-adv}} + (\lambda_{\text{m}} - \lambda)\, \mathcal{Q}_{\text{m}}. \tag{73.96}$$

73.7.1 Circulation driven by surface transformation

The layer mass budget (73.71) and its continuous expression (73.73) provide the basis for inferences about circulation and transformation. As an illustration, consider the continuous

expression (73.73) and integrate from a reference value, $\lambda_{-\infty}$, up to λ

$$\int_{\lambda_{-\infty}}^{\lambda} \Psi \, d\lambda' = \int_{\lambda_{-\infty}}^{\lambda} \left[-\frac{\partial M}{\partial t} + W - G \right] d\lambda'. \tag{73.97}$$

The left hand side is an expression for the circulation in λ-space at the specified interior open boundary. The right hand side means that a nonzero circulation is driven by mass through the ocean surface, convergence of mass transformed across the λ-interfaces, and/or time changes to the mass within the domain. Correspondingly, in the absence of surface boundary mass fluxes, a steady circulation is driven just by water mass transformation

$$\int_{\lambda_{-\infty}}^{\lambda} \Psi \, d\lambda' = - \int_{\lambda_{-\infty}}^{\lambda} G \, d\lambda'. \tag{73.98}$$

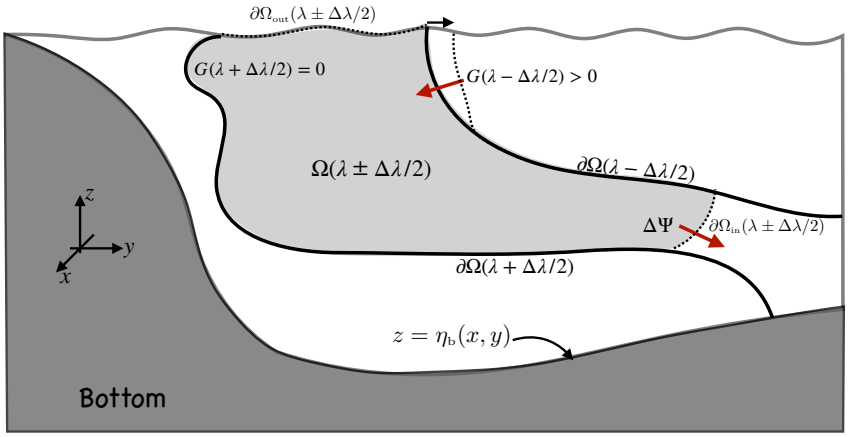

FIGURE 73.9: An example of surface transformation driven circulation oriented according to the Southern Ocean with Antarctica to the left. Here we depict a layer that is exposed to some form of air-sea interaction that causes the interface with $\lambda - \Delta\lambda/2$ to move meridionally. For example, if $\lambda = \gamma$ (neutral density or potential density), then an air-sea buoyancy flux generally causes γ outcrops to move laterally. Movement of the near-surface portion of the $\partial\Omega(\lambda - \Delta\lambda/2)$ interface causes seawater to entrain into the layer and thus contribute to the surface water mass transformation, $G(\lambda - \Delta\lambda/2) > 0$ (red arrow near the surface directed to the south). In turn, the boundary, $\partial\Omega_{\rm in}(\lambda \pm \Delta\lambda/2)$, expands as the near-surface portion of the interface, $\partial\Omega(\lambda - \Delta\lambda/2)$, moves to the north as a result of the entrained new water (black arrow moving to the north). If there is a net convergence of water mass into the layer (as determined by the net mass crossing both layer interfaces $\partial\Omega(\lambda + \Delta\lambda/2)$ and $\partial\Omega(\lambda - \Delta\lambda/2)$), then mass accumulates within the layer $[\lambda - \Delta\lambda/2, \lambda + \Delta\lambda/2]$. There is a steady state mass budget for the layers (i.e., layer mass is constant) only if the same amount of mass that converges into the layer via surface or interior water mass transformation leaves the layer through circulation, Ψ, at the boundary $\partial\Omega_{\rm in}(\lambda \pm \Delta\lambda/2)$.

We depict an example in Figure 73.9 where the surface outcrop of the layer is exposed to air-sea interactions that lead to a meridional movement of the interface $\lambda - \Delta\lambda/2$. This movement laterally entrains mass into the layer. If there is a net convergence of mass into the layer, then the layer mass increases. A steady state mass budget for the layer is reached if the amount of mass entrained through surface transformation is reflected in the same mass leaving through the circulation at the open boundary, $\partial\Omega_{\rm in}(\lambda \pm \Delta\lambda/2)$. We depict another case in Figure 73.10, here focusing on how a meridional gradient in the surface buoyancy loss causes entrainment into buoyancy layers.

These and other statements related to the water mass budget are rather routine mathematically. Yet since the mass budget is formulated over layers, the mass budget offers the means to make very general statements about the circulation even without a direct measurement of the flow. This is a key power of water mass transformation theory.

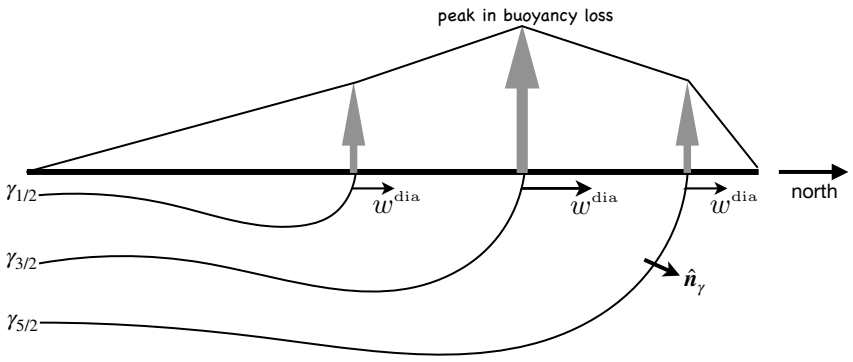

FIGURE 73.10: An example of surface water mass transformation, here illustrating the effects of transformation due to a meridional gradient in the surface buoyancy loss (we here assume that λ is buoyancy as measured by the neutral density, γ). The example is oriented for the northern hemisphere with increasing latitudes to the north/right. Buoyancy loss is denoted by the thick vertical arrows indicating the removal of buoyancy from the ocean, thus causing surface water to loose buoyancy and thus get more dense. The surface buoyancy loss causes γ interfaces to migrate to the south (denser water moves southward)), which in turn causes dianeutral mass flux to move from lighter layers to denser layers (black vectors pointed to the north, w^{dia}). With a peak in the buoyancy loss at a particular latitude, more entrainment is driven into the layer to the north of the peak (water converges to the layer $\gamma_{3/2} \leq \gamma \leq \gamma_{5/2}$) and less entrainment into the layer to the south (water diverges from the layer $\gamma_{1/2} \leq \gamma \leq \gamma_{3/2}$).

73.7.2 Further study

Much of the formalism in this section follows that reviewed by *Groeskamp et al.* (2019). This paper offers specific examples of water mass transformation analysis as well as citations to numerous research papers.

73.8 Buoyancy water mass transformation

In Section 73.2 we considered the transformation of water masses as defined by buoyancy classes, with $\lambda = \gamma$ where γ is a field whose isosurfaces approximate constant buoyancy directions; i.e., the neutral directions from Section 30.5. We here fill in further details for such buoyancy water mass analysis.

73.8.1 Material time changes to S and Θ

The material time derivative of γ can be written as the sum of contributions from salinity and Conservative Temperature

$$\rho \dot{\gamma} = \frac{\partial \gamma}{\partial S} \rho \dot{S} + \frac{\partial \gamma}{\partial \Theta} \rho \dot{\Theta}. \tag{73.99}$$

Following the decomposition of the water mass transformation in Section 73.4.3, for a general tracer, we here write the material time derivatives in the form

$$\rho \dot{S} = -\nabla \cdot \boldsymbol{J}^{(S)}_{\text{int}} - \boldsymbol{J}^{(S)}_{\text{out}} \cdot \hat{\boldsymbol{n}}\, \delta(z-\eta) - \boldsymbol{J}^{(S)}_{\text{bot}} \cdot \hat{\boldsymbol{n}}\, \delta(z-\eta_{\text{b}}) \tag{73.100a}$$

$$\rho \dot{\Theta} = -\nabla \cdot \boldsymbol{J}^{(\Theta)}_{\text{int}} - \boldsymbol{J}^{(\Theta)}_{\text{out}} \cdot \hat{\boldsymbol{n}}\, \delta(z-\eta) - \boldsymbol{J}^{(\Theta)}_{\text{bot}} \cdot \hat{\boldsymbol{n}}\, \delta(z-\eta_{\text{b}}), \tag{73.100b}$$

where we assumed there are no interior sources of S or Θ. The surface and bottom boundary contributions are weighted by Dirac delta distributions and projected into the normal direction along the two respective boundary surfaces. Following from the decomposition of water mass transformation given by equation (73.50), we are thus led to the following form for buoyancy

transformation

$$G(\gamma) = \underbrace{-\lim_{\delta\gamma\to 0}\frac{1}{\delta\gamma}\int_{\Omega(\gamma\pm\delta\gamma/2)}\left(\frac{\partial\gamma}{\partial S}\,\nabla\cdot\boldsymbol{J}^{(S)}_{\text{int}} + \frac{\partial\gamma}{\partial\Theta}\,\nabla\cdot\boldsymbol{J}^{(\Theta)}_{\text{int}}\right)\mathrm{d}V}_{\text{interior buoyancy transformation = volume integral of convergence}}$$
$$\underbrace{-\lim_{\delta\gamma\to 0}\frac{1}{\delta\gamma}\int_{\partial\Omega_{\mathsf{out}}(\gamma\pm\delta\gamma/2)}\left(\frac{\partial\gamma}{\partial S}\,\boldsymbol{J}^{(S)}_{\text{out}} + \frac{\partial\gamma}{\partial\Theta}\,\boldsymbol{J}^{(\Theta)}_{\text{out}}\right)\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}}_{\text{surface buoyancy transformation = area integral of surface boundary fluxes}}$$
$$\underbrace{-\lim_{\delta\gamma\to 0}\frac{1}{\delta\gamma}\int_{\partial\Omega_{\mathsf{bot}}(\gamma\pm\delta\gamma/2)}\left(\frac{\partial\gamma}{\partial S}\,\boldsymbol{J}^{(S)}_{\text{bot}} + \frac{\partial\gamma}{\partial\Theta}\,\boldsymbol{J}^{(\Theta)}_{\text{bot}}\right)\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}}_{\text{bottom buoyancy transformation = area integral of bottom boundary fluxes}}. \tag{73.101}$$

This expression is explored in the remainder of this section.

73.8.2 Interior buoyancy water mass transformation

Contributions from cabbeling, thermobaricity, and halobaricity (Section 72.3) arise from the interior transformation appearing in equation (73.101). Furthermore, in the special case of a linear equation of state, whereby $\nabla(\partial\gamma/\partial\Theta) = 0$ and $\nabla(\partial\gamma/\partial S) = 0$, then equation (73.54) means that the global integral of the interior transformation vanishes

$$\int_{\gamma_{-\infty}}^{\gamma_\infty} G_{\text{int}}(\gamma)\,\mathrm{d}\gamma = \int_{\mathscr{R}}\left(\frac{\partial\gamma}{\partial S}\,\nabla\cdot\boldsymbol{J}^{(S)}_{\text{int}} + \frac{\partial\gamma}{\partial\Theta}\,\nabla\cdot\boldsymbol{J}^{(\Theta)}_{\text{int}}\right)\mathrm{d}V = 0 \quad \text{linear equation of state,} \tag{73.102}$$

where $\mathscr{R}$ is the global ocean domain. By inference, we conclude that any nonzero result for this integral is a global measure of the effects from the nonlinear equation of state

$$\text{contribution from nonlinear equation of state} = \int_{\gamma_{-\infty}}^{\gamma_\infty} G_{\text{int}}(\gamma)\,\mathrm{d}\gamma. \tag{73.103}$$

73.8.3 Surface non-advective flux for S and Θ

We review a few of the distinct characteristics of surface non-advective fluxes of S and Θ as detailed in Section 72.5.2, here working with salinity, S, rather than salt concentration, $\mathsf{S} = S/1000$.

Non-advective salt flux

The non-advective surface boundary flux for salt is given by equation (72.67), here written as

$$-\boldsymbol{J}^{(\mathsf{S})}\cdot\hat{\boldsymbol{n}} = \mathcal{Q}_{\mathsf{S}}^{\text{non-adv}} + (S_{\mathsf{m}} - S)\,\mathcal{Q}_{\mathsf{m}}, \tag{73.104}$$

where $\mathcal{Q}_{\mathsf{S}}^{\text{non-adv}}$ is a non-advective salt flux, such as might arise from parameterized turbulent transfer. For the salt concentration of water crossing the ocean surface, we generally take $S_{\mathsf{m}} = 0$ for precipitation, evaporation, and river runoff, whereas $S_{\mathsf{m}} \neq 0$ for ice melt and formation. Furthermore, the boundary term, $S = S(z = \eta)$, is commonly approximated by the bulk salt concentration in the upper ocean.

Non-advective flux for Conservative Temperature

For Conservative Temperature we follow the discussion in Section 72.5.3, whereby the non-advective flux is given by equation

$$-\boldsymbol{J}^{(\Theta)} \cdot \hat{\boldsymbol{n}} = \mathcal{Q}_{\Theta}^{\text{non-adv}} + (\Theta_{\mathsf{m}} - \Theta)\, \mathcal{Q}_{\mathsf{m}}. \tag{73.105}$$

It is common to approximate the difference $\Theta_{\mathsf{m}} - \Theta(z = \eta) = 0$, in which case the non-advective flux is just due to turbulent and radiative heat fluxes

$$-\boldsymbol{J}^{(\Theta)} \cdot \hat{\boldsymbol{n}} = \mathcal{Q}_{\Theta}^{\text{non-adv}} \text{ if } \Theta_{\mathsf{m}} - \Theta(z = \eta) = 0. \tag{73.106}$$

73.8.4 Surface buoyancy water mass transformation

To touch base with the commonly employed surface buoyancy transformation, insert the surface fluxes into equation (73.101) as per Section 73.8.3 to write

$$G(\gamma)^{\text{surface}} = \lim_{\delta\gamma \to 0} \frac{1}{\delta\gamma} \int_{\partial\Omega_{\text{out}}(\gamma \pm \delta\gamma/2)} \big(\gamma\, \beta\, [\mathcal{Q}_S^{\text{non-adv}} + (S_{\mathsf{m}} - S)\, \mathcal{Q}_{\mathsf{m}}] - \gamma\, \alpha\, [\mathcal{Q}_{\Theta}^{\text{non-adv}} + (\Theta_{\mathsf{m}} - \Theta)\, \mathcal{Q}_{\mathsf{m}}]\big) \mathrm{d}\mathcal{S}, \tag{73.107}$$

where we introduced the thermal expansion and saline contraction coefficients, here defined according to[16]

$$\alpha = -\frac{1}{\gamma} \frac{\partial \gamma}{\partial \Theta} \qquad \text{and} \qquad \beta = \frac{1}{\gamma} \frac{\partial \gamma}{\partial S}. \tag{73.108}$$

Recall that $G(\gamma) > 0$ occurs when water is transformed into regions with larger γ. For example, net surface cooling in the presence of a positive thermal expansion coefficient ($\alpha > 0$) leads to $\mathcal{Q}_{\Theta}^{\text{non-adv}} + (\Theta_{\mathsf{m}} - \Theta)\, \mathcal{Q}_{\mathsf{m}} < 0$. Such cooling then leads to a positive contribution to $G(\gamma)_{\text{surface}}$ as water is transformed from light to heavy γ-classes. Likewise, a positive net salt transport into the upper ocean, $\mathcal{Q}_S^{\text{non-adv}} + (S_{\mathsf{m}} - S)\, \mathcal{Q}_{\mathsf{m}} > 0$, leads to a positive contribution to $G(\gamma)_{\text{surface}}$.

The integrand to equation (73.107) corresponds to minus the surface buoyancy flux derived in Section 72.6.3. The only difference is that we here make use of the surface element, $\mathrm{d}\mathcal{S}$, and the corresponding fluxes $\mathcal{Q}_{\Theta}^{\text{non-adv}}$, $\mathcal{Q}_S^{\text{non-adv}}$, and $\mathcal{Q}_{\mathsf{m}}$. However, if the ocean surface has no overturns, we can write its vertical position as $z = \eta(x, y, t)$ and can also define the horizontal projection of the area element as (see equation (5.33))

$$\mathrm{d}\mathcal{S} = \sqrt{1 + |\nabla \eta|^2}\, \mathrm{d}A. \tag{73.109}$$

In this case we can introduce the fluxes $Q_{\Theta}^{\text{non-adv}}$, $Q_{\mathsf{S}}^{\text{non-adv}}$, and Q_{m} used in Section 72.6.3 via

$$\mathcal{Q}_{\Theta}^{\text{non-adv}}\, \mathrm{d}\mathcal{S} = Q_{\Theta}^{\text{non-adv}}\, \mathrm{d}A \tag{73.110a}$$

$$\mathcal{Q}_S^{\text{non-adv}}\, \mathrm{d}\mathcal{S} = Q_{\mathsf{S}}^{\text{non-adv}}\, \mathrm{d}A \tag{73.110b}$$

$$\mathcal{Q}_{\mathsf{m}}\, \mathrm{d}\mathcal{S} = Q_{\mathsf{m}}\, \mathrm{d}A, \tag{73.110c}$$

to render

$$G(\gamma)^{\text{surface}} = \lim_{\delta\gamma \to 0} \frac{1}{\delta\gamma} \int_{\partial\Omega_{\text{out}}(\gamma \pm \delta\gamma/2)} \big(\gamma\, \beta\, [Q_{\mathsf{S}}^{\text{non-adv}} + (S_{\mathsf{m}} - S)\, Q_{\mathsf{m}}] - \gamma\, \alpha\, [Q_{\Theta}^{\text{non-adv}} + (\Theta_{\mathsf{m}} - \Theta)\, Q_{\mathsf{m}}]\big) \mathrm{d}A. \tag{73.111}$$

[16] In practice, it is common to replace the factor of γ^{-1} with ρ_o^{-1} on the right hand side of equation (73.108), with ρ_o the constant Boussinesq reference density from Chapter 29.

Integrating the surface transformation (73.111) over all γ-classes leads to the identity[17]

$$\int_{\gamma_{-\infty}}^{\gamma_\infty} G(\gamma)^{\text{surface}}\, \mathrm{d}\gamma = \int_{z=\eta} \big(\gamma\, \beta\, [Q_{\mathsf{S}}^{\text{non-adv}} + (S_{\mathsf{m}} - S)\, Q_{\mathsf{m}}] - \gamma\, \alpha\, [Q_{\Theta}^{\text{non-adv}} + (\Theta_{\mathsf{m}} - \Theta)\, Q_{\mathsf{m}}]\big) \mathrm{d}A. \quad (73.112)$$

This equality means that the diagnosed surface transformation, $G(\gamma)^{\text{surface}}$, which is obtained by binning surface fluxes into γ-classes, must properly add up to the area integrated surface fluxes as weighted by the surface value of γ. This equality can be a useful check on the integrity of numerical binning code used to diagnose surface water mass transformation.

73.9 Tracer mass analysis

In Sections 73.5 and 73.6 we developed the budgets for λ within layers defined λ. Here we extend that analysis to develop budgets for a tracer concentration, C, localized in a region within a layer of buoyancy, γ, as depicted in Figure 73.11. The upper panels to this figure illustrate a tracer patch in geographic/depth $\boldsymbol{x}$-space along with isolines of buoyancy, whereas the lower panels show the tracer distribution (histogram) binned within the buoyancy classes ($\boldsymbol{q}$-space). If the tracer is mixed within a layer, such as via the neutral diffusion process of Section 71.4, then the tracer patch is spread laterally within the buoyancy layer and yet the distribution (lower panel) is unchanged. In contrast, if the tracer is mixed across layer interfaces then the tracer distribution is spread within buoyancy space.

Another means to alter the tracer distribution is to modify the buoyancy field. This situation is especially common for tracer near the surface, where boundary buoyancy forcing can act to move the layers thus causing tracer to move between layers even if the tracer patch is stationary in $\boldsymbol{x}$-space. That is, if the tracer moves at a velocity distinct from the buoyancy surfaces, then its distribution within buoyancy classes will change.

73.9.1 General form of the mass budget

As depicted in Figure 73.11 for buoyancy layers, and Figure 73.12 for generic layers, there are two general processes whereby a tracer distribution within layers can be modified: (i) the tracer can mix between layers and (ii) the layers can move relative to the tracer. These ideas transcend buoyancy and thus can be applied to any scalar field, λ, used to classify water masses. We quantify these two processes by writing the time change of tracer content within a λ-layer, which is arrived at by applying the Leibniz-Reynolds transport theorem from Section 20.2.4 to a λ-layer

$$\frac{\mathrm{d}}{\mathrm{d}t} \Delta M_{\mathsf{C}}(\lambda \pm \Delta\lambda/2) = \int_{\Omega(\lambda \pm \Delta\lambda/2)} \rho\, \dot{C}\, \mathrm{d}V - \oint_{\partial\Omega(\lambda \pm \Delta\lambda/2)} \rho\, C\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \quad (73.113)$$

where

$$\Delta M_{\mathsf{C}}(\lambda \pm \Delta\lambda/2) = \int_{\Omega(\lambda \pm \Delta\lambda/2)} \rho\, C\, \mathrm{d}V \quad (73.114)$$

is the mass of tracer within the layer. The volume integral on the right hand side of equation (73.113) arises from material time changes to the tracer within the layer, whereas the surface integral arises from dia-surface transport across the layer boundary.

[17] The density bound $\gamma_{-\infty}$ is a constant that is lower than any γ realized in the global domain, whereas γ_∞ is a constant that is larger than any realized γ.

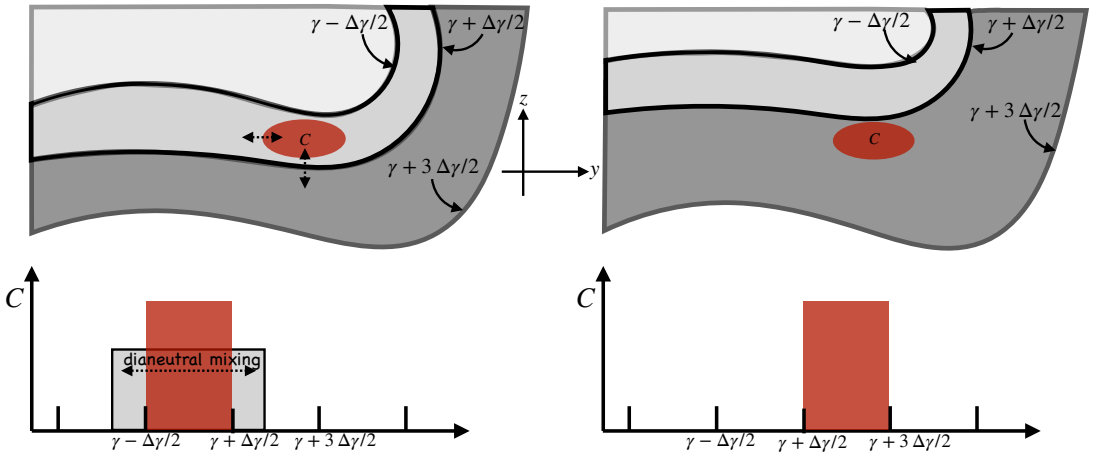

FIGURE 73.11: Depicting a tracer patch within the buoyancy layer bounded by the interface values $[\gamma - \Delta\gamma/2, \gamma + \Delta\gamma/2]$ (left panel) and $[\gamma + \Delta\gamma/2, \gamma + 3\,\Delta\gamma/2]$ (right panel). The upper panels show the tracer and buoyancy in geographic/depth $\boldsymbol{x}$-space whereas the bottom panels show the tracer distribution (histogram) binned according to buoyancy ($\boldsymbol{q}$-space). There are two general means to modify the distribution of tracer within the buoyancy classes. The first occurs via dianeutral mixing that spreads the tracer distribution to other buoyancy layers as depicted by the vertical arrow in the upper left panel and the horizontal arrows in the lower left panel. The lateral arrow in the upper left panel depicts neutral diffusion, which laterally spreads the tracer within a layer but does not alter the distribution across layers (see Section 71.4). The second means to alter the distribution occurs when the buoyancy surfaces move relative to the tracer. This scenario is depicted in the lower right panel whereby the tracer patch originally in buoyancy layer $[\gamma - \Delta\gamma/2, \gamma + \Delta\gamma/2]$ now finds itself in the layer $[\gamma + \Delta\gamma/2, \gamma + 3\,\Delta\gamma/2]$. This depiction is not realistic, since motion of interior buoyancy surfaces generally occurs along with mixing of tracer patches. Nonetheless, this example emphasizes that motion of the buoyancy surfaces need not precisely coincide with motion of the tracer patch.

73.9.2 Tracer processes

We determine the material time changes for a conservative tracer according to the convergence of a flux

$$\rho\, \dot{C} = \rho\, \frac{\mathrm{D}C}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}. \tag{73.115}$$

Many biogeochemical tracers have additional source terms beyond the flux convergence considered here. As in Section 73.4.3, sources can be readily incorporated into the following by adding a source tendency term that acts throughout a layer and not just at the layer boundaries.

The divergence theorem converts the convergence, $-\nabla \cdot \boldsymbol{J}$, into the area integral of fluxes over the layer boundaries, including interior layer interfaces as well as intersections with the surface and bottom boundaries. For the interior interfaces it is typically simpler diagnostically to bin the volume integrated material time changes within the λ-classes. In contrast, the surface and bottom boundary contributions are fed into the budget via Neumann boundary conditions applied to the flux $\boldsymbol{J}$

$$\boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \text{boundary tracer transport}. \tag{73.116}$$

Note that when there is an advective/skew diffusive component to the subgrid scale flux (Chapters 70 and 71), then it adds to the resolved advective component to render a residual mean material time operator

$$\rho\, \frac{\mathrm{D}^{\dagger} C}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}^{\text{non-adv}}, \tag{73.117}$$

where

$$\frac{\mathrm{D}^{\dagger}}{\mathrm{D}t} = \frac{\partial}{\partial t} + (\boldsymbol{v} + \boldsymbol{v}^{*}) \cdot \nabla, \tag{73.118}$$

with $\boldsymbol{v}^{*}$ an eddy-induced velocity (see Section 71.1). For the purposes of water mass transforma-

tion analysis, we write

$$\dot{C} = \frac{\mathrm{D}^{\dagger} C}{\mathrm{D}t}, \tag{73.119}$$

thus incorporating the eddy-induced stirring into the kinematic expression for the material time derivative.

There are many interior and boundary proceses that contribute to $\dot{C}$ within a layer. Write the following as a general expression for these contributions to the layer budget

$$\Delta E_{\mathsf{C}}(\lambda \pm \Delta\lambda/2) = \int_{\Omega(\lambda \pm \Delta\lambda/2)} \rho\, \dot{C}\, \mathrm{d}V = -\int_{\Omega(\lambda \pm \Delta\lambda/2)} \nabla \cdot \boldsymbol{J}\, \mathrm{d}V \tag{73.120}$$

which is sometimes usefully decomposed into interior and surface boundary processes

$$\Delta E^{\mathsf{int}}_{\mathsf{C}}(\lambda \pm \Delta\lambda/2) = \int_{\Omega(\lambda \pm \Delta\lambda/2)} \rho\, \dot{C}^{\mathsf{int}}\, \mathrm{d}V \tag{73.121a}$$

$$\Delta E^{\mathsf{out}}_{\mathsf{C}}(\lambda \pm \Delta\lambda/2) = -\int_{\partial\Omega_{\mathsf{out}}(\lambda \pm \Delta\lambda/2)} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{73.121b}$$

If the region boundary intersects the ocean bottom along $\partial\Omega_{\mathsf{bot}}(\lambda \pm \Delta\lambda/2)$, then there is an additional bottom boundary contribution in the form

$$\Delta E^{\mathsf{bot}}_{\mathsf{C}}(\lambda \pm \Delta\lambda/2) = -\int_{\partial\Omega_{\mathsf{bot}}(\lambda \pm \Delta\lambda/2)} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{73.122}$$

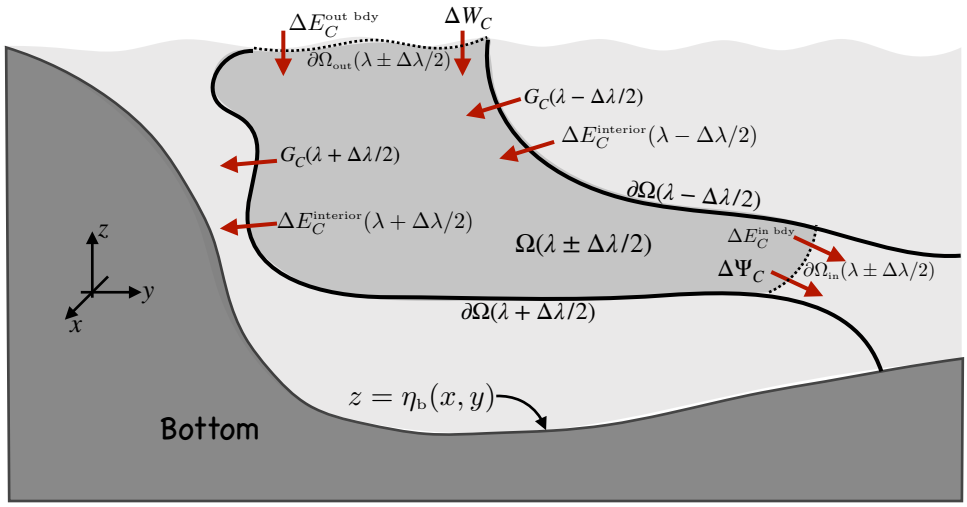

FIGURE 73.12: As for the schematic of a layer seawater mass budget depicted in Figure 73.6, we here illustrate the tracer budget within a layer of seawater with scalar property λ within the range $[\lambda - \Delta\lambda/2, \lambda + \Delta\lambda/2]$ and defined over a geographical/depth domain $\partial\Omega_{\mathsf{in}}(\lambda \pm \Delta\lambda/2) + \partial\Omega_{\mathsf{out}}(\lambda \pm \Delta\lambda/2) + \partial\Omega(\lambda + \Delta\lambda/2) + \partial\Omega(\lambda - \Delta\lambda/2)$. The budget for a tracer, C, over this layer is affected by the transport of tracer substance across the variety of layer boundaries. Transport processes include those determined by mixing and/or radiation across interior and surface boundaries, ΔE_{C} (equation (73.121b)). This term has no associated transfer of seawater mass and thus is absent from the water mass budget in Figure 73.6. Tracer budgets are also affected by processes that move seawater mass across layer boundaries: water mass transformation processes giving rise to $G_{\mathsf{C}}(\lambda \pm \Delta\lambda/2)$ (equation (73.123)); transport across the surface domain boundary, ΔW_{C}, arising from precipitation, evaporation, runoff, and melt (equation (73.124)); and transport within the circulation crossing an interior domain boundary, $\Delta\Psi_{\mathsf{C}}$ (equation (73.125)).

73.9.3 Transport across an interior layer interface

The surface integral in the budget (73.113) involves transport across the layer interfaces, with this transport requiring motion of the interface relative to a fluid particle. The same formalism introduced earlier can be used to compute this transport. That is, we can generalize the transformation equation (73.43e) to write

$$G_{\mathsf{C}}(\lambda) = \int_{\partial\Omega(\lambda)} \rho\, C\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \frac{\partial}{\partial\lambda} \int_{\Omega(\lambda_0 \leq \lambda)} \rho\, \dot{\lambda}\, C\, \mathrm{d}V. \tag{73.123}$$

As a check, note that for the special case where the tracer concentration is a constant along the layer interface, then $G_{\mathsf{C}}(\lambda) = C\, G(\lambda)$. We consider this special case in Section 73.10 when studying budgets over regions bounded by a tracer isosurface.

73.9.4 Transport across interior and surface boundaries

We now consider the impact on layer tracer mass budgets due to boundary transport. The budget contribution from mass fluxes crossing the ocean surface boundary is determined by making use of the surface kinematic boundary condition (20.84)

$$\Delta W_{\mathsf{C}} = \int_{\partial\Omega_{\mathsf{out}}(\lambda \pm \Delta\lambda/2)} \rho\, C\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\partial\Omega_{\mathsf{out}}(\lambda \pm \Delta\lambda/2)} Q_{\mathsf{m}}\, C_{\mathrm{m}}\, \mathrm{d}A, \tag{73.124}$$

where C_{m} is the tracer concentration within the mass transported across the boundary.[18] As a check, note that in the special case of a constant tracer concentration in the mass transported across the boundary, then $\Delta W_{\mathsf{C}} = C_{\mathrm{m}}\, \Delta W$, where ΔW is the water mass transported across the ocean free surface as given by equation (73.66).

For the interior open boundary the contribution is written in the generic manner

$$\Delta \Psi_{\mathsf{C}} = \int_{\partial\Omega_{\mathsf{in}}(\lambda \pm \Delta\lambda/2)} C\, \rho\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{73.125}$$

Again, in the special case where the tracer concentration is a constant, C_{b}, along the interior boundary, then $\Delta \Psi_{\mathsf{C}} = C_{\mathrm{b}}\, \Delta \Psi$, where $\Delta \Psi$ is the seawater mass transport given by equation (73.62).

73.9.5 The layer tracer budget

Bringing all terms together leads to the layer tracer mass budget

$$\frac{\mathrm{d}\Delta M_{\mathsf{C}}}{\mathrm{d}t} + \Delta \Psi_{\mathsf{C}} = \Delta E_{\mathsf{C}} + \Delta W_{\mathsf{C}} - [G_{\mathsf{C}}(\lambda + \Delta\lambda/2) - G_{\mathsf{C}}(\lambda - \Delta\lambda/2)], \tag{73.126}$$

which is directly analogous to the seawater layer mass budget (73.70), with the added term ΔE_{C} arising from material tracer changes. As for the seawater mass budget discussed in Section 73.5.3, the layer tracer budget (73.126) provides the framework for rather general inferences about tracer transport within λ-classes.

73.9.6 Further study

Much in this section follows the treatment given by *Groeskamp et al.* (2019). This paper offers specific examples of tracer mass analysis, which is an area seeing many new applications within

[18] Note that equation (26) in *Groeskamp et al.* (2019) incorrectly writes the integrand in equation (73.124) as $Q_{\mathrm{m}}\, (C_{\mathrm{m}} - C)$.

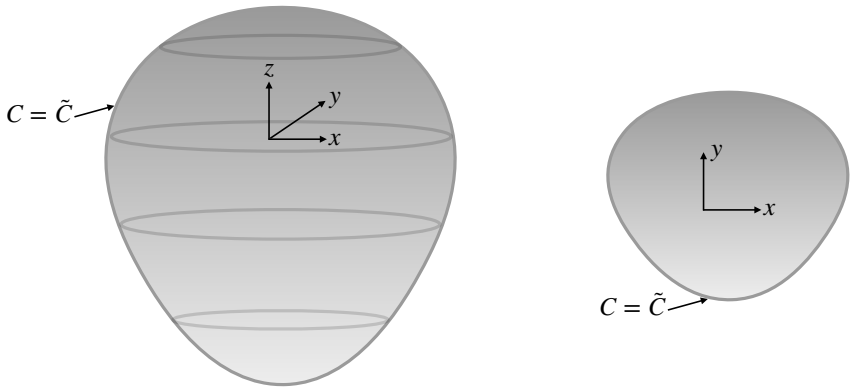

FIGURE 73.13: Left panel: a closed three-dimensional region, $\widetilde{\mathcal{R}}$, with its boundary, $\partial\widetilde{\mathcal{R}}$, defined by a surface of constant tracer concentration, $C = \widetilde{C}$. Right panel: the analog closed two-dimensional region with its boundary defined by a contour of constant tracer concentration, $C = \widetilde{C}$.

the research communities.

73.10 Regions bounded by a tracer contour/surface

In Section 73.9 we developed equations for a layer tracer budget where the scalar field, λ, that defines the layer is generally distinct from the tracer, C, whose budget we are studying. In this section we specialize to the case where we set $\lambda = C$ so that the region boundaries are determined by the tracer whose budget is under study. These budgets were introduced in Sections 73.5 and 73.6, and here we derive some rather useful simplifications that arise as a result of setting $\lambda = C$.

As in Section 73.9, our starting point is the Leibniz-Reynolds budgets from Section 20.2.4 for seawater mass and tracer mass computed over an arbitrary region, $\mathcal{R}$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, C\, \mathrm{d}V\right] = -\int_{\partial\mathcal{R}} \left[\rho\, C\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) + \boldsymbol{J}\right] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{73.127a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, \mathrm{d}V\right] = -\int_{\partial\mathcal{R}} \left[\rho\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})})\right] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{73.127b}$$

The region $\mathcal{R}$ is rather arbitrary, and can in general be disconnected. Throughout this section we make use of the following shorthand notation for region-integrated quantities

$$M = \int_{\mathcal{R}} \rho\, \mathrm{d}V \qquad \text{region seawater mass} \tag{73.128a}$$

$$M_{\mathsf{C}} = \int_{\mathcal{R}} C\, \rho\, \mathrm{d}V \qquad \text{region tracer mass} \tag{73.128b}$$

$$\langle C \rangle = \frac{1}{M}\int_{\mathcal{R}} C\, \rho\, \mathrm{d}V = \frac{M_{\mathsf{C}}}{M} \qquad \text{region averaged tracer concentration.} \tag{73.128c}$$

73.10.1 Closed region bounded by a tracer surface/contour

Consider a closed region, $\widetilde{R}$, bounded by a surface of constant tracer concentration, $C = \widetilde{C}$, such as depicted in Figure 73.13. The tracer budget (73.127a) for this region is given by

$$\frac{\mathrm{d}(M\, \langle C \rangle)}{\mathrm{d}t} = -\widetilde{C} \int_{\partial\widetilde{\mathcal{R}}} \rho\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \int_{\partial\widetilde{\mathcal{R}}} \boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{73.129}$$

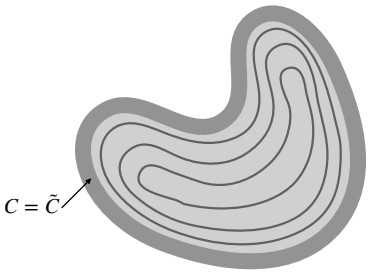

FIGURE 73.14: A two-dimensional region bounded by a finite-thick shell with constant tracer concentration, $C = \widetilde{C}$. Inside the shell region the tracer concentration is not uniform.

where we pulled the tracer concentration outside of the surface integral since, by construction, it is constant on the boundary, $\partial\widetilde{\mathcal{R}}$. Use of the mass budget (73.127b) then leads to the rather tidy result

$$\frac{\mathrm{d}[M\,(\langle C\rangle - \widetilde{C})]}{\mathrm{d}t} = -\int_{\partial\widetilde{\mathcal{R}}} \boldsymbol{J}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{73.130}$$

The left hand side is the time change of the mass-weighted difference between the region averaged tracer concentration, $\langle C\rangle$, and the value of the tracer concentration defining the region boundary, $\widetilde{C}$. These time changes are driven by a nonzero diffusive tracer transport bringing tracer mass across the region boundary. A nonzero diffusive flux on the region boundary arises only when there is a gradient of tracer concentration across that boundary. In the special case of a zero net diffusive tracer transport across the region boundary, the budget equation (73.130) reaches a steady state whereby

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[M\,(\langle C\rangle - \widetilde{C})\right] = 0 \Longleftrightarrow \int_{\partial\widetilde{\mathcal{R}}} \boldsymbol{J}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0. \tag{73.131}$$

A three-dimensional region bounded by a constant tracer concentration is not commonly encountered in large-scale ocean and atmospheric fluids. In contrast, we often encounter quasi-two-dimensional regions as depicted in Figure 73.14, in which one may find two-dimensional regions bounded by a closed contour of constant tracer concentration. For example, in many parts of the ocean and atmosphere transport occurs predominantly along two-dimensional surfaces defined by a constant buoyancy. We may thus find closed contours of tracer concentrations along constant buoyancy surfaces.

To help illustrate a necessary condition to reach a steady state, consider the particular example depicted in Figure 73.14. In this figure, the tracer contour defining the region boundary is a thick shell defined by a uniform concentration $C = \widetilde{C}$. The diffusive flux vanishes at each point within the boundary shell since the tracer concentration is uniform. Hence, the steady budget (73.131) leads to

$$(\langle C\rangle - \widetilde{C})\,\frac{\mathrm{d}M}{\mathrm{d}t} + M\,\frac{\mathrm{d}\langle C\rangle}{\mathrm{d}t} = 0. \tag{73.132}$$

If the total seawater mass within the region is constant, then the averaged tracer concentration is also constant, so that both terms in this steady budget vanish individually. Even so, this configuration does not reach a steady state at each point throughout the domain interior. The reason is that diffusion in the interior causes tracer to move from regions of high concentration to low concentration. Consequently, at any particular point within the domain there is an evolving tracer concentration. The only way for each point to reach a steady state within a region bounded by a tracer contour is for the tracer concentration to be a uniform constant throughout the region interior

$$C = \widetilde{C} \qquad \text{steady state tracer throughout a closed tracer region.} \tag{73.133}$$

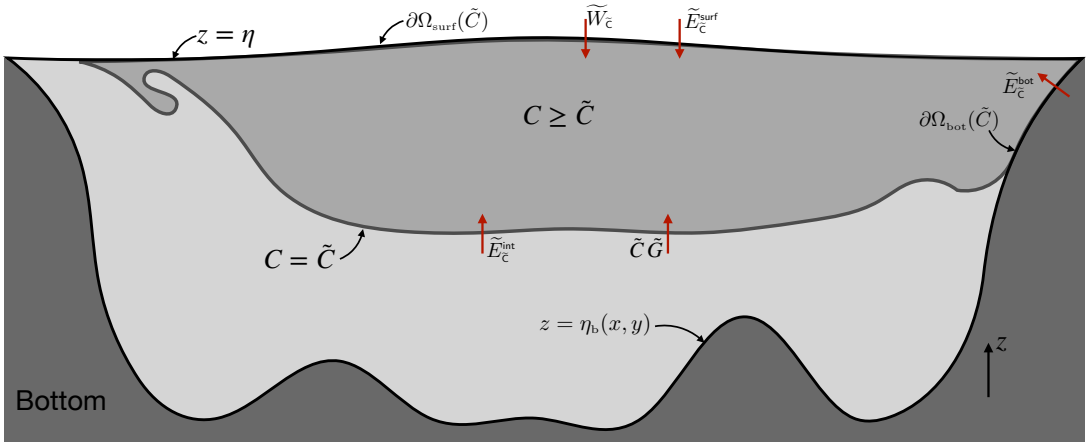

FIGURE 73.15: An ocean region where the tracer concentration is greater than a nominal value, $C \geq \widetilde{C}$. A specific example is with $C = \Theta$, the Conservative Temperature, in which we are concerned with the ocean with temperature greater than $\widetilde{\Theta}$. Here we depict a case where the tracer concentration generally increases upward (as with $C = \Theta$), and yet with vertical stratification not everywhere monotonic, such as for $C = \Theta$ in the high latitudes where salinity effects on density stratification become dominant. Transport processes affecting the budget of C within this region arise from mixing at the interior boundary and surface boundary, $\widetilde{E}^{\text{int}}_{\widetilde{C}}$ and $\widetilde{E}^{\text{surf}}_{\widetilde{C}}$, advection at the surface, $\widetilde{W}_{\widetilde{C}}$, and the tracer weighted water mass transformation across the interior layer boundary, $\widetilde{C}\,\widetilde{G}$. Arrows are oriented in which a positive value for the corresponding term adds tracer to the region.

Diffusion thus expells tracer gradients from steady state regions bounded by closed tracer contours, thus leaving a homogenous interior. We proved this same result from a different perspective in Section 69.8. It is satisfying to see this result follow from the present formalism based on Leibniz-Reynolds.

73.10.2 Region with $C \geq \widetilde{C}$

As a second example of the formalism, consider the tracer budget for a region where the tracer concentration is greater than or equal to a particular tracer value, such as depicted in Figure 73.15. In contrast to the domain in Figure 73.12, here there is no inner boundary. To develop the seawater mass budget and the tracer substance budget, we introduce the seawater mass and tracer mass for the region with $C \geq \widetilde{C}$

$$\widetilde{M} = \int_{C \geq \widetilde{C}} \rho \, dV \tag{73.134a}$$

$$\widetilde{M}_{\widetilde{C}} = \int_{C \geq \widetilde{C}} C \, \rho \, dV = \widetilde{M} \, \langle C \rangle; \tag{73.134b}$$

the terms arising from water mass transformation across the $\widetilde{C}$ interface

$$\widetilde{G} = -\int_{C=\widetilde{C}} \rho \, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} \, d\mathcal{S} = -\int_{C=\widetilde{C}} \rho \, w^{\text{dia}} \, d\mathcal{S} \tag{73.135a}$$

$$\widetilde{G}_{\widetilde{C}} = -\int_{C=\widetilde{C}} C \, \rho \, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} \, d\mathcal{S} = -\int_{C=\widetilde{C}} C \, \rho \, w^{\text{dia}} \, d\mathcal{S}; \tag{73.135b}$$

terms arising from ocean surface boundary mass transport

$$\widetilde{W} = -\int_{\partial\Omega_{\text{surf}}(\widetilde{C})} \rho \, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} \, d\mathcal{S} = \int_{\partial\Omega_{\text{surf}}(\widetilde{C})} Q_m \, dA \tag{73.136a}$$

$$\widetilde{W}_{\widetilde{C}} = -\int_{\partial\Omega_{\text{surf}}(\widetilde{C})} C \, \rho \, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} \, d\mathcal{S} = \int_{\partial\Omega_{\text{surf}}(\widetilde{C})} C \, Q_m \, dA; \tag{73.136b}$$

and finally, terms arising from subgrid scale transport across the $\widetilde{C}$ interface, ocean surface, and ocean bottom

$$\widetilde{E}^{\text{int}}_{\widetilde{\mathsf{C}}} = -\int_{C=\widetilde{C}} \boldsymbol{J} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} \tag{73.137a}$$

$$\widetilde{E}^{\text{surf}}_{\widetilde{\mathsf{C}}} = -\int_{\partial\Omega_{\text{surf}}(\widetilde{C})} \boldsymbol{J} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} \tag{73.137b}$$

$$\widetilde{E}^{\text{bot}}_{\widetilde{\mathsf{C}}} = -\int_{\partial\Omega_{\text{bot}}(\widetilde{C})} \boldsymbol{J} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{73.137c}$$

Recall that $\hat{\boldsymbol{n}}$ is the *outward* normal on a boundary so that positive values for the above transports increase the tracer mass within the region. For equations (73.135a) and (73.135b), we introduced the dia-surface transport velocity according to equation (73.38) for flow across the $C = \widetilde{C}$ layer interface. Likewise, for equations (73.136a) and (73.136b) we made use of the surface kinematic boundary condition (19.88c)

$$\rho \, (\boldsymbol{v} - \boldsymbol{v}^{(s)}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = -Q_{\mathsf{m}} \, \mathrm{d}A, \tag{73.138}$$

where Q_{m} is the mass transport across the free surface, with $Q_{\mathsf{m}} > 0$ adding mass to the ocean, and $\mathrm{d}A$ is the horizontal projection of the surface area element. By inspection of Figure 73.15, the seawater mass and tracer mass budgets for this region are given by

$$\frac{\mathrm{d}\widetilde{M}}{\mathrm{d}t} = \widetilde{G} + \widetilde{W} \tag{73.139a}$$

$$\frac{\mathrm{d}[\widetilde{M} \, \langle C \rangle]}{\mathrm{d}t} = \widetilde{C} \, \widetilde{G} + \widetilde{W}_{\widetilde{\mathsf{C}}} + \widetilde{E}^{\text{surf}}_{\widetilde{\mathsf{C}}} + \widetilde{E}^{\text{bot}}_{\widetilde{\mathsf{C}}} + \widetilde{E}^{\text{int}}_{\widetilde{\mathsf{C}}}, \tag{73.139b}$$

where we assumed that no mass crosses through the solid earth. Furthermore, along the $\widetilde{C}$-boundary we pulled the tracer concentration outside of the surface integral to write $\widetilde{G}_{\widetilde{\mathsf{C}}} = \widetilde{C} \, \widetilde{G}$.

Just as we did in Section 73.10.1, the tracer budget (73.139b) can be simplified by making use of the seawater mass budget (73.139a) to eliminate the water mass transformation contribution $\widetilde{G}$, thus rendering

$$\frac{\mathrm{d}\widetilde{M}_{\mathsf{I}\widetilde{\mathsf{C}}}}{\mathrm{d}t} = [\widetilde{W}_{\widetilde{\mathsf{C}}} - \widetilde{W} \, \widetilde{C}] + \widetilde{E}^{\text{surf}}_{\widetilde{\mathsf{C}}} + \widetilde{E}^{\text{bot}}_{\widetilde{\mathsf{C}}} + \widetilde{E}^{\text{int}}_{\widetilde{\mathsf{C}}}. \tag{73.140}$$

In this equation we introduced the *internal tracer mass* according to

$$\widetilde{M}_{\mathsf{I}\widetilde{\mathsf{C}}} \equiv \widetilde{M} \, (\langle C \rangle - \widetilde{C}) = \int_{C \geq \widetilde{C}} (C - \widetilde{C}) \, \rho \, \mathrm{d}V. \tag{73.141}$$

For completeness we express the internal tracer mass budget (73.140) in its integral form

$$\frac{\mathrm{d}\widetilde{M}_{\mathsf{I}\widetilde{\mathsf{C}}}}{\mathrm{d}t} = \int_{\partial\Omega_{\text{out}}} \left[Q_{\mathsf{m}} \, (C - \widetilde{C}) \, \mathrm{d}A - \boldsymbol{J} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} \right] - \int_{\partial\Omega_{\text{bot}}} \boldsymbol{J} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} - \int_{C=\widetilde{C}} \boldsymbol{J} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{73.142}$$

73.10.3 Comments and further study

Elimination of the water mass transformation, $\widetilde{G}$, from the internal tracer mass budget equations (73.140) and (73.142) offers a practical advantage since $\widetilde{G}$ can be rather noisy in applications. Furthermore, for some applications (e.g., see *Holmes et al.* (2019)) it is sufficient to consider the simpler budget (73.140) for internal tracer mass, rather than the budget (73.139b) for the total tracer mass.

Glossary of concepts and terms

elements pillar The elements pillar of geophysical fluid mechanics comprises the physical and mathematical formulation of conceptual models used to garner insight into rotating and stratified fluid motion. This pillar is concerned with setting the stage by deductively and descriptively exposing how physical concepts are mathematically expressed to describe geophysical fluid flows. x

emergent phenomena pillar The emergent phenomena pillar of geophysical fluid mechanics studies solutions to equations that describe phenomena, such as waves, instabilities, turbulence, and general circulation, all of which emerge from the fundamental equations based on first principles. These phenomena can emerge in manners that are far from simple to understand deductively, particularly when considering nonlinear behavior such as turbulence. xi

geophysical fluid mechanics A branch of theoretical physics concerned with natural fluid motion on a rotating and gravitating body such as a planet or star, making use of concepts and methods from classical continuum mechanics and thermodynamics. ix

hydrodynamics A branch of fluid mechanics concerned with the flow of a homogeneous (constant density) incompressible fluid. ix

internal gravity waves An internal gravity wave is a transverse wave that is comprised of fluid particles undergoing a simple harmonic oscillation within a continuously and stably stratified buoyancy field. The angular frequency of the oscillation is determined by the buoyancy stratification and the sine of the angle the wave's group velocity makes with respect to the vertical (equivalently, the cosine of the angle the wave's phase velocity makes with horizontal). 1601

irreversible process A physical process that results in the increase of entropy. Processes that increase the entropy of a fluid particle include the mixing of momentum such as through viscous friction; the mixing of matter such as through the diffusion of constituents in a multi-component fluid; and the mixing of enthalpy (diffusion of heat) in a fluid with variable temperature. ix

perfect fluid A fluid that flows in the absence of irreversible processes so that the motion is reversible and the specific ntropy remains constant following a fluid particle. Some authors use the term *ideal fluid*, but we eschew that term to avoid confusion with *ideal gas*. ix

real fluid A fluid whose flow is affected by irreversible processes arising from momentum mixing (nonzero viscous friction); enthalpy mixing (nonzero diffusivity for temperature); matter mixing (nonzero diffusivity of matter constituents); and through sources such as radiation and chemical reactions. The specific entropy increases following a fluid particle moving in a real fluid. ix

specular reflection Wave packets, in the geometrical optics approximation, exhibit specular reflection if the angle the incident wave packet makes with the reflecting surface is preserved upon reflection. Rossby waves, electromagnetic waves, and acoustic waves exhibit specular reflection, whereas internal gravity waves and inertial waves exhibit non-specular reflection. 1624

List of Symbols

Many symbols encountered in this book are defined local to their usage and are not used far outside of that location. Many other symbols appear in a variety of places and are included in the tables given below. Additionally, we generally aim to respect the following conventions.

- Many symbols are adorned with extra labels. One usage exposes tensor indices, with tensor indices written using the slanted math font, such as F^i for the component i of the vector $\mathbf{F}$. Another usage expresses part of the name for the symbol, with the label written with the upright sans serif. Examples include the "b" in η_{b} for the position of the bottom solid boundary of a fluid domain, and the "b" in ∇_{h} for the horizontal gradient operator.
- We strive for unique symbols to represent distinct mathematical and/or physical objects. Yet that goal must confront the multitude of mathematical expressions appearing in this book. We have chosen, on rare occasions, to allow some symbols to carry multiple meanings. In such cases we emphasize the particular meaning of the symbol to help avoid confusion with its alternative meaning.

NON-DIMENSIONAL NUMBERS

SYMBOL	NAME	MEANING
Bu	Burger	Bu = (deformation radius/horizontal length scale of flow)^2 = $(L_{\mathsf{d}}/L)^2$
Db	Deborah	Db = relaxation time/observation time
Ek	Ekman	Ek = vertical frictional acceleration/planetary Coriolis acceleration
Fr	Froude	Fr = fluid particle speed/fluid wave speed = U/c
Ge	Geostrophic	Ge = horizontal accelerations from Coriolis/pressure acceleration = $f\,U\,L\,\rho_{\mathsf{o}}/p$
Kn	Knudsen	Kn = molecular mean free path/macroscopic length scale
Ma	Mach	Ma = fluid particle speed/sound wave speed = U/c_{s}
Re	Reynolds	Re = inertial acceleration/frictional acceleration = $U\,L/\nu$
Ri	Richardson	Ri = squared buoyancy frequency/squared vertical shear
Ro	Rossby	Ro = horizontal inertial acceleration/planetary Coriolis acceleration = $U/(f\,L)$

SYMBOL	MEANING
$\mathcal{A}$	wave action
$A^{\mathrm{L}}(\boldsymbol{a}, T)$	Lagrangian representation of a fluid property as a function of material coordinates and time
$\boldsymbol{a}$	coordinate position for a fluid particle using arbitrary material/Lagrangian coordinates
$\mathbf{A}, \boldsymbol{A}$	second order skew symmetric tensor with elements satisfying $A^{mn} = -A^{nm}$
A^{v}	Avogadro's number: $A^{\mathrm{v}} = 6.0222 \times 10^{23}$ mole^{-1}
$\mathbf{B}$	baroclinicity vector: $\mathbf{B} = \nabla\rho \times (-\rho^{-1}\nabla p) = (\nabla\rho \times \nabla p)/\rho^2$
$\mathcal{B}$	base (or reference) manifold for describing the space of continuum matter
b	Archimidean buoyancy with $b > 0$ for relatively light fluid: $b = -g\,(\rho - \rho_{\mathrm{b}})/\rho_{\mathrm{b}}$
C	tracer concentration = mass of tracer per mass of fluid = tracer mass fraction
C_{d}	dimensionless bottom drag coefficient: $C_{\mathrm{d}} > 0$
$\mathcal{C}$	circulation of velocity around the boundary of a surface $\mathcal{C} \equiv \oint_{\partial S} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{r}$
c_{grav}	shallow water gravity wave speed: $c_{\mathrm{grav}} = \sqrt{g\,H}$
$\boldsymbol{c}_{\mathrm{g}}$	wave group velocity, given by wavevector gradient of dispersion relation: $\boldsymbol{c}_{\mathrm{g}} = \nabla_{\boldsymbol{k}}\varpi(\boldsymbol{k})$
$\boldsymbol{c}_{\mathrm{p}}$	wave phase velocity: $\boldsymbol{c}_{\mathrm{p}} = C_{\mathrm{p}}\,\hat{\boldsymbol{k}}$
C_{p}	wave phase speed
c_{s}	sound speed: $c_{\mathrm{s}}^{-2} = [\partial\rho/\partial p]_{\Theta,S}$
c_{p}	heat capacity at constant pressure: $c_{\mathrm{p}} = [\partial\mathcal{H}/\partial T]_{p,C}$
$\mathbf{E}, \boldsymbol{E}$	second order eddy transport tensor for tracers, and with elements E^{mn}
$\mathbb{E}^1, \mathbb{E}^2, \mathbb{E}^3$	one (line), two (plane), and three dimensional Euclidean space
$\mathcal{E}$	total energy per mass of a fluid element = sum of internal plus mechanical energies
$\boldsymbol{e}_a$	basis vectors for a chosen coordinate system, with index $a = 1, 2, 3$ for 3-dimensional space
$\boldsymbol{e}^a$	basis one-forms for a chosen coordinate system, with index $a = 1, 2, 3$ for 3-dimensional space
f	Coriolis parameter, also the planetary vorticity: $f = 2\,\Omega\,\sin\phi$
$f_{\circ}$	Coriolis parameter at a particular latitude: $f_{\circ} = 2\,\Omega\,\sin\phi_0$
$\mathbf{F}$	frictional acceleration vector
$F^i{}_I$	deformation matrix, which transforms between $\boldsymbol{x}$-space (Eulerian) and $\boldsymbol{a}$-space (Lagrangian)
$G = G^{\mathrm{grv}}$	Newton's gravitational constant: $G = 6.674 \times 10^{-11}$ N m^2 kg^{-2} $= 6.674 \times 10^{-11}$ m^3 kg^{-1} s^{-2}
$G(\boldsymbol{x}\vert\boldsymbol{x}_0)$	Green's function with $\boldsymbol{x}$ the observation point (or field point) and $\boldsymbol{x}_0$ the source point
$\widetilde{G}(\boldsymbol{x}\vert\boldsymbol{x}_0)$	modified Green's function for Laplace's operator with Neumann boundary conditions
$G^{\ddagger}(\boldsymbol{x}\vert\boldsymbol{x}_0)$	adjoint Green's function for non-self adjoint operators such as the diffusion operator
$\mathcal{G}(\boldsymbol{x}\vert\boldsymbol{x}_0)$	free space Green's function; i.e., the Green's function without boundaries
$\mathbf{G}$	velocity gradient tensor with elements $G^i{}_j$
$\mathcal{G}$	Gibbs potential per mass of a fluid element
g_{e}	gravitational acceleration from central gravity due to just the mass of the planet
g	effective gravitational acceleration from central gravity + planetary centrifugal: $g \approx 9.8$ m s^{-2}
g^{r}	reduced gravity defined between to shallow water layers: $g^{\mathrm{r}}_{\mathrm{k}+1/2} = g\,(\rho_{\mathrm{k}+1} - \rho_{\mathrm{k}})/\rho_{\mathrm{ref}} \ll g$

SYMBOL	MEANING
$\mathcal{g}$	metric tensor (symmetric positive definite second order tensor) with components $\mathcal{g}_{ab}$
g	square root of the metric tensor determinant: $g = \sqrt{\det(\mathcal{g}_{mn})}$
g^{E}	square root of the metric tensor determinant using Eulerian coordinates: $g^{\mathsf{E}} = \sqrt{\det(\mathcal{g}(\boldsymbol{x})}$
g^{L}	square root of the metric tensor determinant using Lagrangian coordinates: $g^{\mathsf{L}} = \sqrt{\det(\mathcal{g}(\boldsymbol{a}, T)}$
h_{k}	layer thickness for a shallow water fluid: $h_{\mathsf{k}} = \eta_{\mathsf{k}-1/2} - \eta_{\mathsf{k}+1/2} = \delta_{\mathsf{k}}\eta_{\mathsf{k}-1/2}$
h	layer thickness for a continuously stratified fluid: $h = \overline{\hbar}\,\delta\sigma$
$\hbar$	specific thickness for a generalized vertical coordinate: $\hbar = \partial z/\partial\sigma = 1/(\partial\sigma/\partial z)$
$\mathscr{H}(x)$	Heaviside step function: $\mathscr{H}(x) = 0$ for $x < 0$ whereas $\mathscr{H}(x) = 1$ for $x > 0$
H	vertical length scale of the flow under consideration
H	sometimes used as depth of the ocean bottom: $z = -H(x, y) = \eta_{\mathsf{b}}(x, y)$
H	Hamiltonian energy function
$\mathscr{H}$	Hamiltonian density used in field theory; dimensions energy per volume (when in 3d space)
$\mathcal{H}$	enthalpy per mass of a fluid element
$\mathbf{I}$	unit tensor or Kronecker tensor: $\mathbf{I} = \delta^{ab}\,\boldsymbol{e}_a \otimes \boldsymbol{e}_b = \delta^a{}_b\,\boldsymbol{e}_a \otimes \boldsymbol{e}^b = \delta_a{}^b\,\boldsymbol{e}^a \otimes \boldsymbol{e}_b = \delta_{ab}\,\boldsymbol{e}^a \otimes \boldsymbol{e}^b$
$\mathcal{I}$	internal energy per mass of a fluid element
i	$\mathrm{i} = \sqrt{-1}$ used for imaginary numbers
i, j, k	tensor indices/labels for Eulerian coordinates
I, J, K	tensor indices/labels for Lagrangian coordinates
$\mathrm{Im}[\,]$	imaginary part of a complex number; e.g., $\mathrm{Im}[e^{-\mathrm{i}\,\omega\,t}] = -\sin(\omega\,t)$
$\mathbf{J}$	tracer flux; for material tracers the dimensions are mass per time per area
$\boldsymbol{k}$	wavevector (dimensions inverse length) for a wave of wavelength $\Lambda = 2\pi/\lvert\boldsymbol{k}\rvert$
$\hat{\boldsymbol{k}}$	unit vector in the direction of a wave: $\boldsymbol{k} = \hat{\boldsymbol{k}}\,\lvert\boldsymbol{k}\rvert$ (as distinct from the vertical unit vector, $\hat{\boldsymbol{z}}$)
$\lvert\boldsymbol{k}\rvert$	wavenumber: $\lvert\boldsymbol{k}\rvert = 2\pi/\Lambda$
K	kinetic energy for a particle of mass m: $K = m\,\boldsymbol{V}\cdot\boldsymbol{V}/2$
K	kinetic energy for a system of N particles, $\sum_{n=1}^{N} m^n\,\boldsymbol{V}^n\cdot\boldsymbol{V}^n$
$\mathcal{K}$	kinetic energy per mass of a fluid element arising from macroscopic motion: $\mathcal{K} = \boldsymbol{v}\cdot\boldsymbol{v}/2$
$\mathcal{K}^{\mathrm{hyd}}$	kinetic energy per mass for an approximate hydrostatic flow: $\mathcal{K}^{\mathrm{hyd}} = \boldsymbol{u}\cdot\boldsymbol{u}/2$
$\mathcal{K}^{\mathrm{sw}}$	kinetic energy per horizontal area for a shallow water layer: $\mathcal{K}^{\mathrm{sw}} = \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{u}/2$
$\mathbf{K}, \boldsymbol{K}$	positive and symmetric second order tensor parameterizing diffusive mixing
k	integer index to label a layer in a shallow water model with $\mathsf{k} = 1, N$ layers ($\mathsf{k} = 1$ is top layer)
k_{B}	Boltzmann constant: $k_{\mathrm{B}} = 1.3806 \times 10^{-23}$ m^2 kg s^{-2} K^{-1}
k_{R}	Rossby height/depth: $k_{\mathsf{R}} = \lvert\boldsymbol{k}\rvert\,N/f_0$ with horizontal wavenumber $\lvert\boldsymbol{k}\rvert = \sqrt{k_x^2 + k_y^2}$
L	Lagrangian used in Lagrangian mechanics: kinetic minus potential energies: $L = K - P$
L	length scale for a particular physical feature and commonly used in scale analysis

SYMBOL	MEANING
$\mathcal{L}$	Lagrangian density used in field theory; dimensions energy per volume (when in 3d space)
L_{d}	deformation radius: (a) shallow water $L_{\mathsf{d}} = \sqrt{g\,H}/f$; (b) continuous internal $L_{\mathsf{d}} = H\,N/f$
$\mathcal{M}$	mechanical energy per mass of a fluid element arising from macroscopic motion
$\mathcal{M}^{\mathrm{sw}}$	mechanical energy per area of a shallow water fluid column: $\mathcal{M}^{\mathrm{sw}} = \mathcal{K}^{\mathrm{sw}} + \mathcal{P}^{\mathrm{sw}}$
$\mathbf{M}$	moment of inertia tensor
$\mathbf{M}$	potential momentum vector: $\mathbf{M} = \mathbf{u} + 2\,\mathbf{\Omega} \times \mathbf{X}$
M	Montgomergy potential for continuously stratified fluid $M = \varphi - b\,z$
$M_{\mathsf{k}}^{\mathrm{dyn}}$	Montgomergy potential for a shallow water layer: $M_{\mathsf{k}}^{\mathrm{dyn}} = \sum_{\mathsf{j}=0}^{\mathsf{k}-1} g^{\mathsf{r}}_{\mathsf{j}+1/2}\,\eta_{\mathsf{j}+1/2}$
M^{air}	mass per mole of air: $M^{\mathsf{air}} = 28.8 \times 10^{-3}$ kg mole^{-1}
N	buoyancy frequency
$\mathcal{O}$	order of magnitude
P	potential energy of a physical system, with corresponding force $\boldsymbol{F} = -\nabla P$
$\mathcal{P}_{\mathsf{k}}^{\mathrm{sw}}$	potential energy per horizontal area for a shallow water fluid: $\mathcal{P}_{\mathsf{k}}^{\mathrm{sw}} = g\,\rho_{\mathsf{k}} \int_{\eta_{\mathsf{k}+1/2}}^{\eta_{\mathsf{k}-1/2}} z\,\mathrm{d}z$
$\mathcal{P}$	phase of a wave
$\mathcal{P}_\sigma$	generalized momentum for discrete particle system: $\mathcal{P}_\sigma = \partial L/\partial\dot{\xi}^\sigma$
$\mathcal{P}$	generalized momentum density for continuous media: $\mathcal{P} = \partial\mathcal{L}/\partial(\partial_t\psi)$
$\mathbf{P}$	linear momentum of a physical system
p	pressure at a point in the fluid
p_{a}	pressure applied to the ocean surface from the atmosphere or cryosphere
p_{b}	pressure at the bottom of a fluid column, at the fluid-solid earth interface
p_{slp}	sea level pressure with an area average, $\langle p_{\mathrm{slp}} \rangle = 101.325 \times 10^3$ N m^{-2}
$p_{\mathsf{k}-1/2}$	hydrostatic pressure at the layer interface with vertical position $z = \eta_{\mathsf{k}-1/2}$
$p_{\mathsf{k}}^{\mathrm{dyn}}$	dynamic pressure in a shallow water layer: $p_{\mathsf{k}}^{\mathrm{dyn}} = \rho_{\mathsf{ref}} \sum_{\mathsf{j}=0}^{\mathsf{k}-1} g^{\mathsf{r}}_{\mathsf{j}+1/2}\,\eta_{\mathsf{j}+1/2}$
P_{k}	pressure integrated over a shallow water layer: $P_{\mathsf{k}} \equiv \int_{\eta_{\mathsf{k}+1/2}}^{\eta_{\mathsf{k}-1/2}} p_{\mathsf{k}}(z)\,\mathrm{d}z = h_{\mathsf{k}}\,(g\,\rho_{\mathsf{k}}\,h_{\mathsf{k}}/2 + p_{\mathsf{k}-1/2})$
Q	potential vorticity for continuously stratified (Ertel PV) or shallow water (Rossby PV)
q	quasi-geostrophic potential vorticity either for a continuous fluid or shallow water fluid
Q_{m}	mass flux (mass per horizontal area per time) across ocean surface: $Q_{\mathsf{m}} > 0$ enters ocean
$\mathcal{Q}_{\mathsf{m}}$	mass flux (mass per surface area per time) across ocean surface: $\mathcal{Q}_{\mathsf{m}}\,\mathrm{d}\mathcal{S} = Q_{\mathsf{m}}\,\mathrm{d}A$
Q_{C}	turbulent tracer flux (tracer per horiz area per time) across ocean surface: $Q_{\mathsf{C}} > 0$ enters ocean
$\mathcal{Q}_{\mathsf{C}}$	turbulent tracer flux (tracer per surface area per time) across ocean surface: $QCcal\,\mathrm{d}\mathcal{S} = Q_{\mathsf{C}}\,\mathrm{d}A$
r	radial distance of a point relative to an origin
$\mathbf{R}$	rotation tensor: $2\,R_{mn} = \partial_n v_m - \partial_m v_n = -2\,R_{nm}$
$\mathbb{R}^1$	real number line
$\mathbb{R}^2$	two-dimensional space of real numbers
$\mathbb{R}^3$	three-dimensional space of real numbers
R	radius of a sphere

SYMBOL	MEANING
R_{e}	radius of sphere whose volume approximates that of the earth: $R_{\mathsf{e}} = 6.371 \times 10^6$ m
R^{g}	universal gas constant: $R^{\mathsf{g}} = 8.314$ J mole^{-1} K^{-1} $= 8.314$ kg m^2 s^{-2} mole^{-1} K^{-1}
R^{air}	specific gas constant for air: $R^{\mathsf{air}} = R^{\mathsf{g}}/M^{\mathsf{air}} = 2.938 \times 10^2$ m^2 s^{-2} K^{-1}
$\mathcal{R}$	arbitrary region or manifold
$\mathcal{R}^a{}_b$	orthogonal rotation matrix
Re[ ]	real part of a complex number; e.g., $\mathrm{Re}[e^{-\mathrm{i}\,\omega\,t}] = \cos(\omega\,t)$
$\mathcal{S}$	spatial manifold
$\mathcal{S}$	entropy per mass of a fluid element
$\mathcal{S} = \mathcal{S}^{\mathrm{act}}$	action: time integral of the Lagrangian: $\mathcal{S} = \int_{t_A}^{t_B} L\,\mathrm{d}t$
$\mathbf{S}$	strain rate tensor: $2\,S_{mn} = \partial_n v_m + \partial_m v_n$
$\mathbf{S}^{\mathrm{dev}}$	deviatoric strain rate tensor: $S^{\mathrm{dev}}_{mn} = S_{mn} - \delta_{mn}\,S_{qq}/3$
S	salt concentration = mass of salt in a fluid element per mass of seawater
S	Absolute Salinity, generically referred to as salinity: $S = 1000\,\mathsf{S}$
s	expression for a generic surface: $s = s(x, y, z, t)$.
s	arc-length along a curve $\boldsymbol{x}(s)$ with infinitesimal increment $\mathrm{d}s = \sqrt{\mathrm{d}\boldsymbol{x} \cdot \mathrm{d}\boldsymbol{x}}$
$\hat{\boldsymbol{s}}$	unit tangent to a curve, also written as $\hat{\boldsymbol{s}} = \hat{\boldsymbol{t}}$ (see below)
sgn	sign function related to Heaviside step function via $\mathrm{sgn}(x) = 2\,\mathcal{H}(x) - 1$
T	absolute thermodynamic *in situ* temperature (Kelvin if in a thermodynamic equation)
T	time scale for a particular physical process and commonly used in scale analysis
T	time (universal Newtonian time) measured in the Lagrangian reference frame
t	time (universal Newtonian time) measured in the Eulerian reference frame
τ	general symbol for time as considered in the tensor analysis chapters
$\mathbf{T}$	stress tensor with natural elements $T^m n$
$\mathbf{T}^{\mathrm{kinetic}}$	kinetic stress tensor: $\mathbf{T}^{\mathrm{kinetic}} = -\rho\,\mathbf{v} \otimes \mathbf{v}$
$\mathbf{T}^{\mathrm{sw\ kinetic}}$	kinetic stress tensor for shallow water fluid: $\mathbf{T}^{\mathrm{sw\ kinetic}} = -\rho\,\mathbf{u} \otimes \mathbf{u}$
$\hat{\boldsymbol{t}}$	unit tangent to a curve: $\hat{\boldsymbol{t}} = \mathrm{d}\boldsymbol{x}/\mathrm{d}s$, where s is the arc-length so that $\mathrm{d}s = \sqrt{\mathrm{d}\boldsymbol{x} \cdot \mathrm{d}\boldsymbol{x}}$
$\mathbf{u}$	horizontal velocity of a fluid particle, with Cartesian representation: $\boldsymbol{u} = \hat{\boldsymbol{x}}\,u + \hat{\boldsymbol{y}}\,v$
U	horizontal velocity scale of the flow under consideration
$\mathbf{U}$	depth integrated horizontal velocity: $\mathbf{U} = \int_{\eta_{\mathrm{b}}}^{\eta} \mathbf{u}\,\mathrm{d}z$
$\mathbf{v}$	velocity of a fluid particle: $\mathbf{v} = \mathrm{D}\mathbf{x}/\mathrm{D}t$, with Cartesian components $\boldsymbol{v} = \hat{\boldsymbol{x}}\,u + \hat{\boldsymbol{y}}\,v + \hat{\boldsymbol{z}}\,w$
$\mathbf{v}^*$	eddy-induced velocity
$\mathbf{v}^\dagger$	residual velocity of a fluid particle: $\mathbf{v}^\dagger = \mathbf{v} + \mathbf{v}^*$
$\mathbf{v}^{(b)}$	velocity of a point on a region boundary
$\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T)$	Lagrangian velocity of a fluid particle so that $\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T) = \boldsymbol{v}[\boldsymbol{x} = \boldsymbol{\varphi}(\boldsymbol{a}, T), t = T]$
$\mathbf{v}_{\mathrm{I}}$	velocity of a fluid particle measured in the inertial/absolute reference frame: $\mathbf{v}_{\mathrm{I}} = \mathbf{v} + \boldsymbol{\Omega} \times \mathbf{x}$
W	vertical velocity scale of the flow under consideration
w	vertical component to the velocity: $w = \mathrm{D}z/\mathrm{D}t$
w^{dia}	dia-surface flux = volume per *horizontal area* per time crossing a σ-surface: $w^{\mathrm{dia}} = (1/\lvert\nabla\sigma\rvert)\,\dot{\sigma}$
$w^{(\dot{\sigma})}$	dia-surface velocity = volume per *horizontal area* per time crossing σ-surface: $w^{(\dot{\sigma})} = \dot{\sigma}\,\partial z/\partial\sigma$

LATIN SYMBOLS AND THEIR MEANING

SYMBOL	MEANING
(x, y, z)	triplet of Cartesian coordinates
$\mathbf{x}$	spatial position
$\boldsymbol{x}$	spatial position represented by either general coordinates or Cartesian coordinates
$\mathring{\mathbf{x}}$	initial position for a fluid particle using arbitrary coordinates
$(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$	triplet of Cartesian unit vectors oriented in a righthand sense
$\mathbf{X}(t)$	position for a point particle defining a trajectory through space-time
$\boldsymbol{X}(\boldsymbol{a}, T)$	position of a material fluid particle expressed using material coordinates
z_σ	specific thickness for a generalized vertical coordinate: $z_\sigma = \partial z / \partial \sigma = \hbar$

GREEK SYMBOLS AND THEIR MEANING

SYMBOL	MEANING
α	thermal expansion: $\alpha = -\rho^{-1}\,\partial\rho/\partial\theta$ or $\alpha = -\rho^{-1}\,\partial\rho/\partial\Theta$ or $\alpha = -\rho^{-1}\,\partial\rho/\partial T$
α_T	thermal expansion in terms of *in situ* temp: $\alpha = -\rho^{-1}\,\partial\rho/\partial T$
$\alpha^{(\Theta)}$	thermal expansion in terms of Conservative Temperature: $\alpha^{(\Theta)} = -\rho^{-1}\,\partial\rho/\partial\Theta$
α_{aspect}	aspect ratio; ratio of vertical to horizonal scales of the flow: $\alpha_{\text{aspect}} = H/L$
$\beta, \beta^{(\text{S})}$	saline contraction coefficient: $\beta = \beta^{(\text{S})} = \rho^{-1}\,\partial\rho/\partial S$
β	meridional derivative of planetary vorticity: $\beta = \partial_y f$
$\hat{\boldsymbol{\gamma}}$	dianeutral unit direction perpendicular to the neutral tangent plane
δ_{ab}	components to the Kronecker tensor in Cartesian coordinates
δ^a_b	components to the Kronecker tensor in general coordinates
ϵ	kinetic energy dissipation from viscosity (energy per time per mass)
ϵ_{ab}	components to the permutation symbol in two space dimensions
ϵ_{abc}	components to the permutation symbol in three space dimensions
ε_{abc}	components to the Levi-Civita symbol in three space dimensions: $\varepsilon_{abc} = \sqrt{\det(\mathbb{g}_{ab})}\,\epsilon_{abc}$
ζ	vertical component to the relative vorticity; e.g., $\zeta = \partial_x v - \partial_y u$
ζ_{a}	vertical component to the absolute vorticity; e.g., $\zeta_{\mathsf{a}} = f + \zeta$
η	vertical position of the free upper surface of a fluid domain: $z = \eta(x, y, t)$
$\eta_{\mathsf{k}-1/2}$	vertical position of the top interface of the shallow water layer k
$\eta_{\mathsf{k}+1/2}$	vertical position of the lower interface of the shallow water layer k
$\eta_{\mathsf{b}} = -H$	vertical position of static solid-earth boundary: $z = \eta_{\mathsf{b}}(x, y) = -H(x, y)$
θ	potential temperature
Θ	Conservative Temperature
κ	molecular kinematic diffusivity
κ_T	molecular diffusivity for *in situ* temperature in water: $\kappa_T = 1.4 \times 10^{-7}\ \text{m}^2\ \text{s}^{-1}$
κ_S	molecular diffusivity for salt in water: $\kappa_S = 1.5 \times 10^{-9}\ \text{m}^2\ \text{s}^{-1}$
κ_{eddy}	kinematic eddy diffusivity: $\kappa_{\text{eddy}} \gg \kappa$
Λ	wavelength of a wave: $\Lambda = 2\,\pi/\lvert\boldsymbol{k}\rvert$, where $\boldsymbol{k}$ is the wavevector and $\lvert\boldsymbol{k}\rvert$ the wavenumber.
$\lambda\!\!\!^{-}$	reduced wavelength of a wave: $\lambda\!\!\!^{-} = \Lambda/(2\pi) = 1/\lvert\boldsymbol{k}\rvert$.
λ	longitude on the sphere: $0 \le \lambda \le 2\pi$
μ_n	chemical potential for constituent n within a fluid (energy per mass)
$\tilde{\mu}_n$	chemical potential for constituent n within a fluid (energy per mole number)
μ	relative chemical potential for a binary fluid
μ	chemical potential for seawater: $\mu = \mu_{\text{salt}} - \mu_{\text{water}}$
μ_{vsc}	dynamic viscosity $= \rho\,\nu$
ν_{s}	specific volume: $\nu_{\text{s}} = \rho^{-1}$
ν	molecular kinematic viscosity
ν_{air}	molecular kinematic viscosity of air: $\nu_{\text{air}} \approx 1.3 \times 10^{-5}\ \text{m}^2\ \text{s}^{-1}$
ν_{water}	molecular kinematic viscosity of fresh water: $\nu_{\text{water}} \approx 10^{-6}\ \text{m}^2\ \text{s}^{-1}$
ν_{eddy}	eddy viscosity: $\nu_{\text{eddy}} \gg \nu$
ξ^a	a'th component to a generalized coordinate
Π	Exner function
Π	Boussinesq dynamic enthalpy

GREEK SYMBOLS AND THEIR MEANING

SYMBOL	MEANING
ρ	Eulerian *in situ* density (mass per volume) of a fluid element: $\rho = \rho(\boldsymbol{x}, t)$
ρ^{L}	mass density following a fluid particle trajectory (Lagrangian mass density): $\rho^{\text{L}} = \rho^{\text{L}}(\boldsymbol{a}, T)$
$\mathring{\rho}^{\text{L}}$	initial mass density in Lagrangian space-time: $\mathring{\rho}^{\text{L}} = \rho^{\text{L}}(\boldsymbol{a}, T = t_0)$
ρ_{o}	constant reference density used for the Boussinesq ocean
ρ_{ref}	constant reference density used for the shallow water fluid
ϱ	potential density referenced to a specified pressure
σ	generalized vertical coordinate surface with $\sigma(x, y, z, t) =$ constant
$\boldsymbol{\tau}$	stress vector such as from winds or bottom stresses acting on the ocean
$\mathbb{T}$	frictional stress tensor
φ	pressure divided by the Boussinesq reference density: $\varphi = p/\rho_{\text{o}}$
φ	sometimes used as the variable for parameteriing a curve
ϕ	latitude on the sphere: $-\pi/2 \leq \phi \leq \phi/2$
Φ_{e}	gravitational potential from a spherical and homogeneous earth
Φ	geopotential from central gravity plus planetary centrifugal; also, potential energy per mass
$\boldsymbol{\Phi}$	inverse flow map that generates an inverse mapping of the fluid continuum: $\boldsymbol{a} = \boldsymbol{\Phi}(\boldsymbol{x}, t)$
$\boldsymbol{\varphi}$	motion field that maps the fluid continuum as time evolves: $\boldsymbol{x} = \boldsymbol{\varphi}(\boldsymbol{a}, T)$
ψ	streamfunction for two-dimensional non-divergent flow: $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi$
$\boldsymbol{\Psi}$	vector streamfunction for three-dimensional non-divergent flow: $\boldsymbol{v} = \nabla \times \boldsymbol{\Psi}$
$\boldsymbol{\omega}$	relative vorticity: $\boldsymbol{\omega} = \nabla \times \boldsymbol{v}$
ω	angular frequency for a wave so that the wave period is $2\pi/\lvert\omega\rvert$
ϖ	dispersion relation for linear waves, relating angular frequency to the wavevector: $\omega = \varpi(\boldsymbol{k})$
$\boldsymbol{\Omega}$	angular velocity for a rotating reference frame
$\boldsymbol{\Omega}$	earth's angular velocity oriented through the north pole: $\lvert\boldsymbol{\Omega}\rvert = 7.2921 \times 10^{-5}\ \text{s}^{-1}$

SYMBOL	MEANING
$[\equiv]$	"has dimensions" for use in referring to the physical dimensions
$\times$	vector cross product
∇	gradient operator
∇_h	horizontal gradient operator on constant z surface: $\nabla_\mathrm{h} = \hat{\boldsymbol{x}}\,(\partial/\partial x)_z + \hat{\boldsymbol{y}}\,(\partial/\partial y)_z = \hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y$
$\nabla\cdot$	covariant divergence operator that acts on a vector to produce a scalar
$\nabla\times$	curl operator
$\nabla_{\mathrm{h}\sigma}$	horizontal gradient on constant σ-surface: $\nabla_{\mathrm{h}\sigma} = \hat{\boldsymbol{x}}\,(\partial/\partial x)_\sigma + \hat{\boldsymbol{y}}\,(\partial/\partial y)_\sigma$
$\partial/\partial\sigma$	vertical partial derivative with general vertical coordinate: $\partial_\sigma = \partial/\partial\sigma = \partial/\partial\sigma = (\partial z/\partial\sigma)\,\partial/\partial z$
$\partial/\partial t$	Eulerian time derivative acting at a fixed spatial position, $\boldsymbol{x}$, also written as ∂_t
$[\partial/\partial t]_\sigma$	time derivative computed on constant σ-surface
$\mathrm{D}/\mathrm{D}t$	material, Lagrangian, or substantial time derivative following a fluid particle
$\mathrm{D}_\mathrm{r}/\mathrm{D}t$	time derivative following a ray (integral lines of the group velocity): $\mathrm{D}_\mathrm{r}/\mathrm{D}t = \partial/\partial t + \boldsymbol{c}_\mathrm{g}\cdot\nabla$
$\mathrm{D}_\mathrm{g}/\mathrm{D}t$	time derivative following the horizontal geostrophic flow $\mathrm{D}_\mathrm{g}/\mathrm{D}t = \partial/\partial t + \boldsymbol{u}_\mathrm{g}\cdot\nabla_\mathrm{h}$
đ	inexact differential operator commonly found in thermodynamics
δ	virtual displacement (also the variation) for Lagrangian mechanics and Hamilton's principle
δ	differential increment that signals an object following the fluid flow
$\delta(x)$	one-dimensional Dirac delta with dimensions of inverse length
$\delta^{(2)}(\boldsymbol{x})$	two-dimensional Dirac delta with dimensions of inverse area
$\delta(\boldsymbol{x})$	three-dimensional Dirac delta with dimensions of inverse volume
$\delta(t)$	temporal Dirac delta with dimensions of inverse time
Δ	finite difference increment in space: $\Delta_x, \Delta_y, \Delta_z, \Delta_\sigma$
$\mathrm{d}A$	infinitesimal horizontal area element: $\mathrm{d}A = \mathrm{d}x\,\mathrm{d}y$
d^3a	infinitesimal region of material space: $\mathrm{d}^3a = \mathrm{d}a\,\mathrm{d}b\,\mathrm{d}c$
$\mathrm{d}\mathcal{S}$	infinitesimal area element on a surface
$\mathrm{d}V$	infinitesimal volume element, sometimes written $\mathrm{d}V = \mathrm{d}\boldsymbol{x}$
$\mathrm{d}\boldsymbol{x}$	infinitesimal volume element, with Cartesian expression $\mathrm{d}\boldsymbol{x} = \mathrm{d}V = \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z$
δV	infinitesimal volume for a region moving with the fluid (Lagrangian region)
$\int_\mathcal{R}\mathrm{d}V$	volume integral over an arbitrary region, $\mathcal{R}$
$\int_{\mathcal{R}(\boldsymbol{v})}\mathrm{d}V$	volume integral over a region following the fluid flow (Lagrangian integral)
$\int_\mathcal{S}\mathrm{d}\mathcal{S}$	surface integral over an arbitrary surface $\mathcal{S}$
$\oint_{\partial\mathcal{R}}\mathrm{d}\mathcal{S}$	surface integral over a closed surface $\partial\mathcal{R}$ that bounds the volume $\mathcal{R}$
$\oint\mathrm{d}\ell$	closed line integral over a periodic domain
$\oint_{\partial\mathcal{S}}\mathrm{d}\ell$	counter-clockwise closed line integral over the boundary of a surface, $\partial\mathcal{S}$
$\sim$	"similar to" or "scales as"
$\approx$	approximately equal to
$\dot{\Psi}$	time derivative following a trajectory; for fluid particle trajectories then, $\dot{\Psi} = \mathrm{D}\Psi/\mathrm{D}t$
